The second factor is the skewed distribution of addresses in this model. From 1 January 2007 until 20 July 2008, 10,402 allocation or assignments transactions were recorded in the RIRs' daily statistics files. These transactions accounted for a total of 324,022,704 individual IPv4 addresses, or the equivalent of 19.3 /8s. Precisely one-half of this address space was allocated or assigned in just 107 such transactions.

In other words, some 1 percent of the recipients of address space in the past 18 months have received some 50 percent of all the allocated address space. The reason why this distribution is relevant here is that this predictive exercise assumes that although individual actions are hard to predict with any certainty, the aggregate outcome of many individuals' actions assumes a much greater level of predictability.

This observation about aggregate behavior does not apply in this situation, however, and the predictive exercise is very sensitive to the individual actions of a very small number of recipients of address space because of this skewed distribution of allocations. Any change in the motivations of these larger-sized actors that results in an acceleration of demand for IPv4 will significantly affect the predictions of the longevity of the remaining unallocated IPv4 address pool.

The third factor is that this model assumes that the policy framework remains unaltered, and that all unallocated addresses are allocated or assigned under the current policy framework, rather than under a policy regime that is substantially different from today's framework. The related assumption here is that the cost of obtaining and holding addresses remains unchanged, and that the perceptions of future scarcity of addresses do not affect the policy framework of address distribution of the remaining unallocated IPv4 addresses.

Given this potential for variation within this set of assumptions, a more accurate summary of the current expectations of address consumption would be that the exhaustion of the IANA unallocated IPv4 address pool will occur sometime between July 2009 and July 2011, and that the first RIR will exhaust all its usable address space within 3 to 12 months from that date, or between October 2009 and July 2012.[3]

What Next?

Apart from the exact date of exhaustion that is predicted by this modeling exercise, none of the information relating to exhaustion of the unallocated IPv4 address pool should be viewed as particularly novel information. The IETF *Routing and Addressing* (ROAD) study of 1991 recognized that the IPv4 address space was always going to be completely consumed at some point in the future of the Internet[4].

Such predictions of the potential for exhaustion of the IPv4 address space were the primary motivation for the adoption of *Classless Inter-Domain Routing* (CIDR) in the *Border Gateway Protocol* (BGP), and the corresponding revision of the address allocation policies to craft a more exact match between planned network size and the allocated address block. These predictions also motivated the protracted design exercise of what was to become the IPv6 protocol across the 1990s within the IETF. The prospect of address scarcity engendered a conservative attitude to address management that, in turn, was a contributory factor in accelerating the widespread use of *Network Address Translation* (NAT)[5] in the Internet during the past decade. By any reasonable metric this industry has had ample time to study this problem, ample time to devise various strategies, and ample time to make plans and execute them.

And this reality has been true for the adoption of classless address allocations, the adoption of CIDR in BGP, and the extremely widespread use of NAT. But all of these measures were short-term, whereas the longer-term measure, that of the transition to IPv6, was what was intended to come after IPv4. But IPv6 has not been the subject of widespread adoption so far, while the time of anticipated exhaustion of IPv4 has been drawing closer. Given almost two decades of advance warning of IPv4 address exhaustion, and a decade since the first stable implementations of IPv6 were released, we could reasonably expect that this industry—and each actor within this industry—is aware of the problem and the need for a stable and scalable long-term solution as represented by IPv6. We could reasonably anticipate that the industry has already planned the actions it will take with respect to IPv6 transition, and is aware of the triggers that will invoke such actions, and approximately when they will occur.

However, such an expectation appears to be ill-founded when considering the broad extent of the actors in this industry, and there is little in the way of a common commitment as to what will happen after IPv4 address exhaustion, nor even any coherent view of plans that industry actors are making in this area.

This lack of planning makes the exercise of predicting the actions within this industry following address exhaustion somewhat challenging, so instead of immediately describing future scenarios, it may be useful to first describe the original plan for the response of the Internet to IPv4 address exhaustion.

What Was Intended?

The original plan, devised in the early 1990s by the IETF to address the IPv4 address shortfall, was the adoption of CIDR as a short-term measure to slow down the consumption of IPv4 addresses by reducing the inefficiency of the address plan, and the longer-term plan of the specification of a new version of the Internet Protocol that would allow for adoption well before the IPv4 address pool was exhausted.

The industry also adopted the use of NAT as an additional measure to increase the efficiency of address use, although the IETF did not strongly support this protocol. For many years the IETF did not undertake the standardization of NAT behaviors, presumably because NAT was not consistent with the IETF's advocacy of end-to-end coherence of the Internet at the IP level of the protocol stack.

Over the 1990s the IETF undertook the exercise of the specification of a successor IP protocol to Version 4, and the IETF's view of the longer-term response was refined to be advocacy of the adoption of the IPv6 protocol and the use of this protocol as the replacement for IPv4 across all parts of the network.

In terms of what has happened in the past 15 years, the adoption of CIDR was extremely effective, and most parts of the network were transitioned to use CIDR within 2 years, with the transition declared to be complete by the IETF in June 1996. And, as noted already, NAT has been adopted across many, if not most, parts of the network. The most common point of deployment of NAT has not been at an internal point of demarcation between provider networks, but at the administrative boundary between the local customer network and the ISP, so that the common configuration of *Customer Premises Equipment* (CPE) includes NAT functions. Customers effectively own and operate NAT devices as a commonplace aspect of today's deployed Internet.

CIDR and NAT have been around for more than a decade now, and the address consumption rates have been held at very conservative levels in that period, particularly so when considering that the bulk of the population of the Internet was added well after the advent of CIDR and NAT.

The longer-term measure—the transition to IPv6—has not proved to be as effective in terms of adoption in the Internet.

There was never going to be a "flag-day" transition where, in a single day, simultaneously across all parts of every network the IP protocol changed to using IPv6 instead of IPv4. The Internet is too decentralized, too large, too disparate, and too critical for such actions to be orchestrated, let alone completed with any chance of success. A flag day, or any such form of coordinated switchover, was never a realistic option for the Internet.

If there was no possibility of a single, coordinated switchover to IPv6, the problem is that there was never going to be an effective piecemeal switchover either. In other words, there was never going to be a switchover where host by host, and network by network, IPv6 is substituted for IPv4 on a piecemeal and essentially uncoordinated basis. The problem here is that IPv6 is not "backward-compatible" with IPv4. When a host uses IPv6 exclusively, then that host has no direct connectivity to any part of the IPv4 network. If an IPv6-only host is connected to an IPv4-only network, then the host is effectively isolated. This situation does not bode well for a piecemeal switchover, where individual components of the network are switched over from IPv4 to IPv6 on a piecemeal basis. Each host that switches over to IPv6 essentially disconnects itself form the IPv4 Internet at that point.

Given this inability to support backward compatibility, what was planned for the transition to IPv6 was a "dual-stack" transition. Rather than switching over from IPv4 to IPv6 in one operation on both hosts and networks, a two-step process has been proposed: first switching from IPv4 only to a "dual-stack" mode of operation that supports both IPv4 and IPv6 simultaneously, and second—and at a much later date—switching from dual-stack IPv4 and IPv6 to IPv6 only.

During the transition more and more hosts are configured with dual stack. The idea is that dual-stack hosts prefer to use IPv6 to communicate with other dual-stack hosts, and revert to use IPv4 only when an IPv6-based end-to-end conversation is not possible. As more and more of the Internet converts to dual stack, it is anticipated that use of IPv4 will decline, until support for IPv4 is no longer necessary. In this dual-stack transition scenario, no single flag day is required and the dual-stack deployment can be undertaken in a piecemeal fashion. There is no requirement to coordinate hosts with networks, and as dual-stack capability is supported in networks the attached dual-stack hosts can use IPv6. This scenario still makes some optimistic assumptions, particularly relating to the achievement of universal deployment of dual stack, at which point no IPv4 functions are used, and support for IPv4 can be terminated. Knowing when this point is reached is unclear, of course, but in principle there is no particular timetable for the duration of the dual-stack phase of operation.

There are always variations, and in this case it is not necessarily that each host must operate in dual-stack mode for such a transition. A variant of the NAT approach can perform a rudimentary form of protocol translation, where a *Protocol-Translating NAT* (or NAT-PT[6]) essentially transforms an incoming IPv4 packet to an outgoing IPv6 packet, and conversely, using algorithmic binding patterns to map between IPv4 and IPv6 addresses. Although this process relieves the IPv6-only host of some additional complexity of operation at the expense of some added complexity in *Domain Name System* (DNS) transformations and service fragility, the essential property still remains that in order to speak to an IPv4-only remote host, the combination of the local IPv6 host and the NAT-PT have to generate an equivalent IPv4 packet. In this case the complexity of the dual stack is now replaced by complexity in a shared state across the IPv6 host and the NAT-PT unit. Of course this solution does not necessarily operate correctly in the context of all potential application interactions, and concerns with the integrity of operation of NAT-PT devices are significant, a factor that motivated the IETF to deprecate the existing NAT-PT specification[7]. On the other hand, the lack of any practical alternatives has led the IETF to subsequently reopen this work, and once again look at specifying the standard behavior of such devices[8].

The detailed progress of a dual-stack transition is somewhat uncertain, because it involves the individual judgment of many actors as to when it may be appropriate to discontinue all support for IPv4 and rely solely on IPv6 for all connectivity requirements. However, one factor is constant in this envisaged transition scenario, and whether it is dual stack in hosts or dual stack through NAT-PT, or various combinations thereof, the requirement that there are sufficient IPv4 addresses to span the addressing needs of the entire Internet across the complete duration of the dual-stack transition process is consistent.

Under this dual-stack regime every new host on the Internet is envisaged to need access to both IPv6 and IPv4 addresses in order to converse with any other host using IPv6 or IPv4. Of course this approach works as long as there is a continuing supply of IPv4 addresses, implying that the envisioned timing of the transition was meant to have been completed by the time that IPv4 address exhaustion happens.

If this transition were to commence in earnest at the present time, in late 2008, and take an optimistic 5 years to complete, then at the current address consumption rate we will require a further 90 to 100 /8 address blocks to span this 5-year period. A more conservative estimate of a 10-year transition will require a further 200 to 250 /8 address blocks, or the entire IPv4 address space again, assuming that we will use IPv4 addresses in the future in precisely the same manner as we have used them in the past and with precisely the same level of usage efficiency as we have managed to date.

Clearly, waiting for the time of IPv4 unallocated address pool exhaustion to act as the signal to industry to commence the deployment of IPv6 in a dual-stack transition framework is a totally flawed implementation of the original dual-stack transition plan.

Either the entire process of dual-stack transition will need to be undertaken across a far faster time span than has been envisaged, or the manner of use of IPv4 addresses, and, in particular their usage efficiency in the context of dual-stack transition support, will need to differ markedly from the current manner of address use. Numerous forms of response may be required, posing some challenging questions because there is no agreed precise picture of what markedly different and significantly more efficient form of address use is required here. To paraphrase the situation, it is clear that we need to do "something" differently, and do so as a matter of some urgency, but we have no clear agreement on what that something is that we should be doing differently. This situation obviously is not an optimal one.

What was intended as a transition mechanism for IPv6 is still the only feasible approach that we are aware of, but the forthcoming exhaustion of the unallocated IPv4 address pool now calls for novel forms of use of IPv4 addresses within this transitional framework, and these novel forms may well entail the deployment of various forms of address translation technologies that we have not yet defined, let alone standardized. The transition may also call for scaling capabilities from the interdomain routing system that also head into unknown areas of technology and deployment feasibility.

Why?

At this point it may be useful to consider how and why this situation has arisen.

If the industry needed an abundant supply of IPv4 addresses to underpin the entire duration of the dual-stack transition to IPv6, then why didn't the industry follow the lead of the IETF and commence this transition while there was still an abundant supply of IPv4 addresses on hand? If network operators, service providers, equipment vendors, component suppliers, application developers, and every other part of the Internet supply chain were aware of the need to commence a transition to IPv6 well before effective exhaustion of the remaining pool of IPv4 addresses, then why didn't the industry make a move earlier? Why was the only clear signal for a change in Internet operation to commence a dual-stack transition to IPv6 one that has been activated too late to be useful for the industry to act on efficiently?

One possible reason may lie in a perception of the technical immaturity of IPv6 as compared to IPv4. It is certainly the case that many network operators in the Internet are highly risk-adverse and tend to operate their networks in a mainstream path of technologies rather than constantly using leading-edge advance releases of hardware and software solutions. Does IPv6 represent some form of unacceptable technical risk of failure that has prevented its adoption? This reasoning does not appear to be valid in terms of either observed testing or observation of perceptions about the technical capability of IPv6. The IPv6 protocol is functionally complete and internally consistent, and it can be used in almost all contexts where IPv4 is used today. IPv6 works as a platform for all forms of transport protocols, and is fully functional as an internetwork layer protocol that is functionally equivalent to IPv4. IPv6 NAT exists, *Dynamic Host Configuration Protocol Version 6* (DHCPv6) provides dynamic host configuration for IPv6 notes, and the DNS can be completely equipped with IPv6 resource records and operate using IPv6 transport for queries and responses.

Perhaps the only notable difference between the two protocols is the ability to perform host scans in IPv6, where probe packets are sent to successive addresses. In IPv6 the address density is extremely low because the low-order 64-bit interface address of each host is more or less unique, and within a single network the various interface addresses are not clustered sequentially in the number space. The only known use of address probing to date has been in various forms of hostile attack tools, so the lack of such a capability in IPv6 is generally seen as a feature rather than an impediment. IPv6 deployment has been undertaken in a small scale for many years, and although the size of the deployed IPv6 base remains small, the level of experience gained with the technology functions has been significant. It is possible to draw the conclusion that IPv6 is technically capable and this capability has been broadly tested in almost every scenario except that of universal use across the Internet.

It also does not appear that the reason was a lack of information or awareness of IPv6. The efforts to promote IPv6 adoption have been under way in earnest for almost a decade now. All regions and many of the larger economies have instigated programs to promote the adoption of IPv6 and have provided information to local industry actors of the need to commence a dual-stack transition to IPv6 as soon as possible. In many cases these promotional programs have enjoyed broad support from both public and industry funding sources. The coverage of these promotional efforts has been widespread in industry press reports. Indeed, perhaps the only criticism of this effort is possibly too much promotion, with a possible result that the effectiveness of the message has been diluted through constant repetition.

A more likely area to examine in terms of possible reasons why industry has not engaged in dual-stack transition deployment is that of the business landscape of the Internet. The Internet can be viewed as a product of the wave of progressive deregulation in the telecommunications sector in the 1980s and early 1990s. New players in the deregulated industry searching for a competitive edge to unseat the dominant position of the traditional incumbents found the Internet as their competitive lever. The result was perhaps unexpected, because it was not one that replaced one vertically integrated operator with a collection of similarly structured operators whose primary means of competition was in terms of price efficiency across an otherwise undifferentiated service market, as we saw in the mobile telephony industry. In the case of the Internet, the result was not one that attempted to impose convergence on this industry, but one that stressed divergence at all levels, accompanied by branching role specialization at every level in the protocol stack and at every point in the supply chain process. In the framework of the Internet, consumers are exposed to all parts of the supply process, and do not rely on an integrator to package and supply a single, all-embracing solution. Consumers make independent purchases of their platform technology, their software, their applications, their access provider, and their means of advertising their own capabilities to provide goods and services to others, all as independent decisions, all as a result of this direct exposure to the consumer of every element in the supply chain.

What we have today is an industry structure that is highly diverse, broadly distributed, strongly competitive, and intensely focused on meeting specific customer needs in a price-sensitive market, operating on a quarter-by-quarter basis. Bundling and vertical integration of services has been placed under intense competitive pressure, and each part of the network has been exposed to specialized competition in its right. For consumers this situation has generated significant benefits. For the same benchmark price of around US$15 to US$30 per month, or its effective equivalent in purchasing power of a local currency, today's Internet user enjoys multimegabit-per-second access to a richly populated world of goods and services.

The price of this industry restructure has been a certain loss of breadth and depth of the supply side of the market. If consumers do not value a service, or even a particular element of a service, then there is no benefit in incurring marginal additional cost in providing the service. In other words, if the need for a service is not immediate, then it is not provided. For all service providers right through the supply side the focus is on current customer needs, and this focus on current needs, as distinct from continued support of old products or anticipatory support of possible new products, excludes all other considerations.

Why is this change in the form of communications industry operation an important factor in the adoption of IPv6? The relevant question in this context is that of placing IPv6 deployment and dual-stack transition into a viable business model. IPv6 was never intended to be a technology visible to the end user. It offers no additional functions to the end user, nor any direct cost savings to the customer or the supplier. Current customers of ISPs do not need IPv6 today, and neither current nor future customers are aware that they may need it tomorrow. For end users of Internet services, e-mail is e-mail and Web-based delivery of services is just the Web. Nothing will change that perspective in an IPv6 world, so in that respect customers do not have a particular requirement for IPv6, as opposed to a generic requirement for IP access, and will not value such an IPv6-based access service today in addition to an existing IPv4 service. For an existing customer IPv6 and dual stack simply offer no visible value. So if the existing customer base places no value on the deployment of IPv6 and dual stack, then the industry has little incentive to commit to the expenditure to provide it.

Any IPv6 deployment across an existing network is essentially an unfunded expenditure exercise that erodes the revenue margins of the existing IPv4-based product. And as long as sufficient IPv4 address space remains to cover the immediate future needs, looking at this situation on the basis of a quarter-by-quarter business cycle, then the decision to commit to additional expenditure and lower product margins to meet the needs of future customers using IPv6 and dual-stack deployments is a decision that can comfortably be deferred for another quarter. This business structure of today's Internet appears to represent the major reason why the industry has been incapable of making moves on dual-stack transition within a reasonable timeframe as it relates to the timeframe of IPv4 address pool exhaustion.

What of the strident calls for IPv6 deployment? Surely there is substance to the arguments to deploy IPv6 as a contingency plan for the established service providers in the face of impending IPv4 address exhaustion, and if that is the case, why have service providers discounted the value of such contingency motivations? The problem to date is that IPv4 address exhaustion is now not a novel message, and, so far, NAT usage has neutralized the urgency of the message.

The NAT protocol is well-understood, it appears to work reliably, applications work with it, and it has influenced the application environment to such an extent that now no popular application can be fielded unless is can operate across this protocol. For conventional client-server applications, NAT represents no particular problem. For peer-to-peer–based applications, the rendezvous problem with NAT has been addressed through application gateways and rendezvous servers. Even the variability of NAT behavior is not a service provider liability, and it is left to applications to load additional functions to detect specific NAT behavior and make appropriate adjustments to the behavior of the application.

The conventional industry understanding to date is that NAT can work acceptably well within the application and service environment. In addition, NAT usage for an ISP represents an externalized cost, because it is essentially funded and operated by the customer and not the ISP. The service provider's perspective is that considering that this protocol has been so effective in externalizing the costs of IPv4 address scarcity from the ISP for the past 5 years, surely it will continue to be effective for the next quarter. To date the costs of IPv4 address scarcity have been passed to the customer in the form of NAT-equipped CPE devices and to the application in the form of higher complexity in certain forms of application rendezvous. ISPs have not had to absorb these costs into their own costs of operation. From this perspective, IPv6 does not offer any marginal benefits to ISPs. For an ISP today, NATs are purchased and operated by customers as part of their CPE equipment. To say that IPv6 will eliminate NATs and reduce the complexities and vulnerabilities in the NAT service model is not directly relevant to the ISP.

The more general observation is that, for the service provider industry currently, IPv6 has all the negative properties of revenue margin erosion with no immediate positive benefits. This observation lies at the heart of why the service provider industry has been so resistant to the call for widespread deployment of IPv6 services to date.

It appears that the current situation is not the outcome of a lack of information about IPv6, nor a lack of information about the forthcoming exhaustion of the IPv4 unallocated address pool. Nor is it the outcome of concerns over technical shortfalls or uncertainties in IPv6, because there is no evidence of any such technical shortcomings in IPv6 that prevent its deployment in any meaningful fashion. A more likely explanation for the current situation is an inability of a highly competitive deregulated industry to be in a position to factor longer-term requirements into short-term business logistics.

What Next?

Now we consider some questions relating to IPv4 address exhaustion. Will the exhaustion of the current framework that supplies IP addresses to service providers cause all further demand for addresses to cease at that point?

Or will exhaustion increase the demand for addresses in response to various forms of panic and hoarding behaviors in addition to continued demand from growth?

The size and value of the installed base of the Internet using IPv4 is now very much larger than the size and value of incremental growth of the network. In address terms the routed Internet currently (as of 14 August 2008) spans 1,893,725,831 IPv4 addresses, or the equivalent of 112.2 /8 address blocks. Some 12 months ago the routed Internet spanned 1,741,837,080 IPv4 addresses, or the equivalent of 103.8 /8 address blocks, representing a net annual growth of 10 percent in terms of advertised address space.

These facts lead to the observation that, even in the hypothetical scenario where all further growth of the Internet is forced to use IPv6 exclusively while the installed base still uses IPv4, it is highly unlikely that the core value of the Internet will shift away from its predominate IPv4 installed base in the short term.

Moving away from the hypothetical scenario, the implication is that the relative size and value of new Internet deployments will be such that these new deployments may not have sufficient critical mass by virtue of their volume and value as to be in a position to force the installed base to underwrite the incremental cost to deploy IPv6 and convert the existing network assets to dual-stack operation in this timeframe. The corollary of this observation is that new Internet network deployments will need to communicate with a significantly larger and valuable IPv4-only network, at least initially. The fact that IPv6 is not backward-compatible with IPv4 further implies that hosts in these new deployments will need to cause IPv4 packets with public addresses in their packet headers to be sent and received, either by direct deployment of dual stack or by proxies in the form of protocol-translating NATs. In either case the new network will require some form of access to public IPv4 addresses. In other words, after exhaustion of the unallocated address pools, new network deployments will continue to need to use IPv4 addresses.

From this observation it appears highly likely that the demand for IPv4 addresses will continue at rates comparable to current rates across the IPv4 unallocated address pool and after it is exhausted. The exhaustion of the current framework of supply of IPv4 addresses will not trigger an abrupt cessation of demand for IPv4 addresses, and this event will not cause the deployment of IPv6-only networks, at least in the short term of the initial years following IPv4 address pool exhaustion. It is therefore possible to indicate that immediately following this exhaustion event there will be a continuing market need for IPv4 addresses for deployment in new networks.

Although a conventional view is that this market need is likely to occur in a scenario of dual-stacked environments, where the hosts are configured with both IPv4 and IPv6, and the networks are configured to also support the host operation of both protocols, it is also conceivable to envisage the use of deployments where hosts are configured in an IPv6-only mode and network equipment undertakes a protocol-translating NAT function. In either case the common observation is that we apparently will have a continuing need for IPv4 addresses well after the event of IPv4 unallocated pool exhaustion, and IPv6 alone is no longer a sufficient response to this problem.

How?

If demand continues, then what is the source of supply in an environment where the current supply channel, namely the unallocated pool of addresses, is exhausted? The options for the supply of such IPv4 addresses are limited.

In the case of established network operators, some IPv4 addresses may be recovered through the more intensive use of NAT in existing networks. A typical scenario of current deployment for ISPs involves the use of private address space in the customer's network and NAT performed at the interface between the customer network and the service provider infrastructure (the CPE). One option for increasing the IPv4 address usage efficiency could involve the use of a second level of NAT within the service provider's network, or the so-called "carrier-grade" NAT option[9]. This option has some attraction in terms of increasing the port density use of public IPv4 addresses, by effectively sharing the port address space of the public IPv4 address across multiple CPE NAT devices, allowing the same number of public IPv4 addresses to be used across a larger number of end-customer networks.

The potential drawback of this approach is that of added complexity in NAT behavior for applications, given that an application may have to traverse multiple NATs, and the behavior of the compound NAT scenario becomes in effect the behavior of the most conservative of the NATs in the path in terms of binding times and access. Another potential drawback is that some applications have started to use multiple simultaneous transport sessions in order to improve the performance of the download of multipart objects. For single-level CPE NATs with more than 60,000 ports to be used for the customer network, this application behavior had little effect, but the presence of a carrier NAT servicing a large number of CPE NATs may well restrict the number of available ports per connection, in turn affecting the utility of various forms of applications that operate in this highly parallel mode. Allowing for a peak simultaneous demand level of 500 ports per customer provides a potential use factor of some 100 customers per IP address.

Given a large enough common address pool, this factor may be further improved by statistical multiplexing by a factor of 2 or 3, allowing for between 200 and 300 customers per NAT address. Of course such approximations are very coarse, and the engineering requirement to achieve such a high level of NAT usage would be significant. Variations on this engineering approach are possible in terms of the internal engineering of the ISP network and the control interface between the CPE NATs and the ISP equipment, but the maximal ratio of 200 to 300 customers per public IP address appears to be a reasonable upper bound without unduly affecting application behaviors.

Another option is based on the observation that, of the currently allocated addresses, some 42 percent of them, or the equivalent of some 49 /8 address blocks, are not advertised in the interdomain routing table, and are presumed to be either used in purely private contexts, or currently unused. This pool of addresses could also be used as a supply stream for future address requirements, and although it may be overly optimistic to assume that the entirety of this unadvertised address space could be used in the public Internet, it is possible to speculate that a significant amount of this address pool could be used in such a manner, given the appropriate incentives. Speculating even further, if this address pool were used in the context of intensive carrier-grade NATs with an achieved average deployment level of, say, 10 customers per address, an address pool of 40 /8s would be capable of sustaining some 7 billion customer attachments.

Of course, no such recovery option exists for new entrants, and in the absence of any other supply option, this situation will act as an effective barrier to entry into the ISP market. In cases where the barriers to entry effectively shut out new entrants, there is a strong trend for the incumbents to form cartels or monopolies and extract monopoly rentals from their clients. However, it is unlikely that the lack of supply will be absolute, and a more likely scenario is that addresses will change hands in exchange for money. Or, in other words, it is likely that such a situation will encourage the emergence of markets in addresses. Existing holders of addresses have the option to monetize all or part of their held assets, and new entrants, and others, have the option to bid against each other for the right to use these addresses. In such an open market, the most efficient usage application would tend to be able to offer the highest bid, in an environment dominated by scarcity tending to provide strong incentives for deployment scenarios that offer high levels of address usage efficiency.

It would therefore appear that options are available to this industry to increase the usage efficiency of deployed address space, and thereby generate pools of available addresses for new network deployments. However, the motive for so doing will probably not be phrased in terms of altruism or alignment to some perception of the common good. Such motives sit uncomfortably within the commercial world of the deregulated communications sector.

Nor will it be phrased in terms of regulatory impositions. It will take many years to halt and reverse the ponderous process of public policy and its expression in terms of regulatory measures, and the "common-good" objective here transcends the borders of regulatory regimes. This consideration tends to leave this argument with one remaining mechanism that will motivate the industry to significantly increase the address usage efficiency: monetizing addresses and exposing the costs of scarcity of addresses to the address users. The corollary of this approach is the use of markets to perform the address distribution function, creating a natural pricing function based on levels of address supply and demand.

GEOFF HUSTON is the Chief Scientist at APNIC, the Regional Internet Registry serving the Asia Pacific region. He graduated from the Australian National University with a B.Sc. and M.Sc. in Computer Science. He has been closely involved with the development of the Internet for many years, particularly within Australia, where he was responsible for the initial build of the Internet within the Australian academic and research sector. He is author of numerous Internet-related books, and was a member of the Internet Architecture Board from 1999 until 2005; he served on the Board of Trustees of the Internet Society from 1992 to 2001.
E-mail: **gih@apnic.net**

Letters to the Editor

I sincerely congratulate you for Geoff Huston's excellent article in *The Internet Protocol Journal,* June 2008, on the "Decade of Internet Evolution." The article shows an amazing insight into the Internet as it has recently evolved and deserves as wide an audience as possible.

The only comment I could make is that though Huston hints about separating the IP address from the host name, he does not explicitly mention the *Host Identity Protocol* (HIP)[1]. Previous issues of the Journal have this omission as well.

Note: As we struggle in the IETF and everywhere else in the industry with NAT traversal, mobility, and multihoming, we see countless approaches for each application layer protocol separately. HIP seems to fulfill the promise of solving these problems comprehensively.

Thanks for the privilege to continue reading the Journal; keep such papers coming.

—Henry Sinnreich, Adobe Systems, Inc.

The author responds:

Thank you for your generous comments.

At some point I was toying (dangerously!) with writing an article that attempted to predict the next 10 years, looking at what appears to be important today and what that could mean in the future. There is no doubt that the tight binding of identity and location is one of the assumptions that has made the Internet both simple and effective for the past decade. But where we sit today, in a world dominated by scale, mobility, a dense mesh of interconnectivity, highly capable end devices, dense middleware, and a panoply of specialized requirements, we need to look forward to methods that allow separation of identity and location. Now this separation could be at the level of the Internet Protocol itself, as in HIP or *Site Multihoming by IPv6 Intermediation* (SHIM6); or at the level of the transport session, as exemplified at present by the *Stream Control Transmission Protocol* (SCTP); or even at the application level, where the various offerings related to *Voice over IP* (VoIP) and *Peer-to-Peer* (P2P) have been working at the level of multiparty application rendezvous and application identity that sit on top of an adaptive platform of dynamic discovery of the characteristics of the underlying transport subsystem.

Each approach appears to offer some significant leverage in scaling the network in diverse ways, while at the same time presenting us with some fascinating insights into possible architectures that could address our needs in the next decade. No doubt the next 10 years will present us with some quite novel challenges with the imminent exhaustion of the unallocated IPv4 address pool and the associated observation that the schedule for the update of IPv6 has proceeded so slowly that we will be forced to be remarkably inventive with IPv4. HIP may well be a central part of such invention, but, more generally, I have no doubt that we will examine more generally how we can devise refinements to the networking model that preserve useful notions of identity across a rather fluid sea of shared location tokens.

Regards,

—Geoff Huston, APNIC
gih@apnic.net

Ten Years of IPJ

We received many congratulatory messages in response to our June 2008 Anniversary Issue. The following are some quotes from our readers:

"Compliments and congratulations for the tenth anniversary of this great Journal. It is great because it is making us realize the synergy between what has been and what is to come."

—John Okewole, Lagos, Nigeria

"This week I received the June 2008 issue of IPJ. I have been a subscriber for several years and it has been a great pleasure to find great contents in IPJ, such as the current issue that brings reviews on Internet evolution. I would like to send my congratulations to the IPJ team for 10 years of publication and my best wishes for future success."

—Frederico Fari, Belo Horizonte, Brazil

"I think that IPJ is a great journal. I hope you will not be forced to give up the paper edition because is a beautiful one (and it allows me to read during the evening hours when all computers and children in the house are shut down :–)"

—Andrea Montefusco, Rome, Italy

Book Reviews

Two Books on Cyber Law

Code and Other Laws of Cyberspace

Code and Other Laws of Cyberspace, by Lawrence Lessig, Basic Books, 1999, ISBN 0-465-03913-8. `http://code-is-law.org/`

Code 2.0

Code 2.0, by Lawrence Lessig, Basic Books, 2006, ISBN-10: 0-465-03914-6, ISBN 13: 978-0-465-03914-2. `http://codev2.cc/`

First published in 1999, then Harvard Law School Professor Lawrence Lessig's cautionary tale about the inescapable influence of certain material features of the built Internet has since become a foundational "Internet studies" text in universities and laws schools around the world. Lessig, who now occupies an endowed chair at Stanford Law School, makes a series of troubling observations about the Internet, his chosen sector of focus since setting aside his mid-1990s work on legal and institutional development in post-Soviet societies.

Lessig's key findings from that previous work are that rules matter—especially the sort of rules embodied in "constitutions" and other foundational institutions; that rules are artifacts of contingent human intent and design; and that rules can be changed. Being a "classical liberal" on the model of John Stuart Mill, Lessig advocates the sort of rules that afford maximum liberty for individuals against a triumvirate of coercive influences, including not only governments but also market power and oppressive social mores.

Now however, a fourth challenge to personal liberty has been exposed by the advent of the Internet—or rather, of *cyberspace,* which Lessig describes as the lived experience of participants in the rich application space that has been built atop the Internet. This new constraining factor is "architecture," which Lessig defines as "the built environment," or "the way the world is," that is, the cumulative result of all of the contingent historical events and decisions that have shaped the material circumstances confronting Internet users (or *cyberspace denizens*) today. *Code* is Lessig's term for the instruction sets (that is, programs, applications, etc.) that are the building blocks of the architecture of cyberspace; it is the stuff that emerges from the decision making of a relatively few (the *code writers*), which accretes over time into the less-malleable architecture that shapes the everyday choices and possibilities of everyone else whom the Internet or cyberspace touches.

New Code Means New Power(s)

According to Lessig, the code that defines cyberspace—which he calls "West Coast Code"—demands particular attention, both because of its omnipresence and because of how it differs from the other, more familiar factors that can impinge on individual liberty.

Like the canons of law (also known as "East Coast Code"), code is basically a collection of rules written with human goals and objectives in mind. However, in its effects code more closely resembles the laws of nature, because it requires neither the awareness nor the consent of its subjects in order to be effective. Although this claim sounds suspiciously like a variant, or perhaps an illustration of Arthur C. Clarke's *Third Law of Prediction* (which states that any sufficiently advanced technology will be indistinguishable from the supernatural), there is purpose behind Lessig's observation. The self-enforcing character of code is doubly problematic in the case of cyberspace, he suggests, because unlike the law, code affords no appeal, no recourse, and no formal, institutional review and interpretation of the kind that lawyers and judges exercise in legal matters. Without such expert oversight, code might come to be used as a tool to subvert individual liberties or public values, for either commercial or political gain, without anyone's being the wiser. In fact, he implies, the lack of transparency of code almost invites such abuses.

At this point some might be tempted to dismiss Lessig's program as just "sour grapes" from a high-profile industry spokesman sensing this erosion of the traditional prominence and centrality of his profession in a new code-centric world. Lessig believes passionately in the exercise of law and judicial review as master tools for keeping other important forces—government power, market power, and social norms—broadly aligned with "important public values." He extols the relationships among the rule of law, democracy, and politics, the latter of which invests law with legitimacy to raise or lower the cost of particular individual actions (for example, by taxing, criminalizing, valorizing, or subsidizing them) to encourage conformity with publicly chosen goals and values. He observes that "architecture is a kind of law" and that "code codifies values, and yet, oddly, most people speak as if code were just a question of engineering." It takes no great leap of imagination to conclude that code too should be subject to the same kind of legal and judicial oversight that keeps the rest of society running smoothly. Eliminating any doubt, Lessig asserts that:

> Technology is plastic. It can be remade to do things differently. We should expect—and demand—that it can be made to reflect any set of values that we think important. The burden should be on the technologists to show us why that demand can't be met.

However, such a dismissal would indeed be too easy, for Lessig also expresses misgivings about the professionalization and segregation of "constitutional thinking" within the legal sector. "Constitutional thought has been the domain of lawyers and judges for too long," Lessig writes, and as a result everyone else has grown less comfortable—and also less competent—in engaging in fruitful conversation about fundamental, "constitutional" values.

And yet Lessig suggests that this skill has also atrophied within the legal community, as more and more jurists have embraced an "originalist" interpretive philosophy that holds that the U.S. Constitution provides no guidance for how to resolve conflicts between old values—what Lessig calls *latent ambiguities*—or how to address wholly novel concerns raised by technologies such as the Internet. Originalists (Lessig mentions U.S. Supreme Court Justice Antonin Scalia) assert that in such cases the only recourse is the political and legislative processes—where, one assumes, limited experience with both technology and constitutional debate make the prospects for success even dimmer. Lessig writes that "We (legal scholars) have been trapped by a mode of reasoning that pretends that all the important questions have already been answered," but that "the constitutional discourse of our present Congress is far below the level at which it must be to address the questions about constitutional values that will be raised by cyberspace."

Diagnosis from a Distance

Lessig is without question eminently qualified to make such observations about his home-turf legal and political spheres. However, it is less clear that his blanket charge of deliberative incompetence is equally valid across the full range of Internet and cyberspace stakeholders. Neither is it clear that the architecture of cyberspace is as uniquely problematic as he suggests, compared to the architecture of other, more familiar domains. Finally, Lessig's own admittedly limited technical expertise may lead him to misapprehend the boundary between cyberspace and the Internet, and to underestimate the radicalness of his proposed cyberspace fix.

Taking these ideas in reverse order, Lessig's conception of the structural and functional distinction between the Internet and cyberspace merits closer scrutiny. As explained later, Lessig advocates profound technical changes to bring the functions of code under the rule of law (or laws, because Lessig wishes to accommodate subsidiary jurisdictions as well as sovereign differences in law). However, he envisions this intervention affecting only the "code" domain, not the "Internet's core protocols":

> When I speak about regulating the code, I'm not talking about changing these core TCP/IP protocols...In my view these components of the network are fixed. If you required them to be different, you'd break the Internet. Thus rather than imagining the government changing the core, the question I want to consider is how the government might either (1) complement the core with technology that adds regulability, or (2) regulate applications that connect to the core.

Lessig's specific ideas for achieving this function while preserving the core are not fully detailed in this context until *Code 2.0* (2006), which Lessig describes as an update rather than a full rewrite, albeit one with new relevance to match a "radically different time." The central idea involves the introduction of an "identity layer" that permits authoritative in-band querying and signaling of the jurisdiction(s) to which every would-be Internet user is subject. The deployment of this system would be accompanied by the development of a comprehensive distributed database of Internet usage restrictions mandated by every legally recognized jurisdiction around the world. Together, these components would operate as a kind of "domain interdiction system" that would automatically black-hole all Internet resource queries that are legally impermissible to individuals based on their jurisdiction(s) of origin, regardless of their actual location.

This proposal is clearly vulnerable to criticism of many kinds—technical, ethical, practical, etc.—and to be fair Lessig anticipates and preemptively responds to several of the most obvious ones. Space limitations preclude any review of those arguments here, but it is impossible to resist a few short observations. First, it is not clear why Lessig imagines that his proposed system would be anything less than a fundamental intervention in the core function and protocols of the Internet. Today several different high-profile technical developments that could plausibly be described as changing TCP/IP are under way, but they (hopefully) will not break the Internet. At the same time, TCP/IP is not the only technology that is essential to the Internet "core." The system that Lessig advocates is clearly inspired by the *Domain Name System* (DNS), it would of necessity be similarly global and ubiquitous in scope and scale, and it would likely function by selectively blocking some DNS responses based on the initiator's identity. Although some once regarded the DNS as a mere application (for example, shortly after it was invented), few today would categorize it as anything other than a core protocol. Also, given the degree to which any implementation of the proposed identity system would preempt many "normative" features that are associated with the Internet core (for example, the principles behind the *end-to-end* arguments), it is unclear what would remain "unbroken" therein that might still warrant any special consideration or separate treatment. We can only hope that Lessig's optimism on this question is justified, because looming developments in certain wireless standards as well as in the management of IP addressing may provide for more concrete—and less revisable—answers in the very near future.

Objects in View May Be Closer Than They Appear

Then there is the question of how much code really makes the architecture of cyberspace different from the architecture of other domains. Many of Lessig's claims on this point date back to the first version of the book, when Internet exceptionalism was still new enough for deflationary counterarguments to seem provocative.

Although the revolutionary potential of the Internet continues to inspire many (this reviewer included), the past decade of booms, busts, compromises, and indictments have done much to temper that faith. It is not that Lessig's concerns about the opaque nature of cyberspace architecture, about the substantial influence that code writers and network owners command, and about the vulnerability of the whole system to a crisis-induced authoritarian turn aren't reasonably well-founded. But they are equally apropos to most other important spheres of life. The phrase "possession is nine-tenths of the law" has multiple meanings, and was coined many decades before the Internet was invented. The inexplicability of many current "real-world" legislative and judicial outcomes without recourse to some cynical theory of unacknowledged interests and unobservable influence certainly raises many questions about the architecture of the space beyond cyberspace. And Lessig's warnings about national security fears precipitating a sudden loss of freedoms (taken from Jonathan Zittrain's *Z-Theory*) now seem prophetic—albeit less for the Internet than for the earliest and largest host society of the Internet. One might observe that Lessig is guilty of his own kind of exceptionalism—one that, ironically, may obscure the degree to which constitutional challenges in the real and virtual worlds are more or less the same. In fact, Lessig's subsequent shift of priorities from code to intellectual property law recently ended with a return to his original home turf of law and politics—perhaps in belated recognition that sometimes, even when you have a good story, East Coast Code is still the only durable recourse.

Finally, there is the question of constitutional acumen. This question is the critical one for Lessig (he uses some form of the term *constitution* more than 250 times in the main text), because for him the term evokes nothing less than "an architecture... a way of life that structures and constrains social and legal power, to the end of protecting fundamental values." In this sense, he adds, constitutions are built rather than found. Moreover, they have been built in different (albeit sometimes overlapping) places by different institutions and societies, many with quite different conceptions of which fundamental values to uphold. From whence will the architecture of values of cyberspace emerge? Who will be its authors? Lessig never quite gives a final answer, even for his own home jurisdiction, but he does help to winnow out several likely suspects. As noted previously, he invests little faith in the current U.S. legislative branch. He also has reservations about many members of his own legal profession, although the need to preserve backward compatibility with the primary U.S. Constitution and to reconcile newly revealed "latent ambiguities" therein obviously recommends some legal training at the very least. Government and industry represent the most likely perpetrators of liberty-undermining code, Lessig claims, so he looks for no help from those quarters.

In the end Lessig provides some oblique advice for judges (abandon formalism), hackers (open source), and voters (educate yourself, and don't give up hope), but ultimately concludes with a call for more lawyerly deliberation: if only our leaders could act more like lawyers, telling stories that persuade "not by hiding the truth or exciting the emotion, but by using reason," and our fellow citizens could act like juries, resisting the fleeting passions of the mob and making decisions based on the facts alone, then perhaps we could overcome the architectural challenges of both cyberspace and physical space.

Story Boards and Internet Constitutions

Notwithstanding its solipsistic aspects, advice like that discussed in the last section is hard to find fault with. Professor Lessig is unquestionably a person of good conscience, and has a long, distinguished, and very well-documented record of putting this advice into practice in a wide range of good causes, including many that are wholly unrelated to code or cyberspace. However, one could argue (perhaps with equal solipsism) that many of the behaviors and virtues that he commends are now regularly on display in the mailing lists, message boards, and other deliberative records of the Regional Internet Registries, the IETF, and the IAB—in particular in discussions on the form that IPv4 and IPv6 address-allocation policies should take, in the design of future routing systems that balance scalability with the freedom to choose between competing providers, and in the reconciliation of traditional policies and their beneficiaries with the changing realities of Internet resource stewardship. Closer scrutiny of these records reveals that successful consensus policies are almost invariably borne of good, well-reasoned stories, the vast majority of which are offered by individuals who are affiliated neither with government agencies nor with any of the largest and most powerful ISPs. Many of the storytellers are old hands, but new voices regularly emerge and command attention based on nothing more than the strength of their reasoning. Participating in these discussions, one can *occasionally* experience the same feeling that inspires Lessig in the courtroom, where "some, for the first time in their lives, see power constrained by reason. Not by votes, not by wealth, not by who someone knows—but by an argument that persuades."

That this "architectural" work has gone largely unrecognized to date in law schools, university humanities and social science departments, and even in some civil society-oriented Internet governance fora is not entirely unexpected, because the context and terminology of those discussions is invariably technical, even if many participants recognize that the underlying principles are essentially "constitutional" in nature. No doubt a more complete conversation between code writers and constitutionalists is inevitable over time, and with luck more cross-fertilization will lead to better protocols, better policies, and better architecture.

However, this rapprochement is unlikely to be initiated by technologists seeking to take up the study and application of legal principles. Lessig, whose own intellectual project builds substantially on the antiformalist, "legal realist" school of thought, should understand this reality better than most. In the crudest of forms, legal realism holds that "the Law is whatever lawyers happen to say it is." Stated as neither a boast nor a claim of entitlement but rather as a practical observation of the challenges that lawyers face in applying ambiguous old laws to incommensurable new circumstances, this maxim nevertheless clearly conveys a sense of both the great responsibility and the great power that lawyers command. Perhaps it is time that Mr. Lessig and his counterparts consider the possibility that a similar school of thought may inform (consciously or unconsciously) the perspectives of network builders and code writers. Being of no less good conscience, perhaps code writers and other "cyberspace realists" are merely waiting for the moment when the Law and lawyers come calling with a good story, under the banner of reason rather than power. So long as the story now unfolding continues to make sense and satisfy the ever-expanding audience, we needn't fear either.

Code may not be *that* particular story, but it's an excellent read, and an important contribution to a dialogue that must be engaged.

—Tom Vest

Fragments

Global Policy Proposal for Remaining IPv4 Address Space

Global Internet Number Resource Policies are defined by the *Address Supporting Organization* (ASO) MoU[1]—between the *Internet Corporation for Assigned Names and Numbers* (ICANN) and the *Number Resource Organization* (NRO)—as "Internet number resource policies that have the agreement of all RIRs according to their policy development processes and ICANN, and require specific actions or outcomes on the part of the *Internet Assigned Numbers Authority* (IANA) or any other external ICANN-related body in order to be implemented." Attachment A of this MoU describes the *Development Process of Global Internet Number Resource Policies,* including the adoption by every *Regional Internet Registry* (RIR) of a global policy to be forwarded to the ICANN Board by the ASO, as well as its ratification by the ICANN Board. In this context, the ICANN Board adopted its own Procedures[2] for the Review of Internet Number Resource Policies Forwarded by the ASO for Ratification.

Among other features, these Procedures state that the Board will decide, as and when appropriate, that ICANN staff should follow the development of a particular global policy, undertaking an "early awareness" tracking of proposals in the addressing community. To this end, staff should issue background reports periodically, forwarded to the Board, to all ICANN Supporting Organizations and Advisory Committees and posted at the ICANN Web site.

At its meeting on 20 November 2007, the Board resolved to request tracking of the development of a global policy proposal for allocation of remaining IPv4 address space, under discussion in the Regional Internet Registries. The status overview presented below is compiled in response to this request and will be further updated as developments proceed, for information to ICANN entities and the wider community. This is the fifth issue of the tracking of this policy.

Originally, two slightly different global policy proposals were introduced for allocation of the remaining IPv4 address space:

- A version (1) "Global Policy for the Allocation of the Remaining IPv4 Address Space," first presented at LACNIC X in May 2007
- A version (2) "End Policy for IANA IPv4 allocations to RIRs," first presented at APNIC 24 in September 2007

Both featured the same approach, distribution of an equal number *N* of /8 IPv4 address blocks to each RIR when the IANA free pool would reach the threshold value of $5 \times N$, but differed in the proposed value of *N*, notably 2 or 1, respectively. The proposals were discussed in parallel in the RIRs and regarded essentially as one proposal, with a view to converging on a value for *N*. In February 2008, agreement was reached for a unified proposal (3).

The current proposal is thus:

- Version (3) "Global Policy for the Allocation of the Remaining IPv4 Address Space," first presented at APNIC 25 in February 2008.

The proposal was introduced at the subsequent meetings of all other RIRs. It has now been adopted in ARIN, AfriNIC, LACNIC and RIPE, and is in final call in APNIC. If adopted by all the RIRs, the proposal will subsequently be handled by the NRO Executive Council and the ASO Advisory Council according to their procedures before being submitted to the ICANN Board for ratification. A table[3] can be found on the ICANN Website that indicates the status within each RIR for the current proposal. Hyperlinks are included for easy access.

It should be noted that other policy proposals have been put forward and are being discussed regarding IPv4 address space exhaustion, although only those mentioned above have been scoped as global policy proposals in the sense of the ASO MoU, that is, focusing on address allocation from IANA to the RIRs, and recognized by the ASO AC as global policy proposals in that meaning.

From The Editor

Response to our use of a new printing paper has been very positive, so we will continue to use the uncoated and recycled Exact® paper introduced with our September 2008 issue. We are still interested in hearing your feedback on the paper, as well as any other aspect of this journal. Send your comments to: **ipj@cisco.com**

The last decade has seen many developments in the area of *wireless* networking technologies. Wireless Internet access is now available in thousands of locations ranging from private homes to hotels, trains, airplanes, ships at sea, and even entire cities. Wireless systems, specifically Bluetooth, are also used for short-range device connectivity such as between a mobile phone and a headset, while WiMAX systems are being deployed for larger area coverage. In our first article, T. Sridhar gives an overview of Wi-Fi, Bluetooth, and WiMAX.

As stated in our previous issue, the topic of IP Version 4 address exhaustion and migration to IP Version 6 is being debated in many Internet-related organizations, including the IETF, *Internet Corporation for Assigned Names and Numbers* (ICANN), and the *Regional Internet Registries* (RIRs). In our last issue, Geoff Huston outlined the history of IPv4 address depletion. This time we bring you the first in a two-part series of articles entitled "The End of Eternity." The article is by Niall Murphy and David Wilson. Part Two will follow in our March 2009 issue. As you will see from our "Letters to the Editor," views on the right way to tackle the address exhaustion and protocol migration challenge abound, and I predict we will carry yet more articles on this topic in future issues.

Just over 10 years ago, Jonathan B. Postel, Internet pioneer and a key player in many core Internet activities, passed away. In this issue we bring you a remembrance article written by another Internet pioneer, Vint Cerf. In connection with this anniversary, special events were held in Minneapolis in conjunction with the 73rd meeting of the IETF. The *Jonathan B. Postel Service Award* for 2008 was awarded to EsLaRed of Venezuela by a committee of former award winners. You will find more information about the award in our "Fragments" section on page 42.

Remember to let us know if your mailing address changes and to visit our online companion, *The Internet Protocol Forum,* where you will find additional articles and other material: **http://ipjforum.org**

Wi-Fi, Bluetooth and WiMAX—Technology and Implementation

by T. Sridhar, Flextronics

Wireless networks can be classified broadly as *Wireless Personal-Area Networks* (WPAN), *Wireless LANs* (WLANs), and *Wireless Wide-Area Networks* (WWANs). WPANs operate in the range of a few feet, whereas WLANs operate in the range of a few hundred feet and WWANs beyond that. In fact, wireless WANs can operate in a wide range—a metropolitan area, cellular hierarchy, or even on intercity links through microwave relays.

This article examines wireless technologies for the WLAN, WPAN, and WWAN areas, with specific focus on the IEEE 802.11 WLAN (often known as Wi-Fi®), *Bluetooth* (BT) in the WPAN, and WiMAX for WWAN as representative technologies. It discusses key aspects of the technology—medium access and connectivity to the wired network—and concludes by listing some common (mis)perceptions about wireless technology.

WLANs

The *Institute of Electrical and Electronic Engineers* (IEEE) defined three major WLAN types in 802.11–802.11 b and g, which operate in the 2.4-GHz frequency band, and 802.11a, which operates in the 5-GHz band. The 2.4- and 5-GHz bands used here are in the license-free part of the electromagnetic spectrum, and portions are designated for use in *Industrial, Scientific, and Medical* (ISM) applications—so these portions are often called ISM bands. More recently, a high-speed 802.11 WLAN has been proposed—the 802.11n WLAN, which operates in both the 2.4- and 5-GHz bands.

The 2.4-GHz frequency band used for 802.11 is the band between 2.4 and 2.485 GHz for a total bandwidth of 85 MHz, with 3 separate nonoverlapping 20-MHz channels. In the 5-GHz band, there are a total of 12 channels in 3 separate subbands—5.15 to 5.25 GHz (100 MHz), 5.25 to 5.35 GHz (100 MHz), and 5.725 to 5.825 GHz (100 MHz).

The more common mode of operation in 802.11 is the *infrastructure* mode, where the stations communicate with other wireless stations and wired networks (Ethernet typically) through an *access point*. The other mode is the *ad-hoc* mode, where the stations can communicate directly with each other without the need for an access point; we will not discuss this mode in this article. The access point bridges traffic between wireless stations through a lookup of the destination address in the 802.11 frame (see Figure 1a).

The *Media Access Control* (MAC) header of 802.11 has four addresses. Depending upon the value of a *FromDS* (from access point), or a *ToDS* (to access point) bits in the header (see Figure 1b), the addresses have different connotations. The first two addresses are for the receiver and transmitter, respectively.

Figure 1a: WLAN Network with Ethernet Connectivity

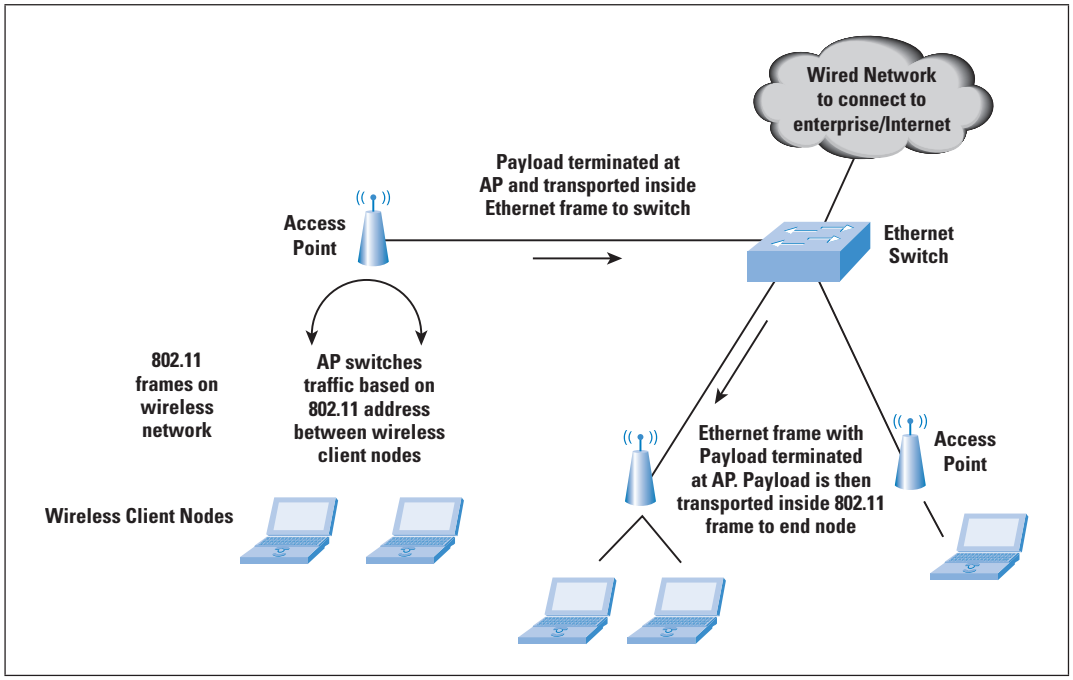

Figure 1b: 802.11 Frame Format

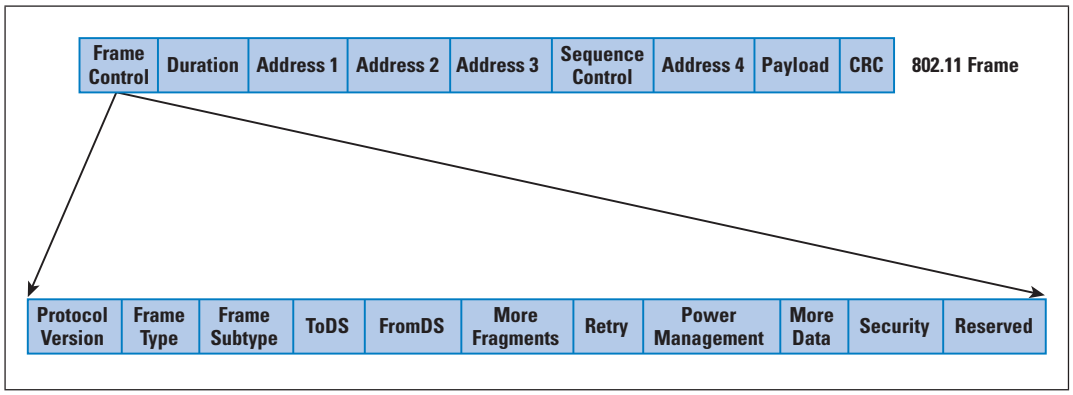

Address 4 is not used except when both FromDS and ToDS are set to 1—it is for a special mode of communication for access point-to-access point traffic, whence addresses 3 and 4 refer to the source- and destination-station MAC addresses, respectively, whereas addresses 1 and 2 refer to the access point addresses (that is, the transmitter and receiver on this inter-access point channel). When FromDS is set to 1, address 1 is the destination-station MAC address, address 2 is the access point address, and address 3 is the source-station MAC address. When ToDS is set to 1, address 1 is the access point MAC address, address 2 is the transmitting-station MAC address, and address 3 is the destination-station MAC address.

Although earlier versions of 802.11 LANs used *Frequency Hopping Spread Spectrum* (FHSS), 802.11b typically uses *Direct Sequence Spread Spectrum* (DSSS) for 1-, 2-, 5.5-, and 11-Mbps speeds. Both schemes involve transmission of a narrowband signal over a wider frequency range to mitigate the possibility of interference at any one frequency. The nodes and access points typically transmit at the highest data rate possible based on the current signal-to-noise ratio.

At the MAC level, 802.11 LANs involve the use of *Carrier Sense Multiple Access/Collision Avoidance* (CSMA/CA). Stations back off if they detect that another station is transmitting on that channel. The station then waits for a random period after the end of the transmission before it attempts to transmit on that channel. In addition, control frames such as *Request to Send* (RTS) and *Clear to Send* (CTS) are used to facilitate the actual data transfer. The CTS control frame has the duration for which the transmitting node is allowed to transmit. Other stations sense this frame and back off for at least the specified duration before sensing the radio link again.

When the access points are connected through a LAN, the entire system is known as a *Distribution System*. The access points perform an integration function—that is, bridging between wired and wireless LANs. In this scenario, (see Figure 1a) the wireless control and data frames are terminated at the access point or tunneled from the access point to a centralized controller over Ethernet. When terminated at the access point, the payload is transmitted from the access point to the network over Ethernet. This transmission is done in the following manner:

The source and destination addresses are set to the station and access point addresses, respectively. At the access point, the payload is stripped from the 802.11 data frame and sent as part of an Ethernet packet either as a broadcast packet or to a specific destination. If the packet sizes (when reassembled) are larger than the Ethernet frame size, they are discarded. In the reverse direction, the Ethernet frame can be directly encapsulated into an 802.11 frame for transmission from the access point to the end node. At the WLAN end node, the complete Ethernet frame shows up at the driver level as though it were a frame received on a pseudo Ethernet interface.

The most common 802.11b WLAN speed is 11 Mbps. However, based on the interframe spacing, preamble, header encapsulation, and acknowledgements for frames required, the actual throughput for user data would be about 50 percent of the actual speeds. This throughput of 50 percent of actual link speed is a common theme on 802.11g and 802.11a also.

Stations connect to the access point through a scanning process. Scanning can be passive or active. In the passive mode, the station searches for access points to find the best access point signal (which contains the *Service Set Identifier* [SSID], data rates, and so on).

The access point frame that the stations look for is a management frame known as the *beacon frame*. In the active mode, the station initiates the process by broadcasting a probe frame. All access points that receive the probe send back a probe response, helping the station build up the list of available access points. The sequence of a station "connecting" to an access point involves two steps. The first is *authentication,* where the station sends an authentication request frame to the access point. Depending upon the authentication through 802.1X or internal configuration, the access point can accept or reject the request with an authentication response. The second step is *association,* which is required to determine the data rates supported between the access point and the station. At the end of the association phase, the station is allowed to transmit and receive data frames.

Power Concerns in 802.11

Although it is not a part of the standard, the access points might adjust their transmitting power based on the environment they are in (they do have maximum limits based on regional restrictions). If they do not perform this adjustment, all the stations might connect to the access point with the highest transmitting power, even if the access point is far away. The other concern is, of course, the interference between access points. The power adjustment is usually done through configuration and, in some cases, through a monitoring function on the network. In the latter case, the monitoring function reports the information to a central controller.

A new initiative within the IEEE (802.11k) has been started to improve traffic distribution within the network. Specifically, it addresses the problem of access point overloading so that stations can connect to underused access points for a more efficient use of network resources.

With respect to power management on the client side, a station can indicate that it is going into a "sleep" or low-power state to the access point through a status bit in a frame header (refer to Figure 1b). The access point then buffers packets for the station instead of forwarding them to the station as soon as they are received. The sleeping station periodically wakes up to receive beacons from the access point. The beacons include information about whether frames are being buffered for the station. The station then sends a request to the access point to send the buffered frames. After receiving the frames, the station can go back to sleep.

802.11a/g Technology—Orthogonal Frequency-Division Multiplexing

Sometimes called *discrete multitone* (DMT) in the *Digital Subscriber Line* (DSL) world, *Orthogonal Frequency-Division Multiplexing* (OFDM) is used as the underlying technology in 802.11g and 802.11a. OFDM is a form of *Frequency-Division Multiplexing* (FDM); normally, FDM uses multiple frequency channels to carry the information of different users. OFDM uses multicarrier communications, but only between one pair of users—that is, a single transmitter and a single receiver.

Multicarrier communications splits a signal into multiple signals and modulates each of the signals over its own frequency carrier, and then combines multiple frequency carriers through FDM. OFDM uses an approach whereby the carriers are totally independent of (orthogonal to) each other. Note that the total bandwidth consumed with OFDM is the same as with single carrier systems even though multiple carriers are used—because the original signal is split into multiple signals. OFDM is more effective at handling narrowband interference and problems related to multipath fading, simplifying the building of receiver systems.

We can illustrate this process with a simple example—one often used in discussions about OFDM. For a "normal" transmission at 1 Mbps, each bit can take 1 microsecond to send. Consider bit 1 and bit 2 sent with a gap of 1 microsecond. If two copies of bit 1 are received at the destination, one of them is the reflected or delayed copy. If the delay is around 1 microsecond, this delayed copy of bit 1 can interfere with bit 2 as it is received at the destination because they arrive at approximately the same time. Now consider an OFDM transmission rate of 100 kbps, that is, the bits are sent "slower" but over multiple frequencies. A multipath delay of around 1 microsecond will not affect bit 2, because bit 2 is now arriving much slower (around 10 microseconds). The delay in bit arrival (1 microsecond in our example) is not a function of the transmission—rather it is due to the various paths taken by the signal.

Orthogonal Frequency-Division Multiple Access (OFDMA) superimposes the multiple-access mechanism on OFDM channels, so that multiple users can be supported through subsets of the subcarriers assigned to different users. Note that 802.16-2004 ("Fixed" WiMAX) uses OFDM, whereas 802.16e-2005 ("Mobile" WiMAX) uses OFDMA.

MIMO and 802.11n

Multiple Input Multiple Output (MIMO) antennas are the basis for the 802.11n wireless LAN standard, currently in draft form but on the way to final standardization. Signals often reflect off objects and are received at different times and strengths at the receiver, resulting in a phenomenon called *multipath distortion*. (Note: 802.11n in this article implies the draft 802.11n standard at the time of writing.) MIMO actually takes advantage of this distortion by sending a single data stream split into multiple parts to be transmitted from multiple antennas (typically 3 in 802.11n) and letting the reflected signals be processed at the receiver (through multiple antennas). The transmission of multiple data streams over different spatial channels, sometimes known as *Space Division Multiplexing* (SDM), also allows a larger amount of data to be sent over the air. Through advances in the *Digital Signal Processing* (DSP)-based processing, the receiver can process the signals, cross-correlate them, and reconstitute them accurately despite interference. Also, because of the multiple signals received over multiple paths, link reliability is increased.

The 802.11n standard uses three antennas and also supports two radios (for the 2.4- and 5-GHz bands where 802.11n can operate). It can also use 40-MHz channels through *channel bonding*—that is, two adjacent 20-MHz channels are combined into a single 40-MHz channel, possibly resulting in a data rate of up to 150 Mbps of effective throughput.

One concern with 802.11n that is starting to gain attention is the power requirement of 802.11n access points. With radios in both bands and the use of MIMO, 802.11n access points tend to consume more power than the 802.11 a/b/g access points, leading to problems when the access point is powered by *Power over Ethernet* (PoE) power-sourcing equipment. The 802.3af standard permits a maximum of 12.95W per Ethernet port, which is often less than the power that most 802.11n APs need. The IEEE 802.3at working group is working toward a higher-power PoE standard. This initiative, commonly called *PoE Plus*, will peak at 25W per Ethernet port (on Category 5 Ethernet cable).

Ethernet Backhaul

The access point has two primary functions—connecting wireless clients to each other as well as connecting wireless and wired clients. In the latter, the access point can act as an Ethernet bridge by passing Layer 2 frames between the wired and wireless networks, or as a router, terminating WLAN and Ethernet Layer 2 frames and performing IP-level forwarding. The Layer 3 routing model is less popular and we will not consider it here.

The access point typically terminates WLAN management and control frames. However, there is another model of a *thin access point* wherein these frames can be backhauled to a WLAN switch for processing. The access point connection to the wired network is typically an Ethernet link to a dedicated Ethernet switch port at 100-Mbps or Gigabit Ethernet speeds. With the advent of 802.11g and 802.11a WLANs, 10-Mbps links are not sufficient because these WLANs can operate at close to 27-Mbps throughput over the wireless network.

When considering 802.11n, we find that 100-Mbps backhaul links to the switch are insufficient for the 802.11n throughput of 150, or even 300 Mbps with channel bonding. Gigabit Ethernet links are often considered for connectivity between the 802.11n access point and the Ethernet switch. The next speed for Ethernet connectivity is 10 Gbps, which is well-established in the enterprise for data center and core Ethernet network applications. Work is ongoing in the IEEE for 40- and 100-Gbps Ethernet, so that should cover advances in wireless speeds for efficient backhaul to the wired network.

Bluetooth

Bluetooth started as a "wire-replacement" protocol for operation at short distances. A typical example is the connection of a phone to a PC, which, in turn, uses the phone as a modem (see Figure 2). The technology operates in the unlicensed 2.4-GHz ISM band. The standard uses FHSS technology. There are 79 hops in BT displaced by 1 MHz, starting at 2.402 GHz and ending at 2.480 GHz.

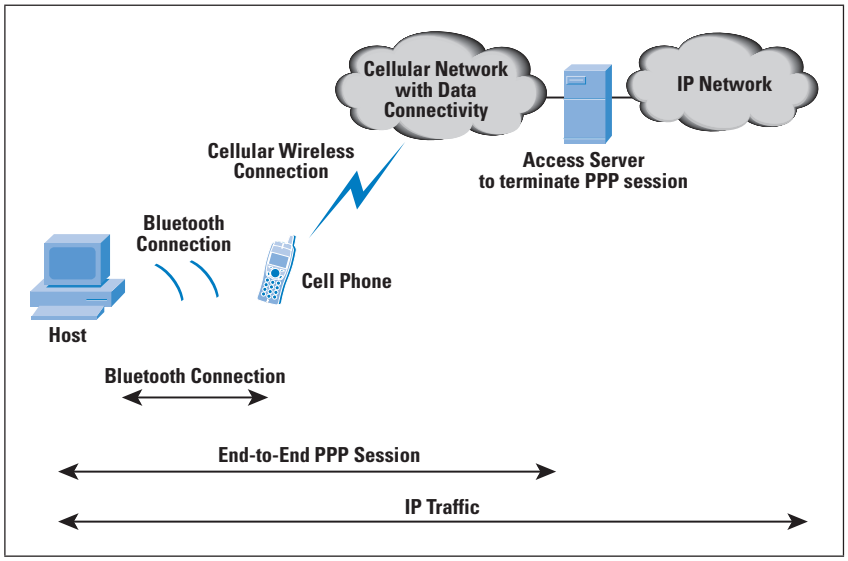

Figure 2: Typical Use of a Bluetooth enabled phone as a data modem for a PC

Bluetooth belongs to a category of *Short-Range Wireless* (SRW) technologies originally intended to replace the cables connecting portable and fixed electronic devices. It is typically used in mobile phones, cordless handsets, and hands-free headsets (though it is not limited to these applications). The specifications detail operation in three different power classes—for distances of 100 meters (long range), 10 meters (ordinary range), and 10 cm (short range).

Bluetooth operates in the unlicensed ISM band at 2.4 GHz (similar to 802.11 b/g wireless), but it is most efficient at short distances and in noisy frequency environments. It uses FHSS technology—that is, it avoids interference from other signals by hopping to a new frequency after transmitting and receiving a packet. Specifically, 79 hops are displaced by 1 MHz, starting at 2.402 GHz and finishing at 2.480 GHz.

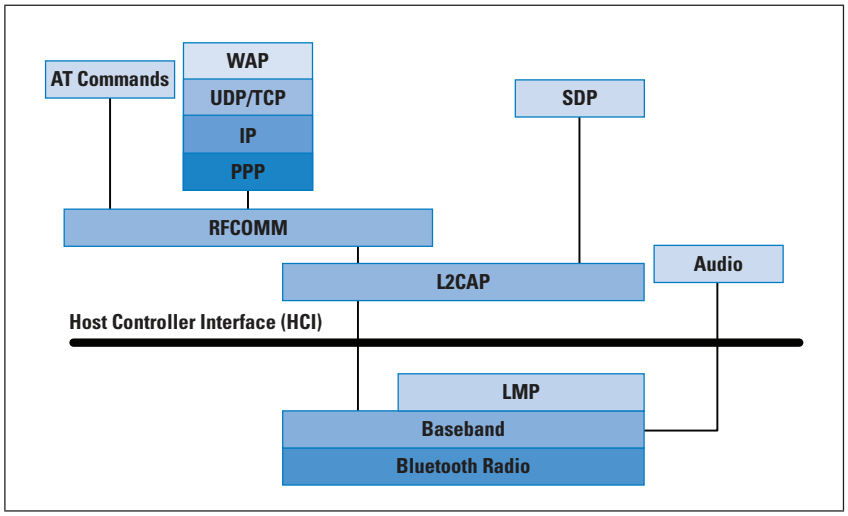
Bluetooth can operate in both point-to-point and logical point-to-multipoint modes. Devices using the same BT channel are part of a *piconet* that includes one master and one or more slaves. The master BT address determines the frequency hopping sequence of the slaves. The channel is also divided into time slots, each 625 microseconds in duration. The master starts its transmission in even-numbered time slots, whereas the slave starts its transmission in odd-numbered slots.

BT specifies two types of links, a *Synchronous Connection-Oriented* (SCO) link and an *Asynchronous Connectionless Link* (ACL). The SCO link is a symmetric point-to-point link between a master and a single slave in the piconet, whereas the ACL link is a point-to-multi-point link between the master and all the slaves participating in the piconet. Only a single ACL link can exist in the piconet, as compared to several individual SCO links.

Bluetooth Stack

Other than the radio and baseband components (the physical layer of Bluetooth that manages physical channels and links), the Bluetooth stack (see Figure 3) includes a *Link Manager Protocol* (LMP) used for link management between the endpoints, a *Logical Link Control and Adaptation Protocol* (L2CAP) for the data link, a *Radio Frequency Communication* (RFCOMM) protocol to provide emulation of serial ports over L2CAP, and a *Service Discovery Protocol* (SDP) for the dynamic discovery of services—because the set of services changes dynamically based on the RF proximity of the devices. In addition, the *Host Controller Interface* (HCI) provides a uniform command interface to the baseband controller and the link manager to have access to the hardware registers.

Figure 3: Key Elements of the Bluetooth Stack



LMP is required for authentication, encryption, switching of roles between master and slave, power control, and so on. L2CAP provides both connection-oriented and connectionless data services functions, including protocol multiplexing, segmentation and reassembly, and piconet-based group abstraction. As part of the multiplexing function, L2CAP uses the concept of channels, with a channel ID representing a logical channel endpoint on a BT device. L2CAP offers services to the higher layers for connection setup, disconnect, data reading and writing, pinging the endpoint, and so on.

RFCOMM, which provides emulation of serial ports on the BT link, can support up to 60 simultaneous connections between two BT devices. The most common emulation is of the RS-232 interface, which includes emulation of the various signals of this interface such as *Request To Send* (RTS), *Clear To Send* (CTS), *Data Terminal Ready* (DTR), and so on. RFCOMM is used with two types of BT devices—endpoints such as printers and computers and intermediate devices such as modems. In Figure 3, the IP stack over *Point-to-Point Protocol* (PPP) over RFCOMM emulates the mode of operation over a dialup or dedicated serial link. Because the various BT devices in a piconet may offer or require a different set of services, the *Service Discovery Protocol* (SDP) is used to determine the nature of the services available on the other nodes. SDP uses a request-response packet scheme for its operation.

Bluetooth Profiles

BT includes multiple profiles that correlate to the type of services that are available from BT nodes. For example, the BT headset profile is used between an audio source and a headset, both connecting wirelessly through BT—it involves a subset of the well-known AT commands used with modems. The audio source (typically a cell phone or cordless phone) implements the BT audio gateway profile for communicating with the device implementing the headset profile. Other profiles include a basic printing profile (often used for printing between a PC and a BT-enabled printer), dialup networking profile, fax profile, cordless telephony profile, *Human Interface Device* (HID) profile, and so on. The last profile is used for BT-enabled keyboards and mice—it is based on the HID protocol defined for USB.

The Bluetooth dialup networking profile is interesting from an IP perspective; as shown in Figures 2 and 3, it involves the IP stack running over RFCOMM to provide the appearance of a serial port running PPP, which is very similar to dialup networking over a basic telephone service line.

Bluetooth Frame Format and Speeds

The frame format in BT consists of a 72-bit field for the access code (including a 4-bit preamble, 64-bit synchronization field, and 4 bits of trailer), followed by a 54-bit header field that includes information about the frame type, flow control, acknowledgement indication, sequence number, and header error check. Following the header field is the actual payload, which can be up to 2745 bits. In all, the frame length can be a maximum of 2871 bits. Whereas synchronous BT traffic has periodic reserved slots, asynchronous traffic can be carried on the other slots.

BT ranges can vary from a low-power range of 1 meter (1 mW) for Class 3 devices, 10 meters (2.5 mW) for Class 2 devices, to 100 meters (100 mW) for Class 1 devices. BT Version 1.2 offers a data rate of 1 Mbps, and BT Version 2.0 with *Enhanced Data Rate* (EDR) supports a data rate of 3 Mbps. BT Version 1.1 was ratified as the IEEE Standard 802.15.1 in 2002.

Bluetooth versus Wi-Fi

A few years ago, some marketing literature tried to emphasize BT and Wi-Fi as competing technologies. Though both operate in the ISM spectrum, they were invented for different reasons. Whereas Wi-Fi was often seen as a "wireless Ethernet," BT was initially seen purely as a cable- or wire-replacement technology. Uses such as dialup networking and wireless headsets fit right into this usage model. Recently, the discussion has focused more on coexistence instead of competition because they serve primarily different purposes. There are still some concerns related to their coexistence because they operate over the same 2.4-GHz ISM band.

To recapitulate, the Bluetooth physical layer uses FHSS with a 1-MHz-wide channel at 1600 hops/second (that is, 625 microseconds in every frequency channel). Bluetooth uses 79 different channels. Standard 802.11b/g uses DSSS with 20-MHz-wide channels—it can use any of the 11 20-MHz-wide channels across the allocated 83.5 MHz of the 2.4-GHz frequency band. Interference can occur either when the Wi-Fi receiver senses a BT signal at the same time that a Wi-Fi signal is being sent to it (this happens when the BT signal is within the 22-MHz-wide Wi-Fi channel) or when the BT receiver senses a Wi-Fi signal.

BT 1.2 has made some enhancements to enable coexistence, including *Adaptive Frequency Hopping* (AFH) and optimizations such as Extended SCO channels for voice transmission within BT. With AFH, a BT device can indicate to the other devices in its piconet about the noisy channels to avoid. Wi-Fi optimization includes techniques such as dynamic channel selection to skip those channels that BT transmitters are using. Access points skip these channels by determining which channels to operate over based on the signal strength of the interferers in the band. Adaptive fragmentation is another technique that is often used to aid optimization. Here, the level of fragmentation of the data packets is increased or reduced in the presence of interference. For example, in a noisy environment, the size of the fragment can be reduced to reduce the probability of interference.

Another way to implement coexistence is through intelligent transmit power control. If the two communicating (802.11 or Wi-Fi) devices are close to each other, they can reduce the transmit power, thus lowering the probability of interference with other transmitters.

WiBree to Low-Energy Bluetooth

WiBree is a technology first proposed by Nokia to enable low power communication over the 2.4-GHz band for button cell (or equivalent) battery-powered devices. A consequence of the low power requirement is the need for the wireless function to perform a very small set of operations when active and go back to the sleep or to standby mode when inactive.

The WiBree technology has been adapted by the *Bluetooth Special Interest Group* (SIG) as part of the lower-power BT initiative—also known as *Low Energy* (LE) BT technology. The LE standard is expected to be finalized sometime in 2009. When this standardization is completed, three types of BT devices will be available: traditional BT, LE BT, and a mixed or dual-mode BT. A mixed-mode device can operate in low power mode when communicating with other LE devices (for example, sensors) and traditional BT mode when communicating with BT devices, implying the presence of both a BT stack and an LE stack on the same device.

WiMAX

WiMAX stands for *Worldwide Interoperability for Microwave Access* and is defined under the IEEE 802.16 working group. Two standards exist for WiMAX—802.16d-2004 for fixed access, and 802.16e-2005 for mobile stations[9]. The WiMAX forum certifies systems for compatibility under these two standards and also defines network architecture for implementing WiMAX-based networks.

WiMAX can be classified as a last-mile access technology similar to DSL, with a typical range of 3 to 10 kilometers and speeds of up to 5 Mbps per user with non-line of sight coverage. WiMAX access networks can operate over licensed or unlicensed spectra in various regions or countries—though licensed spectrum implementations are more common. WiMAX operation is defined over frequencies between 2 and 66 GHz, parts of which may be unlicensed spectrum deployments in some countries. The lower frequencies can operate over longer ranges and penetrate obstacles, so initial network rollouts are in this part of the spectrum—with 2.3-, 2. 5-, and 3.5-GHz frequency bands being common. Channel sizes vary from 3.5, 5, 7, and 10 MHz for 802.16d-2004 and 5, 8.75, and 10 MHz for 802.16e-2005. WiMAX networks are often used to backhaul data from Wi-Fi access points. In fact, they are often envisaged as replacements for the current implementation of metro Wi-Fi networks that use 802.11b/g for client access and 802.11a for backhaul to connect to the other parts of the network.

Technology

The 802.6d-2004 standard uses OFDM similar to 802.16a and 802.16g, whereas 802.16e-2005 uses a technology called *Scalable Orthogonal Frequency Division Multiplexed Access* (S-OFDMA). This technology is more suited to mobile systems because it uses subcarriers that enable the mobile nodes to concentrate the power on the subcarriers with the best propagation characteristics (because a mobile environment has more dynamic variables). Likewise, the 802.16e radio and signal processing is more complex.

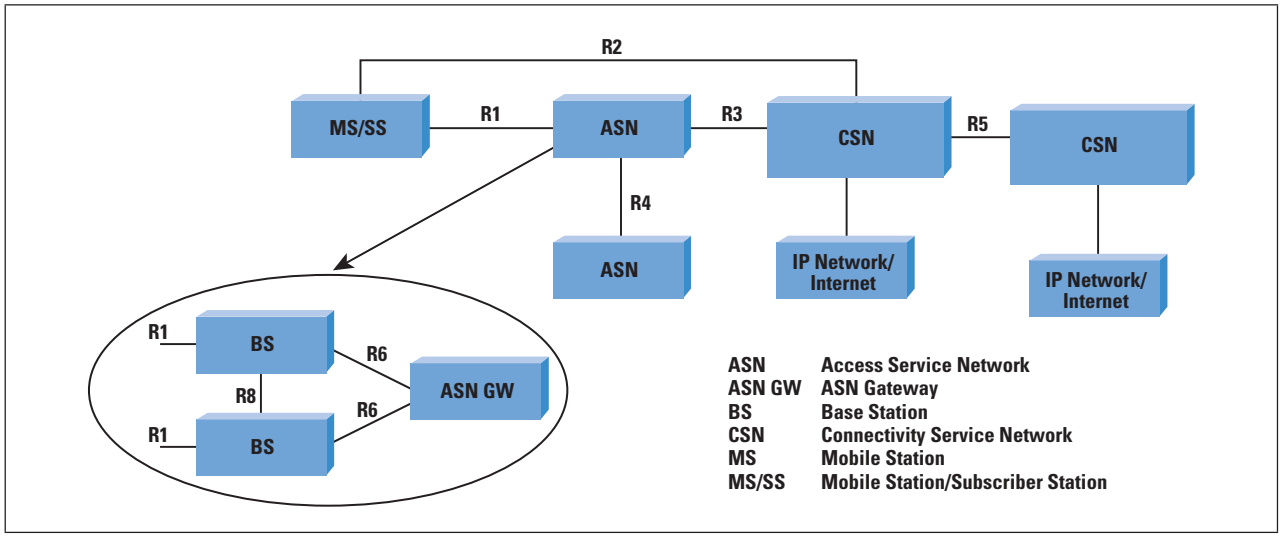
Unlike 802.11, which supports only *Time-Division Duplexing* (TDD)—where transmit and receive functions occur on the same channel but at different times), 802.16 offers TDD, *Frequency-Division Duplexing* (FDD) (transmit and receive on different frequencies, which could also be at different times). Another innovation in WiMAX is similar to the scheme in *Code Division Multiple Access* (CDMA)—subscriber stations are able to adjust their power based on the distance from the base station, unlike the case of client stations in an 802.11 network.

WiMAX base stations use a scheduling algorithm for medium access by the subscriber stations. This access is through an access slot that can be enlarged or contracted (to more or fewer slots) that is assigned to the subscriber stations. *Quality-of-Service* (QoS) parameters can be controlled through balance of the time-slot assignments among the base stations. The base-station scheduling types can be unsolicited grant service, real-time polling service, non-real time polling service, and best effort. Depending upon the time of traffic and service requested, one of these scheduling types can be used.

WiMAX Network Architecture

The WiMAX network architecture is specified through functional entities (see Figure 4), so you can combine more than one functional entity to reside on a network element. The *Mobile Station* (MS) connects the *Access Service Network* (ASN) through the R1 interface—which is based on 802.16d/e. The ASN is composed of one or more *base stations* (BSs) with one or more ASN gateways to connect to other ASNs and to the *Connectivity Service Network* (CSN). The CSN provides IP connectivity for WiMAX subscribers and performs functions such as *Authentication, Authorization, and Accounting* (AAA)[10,11], ASN-CSN tunneling, inter-CSN tunneling for roaming stations, and so on. A critical tenet of the WiMAX Forum network architecture is that the CSN must be independent of the protocols related to the radio protocols of 802.16.

Figure 4: WiMAX Forum Network Architecture Functional Blocks and Interface Points



The R3 interface (reference point) is used for the control-plane protocols and bearer traffic between the ASN and CSN for authentication, policy enforcement, and mobility management. The base station connects to an ASN gateway to provide the MS with external network access. The R6 interface between the BS and ASN-GW could be open or closed based on the profile—in fact, you could have a co-located base station and *ASN gateway* (ASN-GW), depending upon the network implementation. The ASN gateway uses the R3 interface to communicate with the AAA services in the visited CSN (that is, the CSN "corresponding" to the ASN). The servers in the visited CSN can communicate with the home CSN (that is, the CSN corresponding to the "home" network of the MS). In the simplest case multiple ASNs (WiMAX networks) connect through ASN gateways to the public Internet (that is, there is only one *Network Service Provider* (NSP) and the visited and home CSNs are the same). Note that you could implement a WiMAX network with just one ASN and one CSN—in that case, the R3 interface would be completely internal and not exposed.

Three profiles are identified to map ASN functions into ASN-GW and BS functions. These profiles are considered an implementation guideline for how you would build the various devices implementing these functions. Profile A is a strict separation of the BS and ASN-GW functions, where the ASN-GW controls and manages radio resources that are located on the BS and also provides the handover and data-path functions. The R6 interface is exposed in this profile.

Profile B is a more integrated function, where the BS has more functions than in profile A; in fact, the BS might even integrate most of the ASN functions. The R6 interface is a closed interface in this profile. The third profile is profile C, which is similar to profile A except that the base stations to incorporate more functions, including radio resource management and control as well as hand-offs.

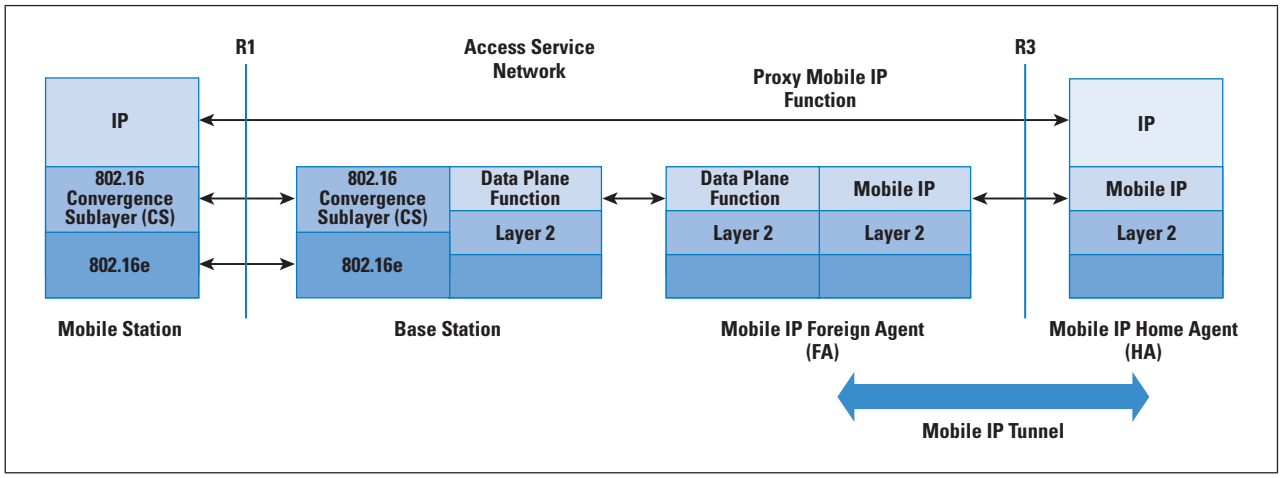
IP Connectivity and Data Transfer

The MS can be a fixed IP gateway (think of an 802.11 access point that provides connectivity to users in a coffee shop and connects to the IP network of the service provider through WiMAX) or a mobile end node (for example, a laptop with WiMAX connectivity). The IP address used by the gateway on the connection to the WiMAX network is known as the *Point of Attachment* (PoA) address. A third type of access is nomadic access, where the IP gateway can be moved from one location to another but connects to the network only after it has been relocated.

When the station is mobile, the WiMAX Forum specifies that the *Mobile IP* (MIP) architecture and protocols should be used. There are two types of Mobile IP possible: *Client Mobile IP* (CMIP) and *Proxy Mobile IP* (PMIP). The former involves changes to the MS protocol stack, but the latter does not.

The architecture can support both models. In the P-MIP scenario (see Figure 5), the ASN implements the Foreign Agent (see William Stallings' article in IPJ on Mobile IP[8]), and terminates Mobile IP tunnels for the various mobile stations in the same ASN.

Figure 5: Data Transport and Proxy Mobile IP in WiMAX



In the figure, the MS has an address at the point of attachment that is used to forward packets from the MIP Foreign Agent inside the ASN. Because the ASN acts as a proxy of the attached MS, this implementation is known as a *Proxy MIP* implementation—also, there is no need for the MS to be aware of the MIP function being performed by the network.

Perspective on WiMAX versus Cellular Services

The WiMAX Forum has specified that the *Network Working Group* (NWG) architecture should be capable of supporting voice, multimedia services, and priority services such as emergency voice calls. It also supports interfacing with interworking and media gateways. Also, the service permits more than one voice session per subscriber, as well as simultaneous voice and data sessions. Support of IP Broadcast and Multicast services over WiMAX networks is also included. The architecture is also expected to support differentiated QoS levels at a per-MS or -user level (coarse grained) and at a per-service flow (fine-grained) level. It shall also support admission control and bandwidth management.

Initially, WiMAX was touted by some as a replacement for cellular services. An important consideration was using *Voice over IP* (VoIP) for voice calls—that is, where voice was another service over the data network. This model was in contrast to the existing cellular service where data was an adjunct to the basic service of TDM-based voice. More recently, WiMAX is being positioned as a data-connectivity option for remote locations, especially where it would be difficult to lay new copper or optical cable. Not surprisingly, these options are being pursued aggressively in developing countries.

Common Misperceptions About Wi-Fi, BT, and WiMAX Technologies

We have considered the key aspects of the three technologies—Wi-Fi, BT, and WiMAX—and their position in IP networks. In this section, we will outline and clarify some common perceptions and misperceptions about these technologies.

1. *BT and Wi-Fi are competing technologies*—Actually, they address a different set of requirements despite operating in the same 2.4-GHz space. BT is a "wire replacement" usually for short distances. Wi-Fi is typically used for data, voice, and video traffic over distances up to 300 meters.
2. *WiMAX is Wi-Fi on steroids*—To clarify, this statement is an oversimplification used often in the trade press. WiMAX operates in licensed spectra and uses a different network architecture as compared to Wi-Fi, which is in the unlicensed spectrum and uses a simple access point to wired Ethernet architecture. One overlapping function is for backhauling Wi-Fi traffic, which can be done by Wi-Fi (typically 802.11a) or WiMAX.
3. *Unlike BT, Wi-Fi cannot be used for voice*—This perception is not true because you can send multimedia traffic over Wi-Fi networks implementing 802.11e QoS functions that rely on the access point and stations implementing priority-based traffic transmission and scheduling.
4. *Wireless networks are not secure*—Although there is some validity to this argument because it is easier to eavesdrop on wireless networks, implementation of security schemes such as *Wi-Fi Protected Access* (WPA/WPA2) will help alleviate this problem.
5. *Wireless and radio technologies consume more power*—This statement is often true if the devices transmit continuously or have to increase their power because of the distance between the transmitter and receiver. Noisy channels contribute to this power use also. However, with careful engineering of the wireless implementation and techniques such as power save (in Wi-Fi) and short duty cycle transmissions, the power requirement can be lowered.

Summary

In this article, we have provided a flavor for IEEE 802.11 WLAN, Bluetooth, and WiMAX technologies and their implementation—specifically, how the nodes on these networks connect to an IP network. These technologies often serve complementary functions for end-to-end connectivity.

The End of Eternity
Part One: IPv4 Address Exhaustion and Consequences

by Niall Murphy, Google, and David Wilson, HEAnet

"Eternity is a very long time, especially towards the end," said Woody Allen[22,23], and he was mostly right. The eternity that the 32 bits of IPv4 address space promised is now almost at an end, and we are faced with the task of deciding what to do after the "end of eternity."

The size of the problem of IPv4 exhaustion is, unfortunately, also proportional to its longevity[1,2,3]. Although the next-generation (IPng) effort[4] kick-started the development of IPv6 partially in response to concern about the IPv4 consumption rate, the industry as a whole largely ignored the problem after *Classless Inter-Domain Routing* (CIDR) and the *Regional Internet Registries* (RIR) system contained the depletion problem to a manageable horizon. More recently, after Geoff Huston's[5] work showing that the expected depletion time was sooner than many organizations had expected, the concern has received considerable attention in address-allocation policy circles.

In this article, we examine IPv4 exhaustion in more detail. We talk about what exactly exhaustion will mean and what we can do about it, and then present a vision for the postexhausted world. Those familiar with our RIPE-55 talk[6] will find much that is familiar, but the arguments have been expanded for a more general audience. The authors, as in that talk, are speaking only for themselves, and not their organizations.

What Does Exhaustion Mean?

Trivially, the point of IPv4 exhaustion is the point at which the guaranteed-free-and-unused pool runs out and the current allocation mechanism comes to an end. Although the depletion of the free pool defines the technical point of exhaustion, it is not the depletion itself that is of primary importance. After all, if it were, we could simply declare a moratorium on allocations with immediate effect, to preserve the resource for some notional future requirements. Rather, it is the effect on the practices and procedures, within the RIRs and within the *Local Internet Registries* (LIRs), administrative and technical, that will practically define exhaustion. These practices, which have grown to fit around the current behavior of the addressing system, the free pool, and so on, will require urgent reform after exhaustion, as indeed will the RIR system in general.

Currently organizations use and require new addresses for essentially every IP-related additional deployment (for example, adding customers to a publicly numbered DSL service, adding extra *Secure Sockets Layer* (SSL)-enabled websites to a Web hosting service, and adding extra publicly reachable servers to almost any service).

It has been emphasized that this problem affects only the *growth* of organizations performing IP deployments[7]. Although it is important to acknowledge the partial correctness of this statement, much about the postexhaustion state could undermine the stability of well-established advertisements and routes unless the transition is well-handled. It seems intuitively correct that those who received allocations before exhaustion will be unaffected by exhaustion turmoil[8], but we regard this premise as optimistic, as you will see later.

Along those lines, one less well-examined consequence of exhaustion is the erosion of the consensus model of Internet governance. There is potential for wide divisions to open up at the local and regional level unless this consensus is carefully conserved. No clear successor to the current model as yet exists; the RIRs appeared to be heading toward a spectrum of positions on, for example, the allocation of the last portions of the IPv4 free pool[9, 10] until quite recently[24].

The erosion of this model of governance as a consequence of exhaustion has been neither widely examined nor expected in the Internet community. Partially, this situation arose because of the useful and well-executed role that the RIRs have historically filled in providing sensible and stable conditions for decision making; some proportion of the membership of the RIRs might well feel that IPv4 exhaustion is a problem like any other, which the RIRs themselves are in the perfect position to resolve. However, although the atmosphere of mutual cooperation fostered by the RIRs has produced many useful service-related outputs (for example, the *Test Traffic Measurement* service of *Réseaux IP Européens* [RIPE][25]), one of the major nonobvious benefits they have brought is to provide a centralized focus for discussion with governments and regulatory agencies. Not only is it more efficient and therefore less time-wasting to centralize through one representative organization, it has also created expectations that similar matters can be dealt with in the same coordinated way—a very valuable expectation, which has helped to increase the credibility of industry self-regulation. This credibility allowed, for example, the *Number Resource Organization* (NRO) to help forestall a proposal to allocate IPv6 according to geographical boundaries[27, 28].

Indeed, without credible industry self-regulation, it is not at all clear that this community could have grown as fast as it did. Although it seems clear today that the RIRs are the correct place for this kind of activity to go on (witness RIPE's "enhanced cooperation" task force[26]), if they had not been around, government would either have had to deal with an organization with less of a pedigree or one with more inherent bias, or multiple organizations with competing biases, all of which could compel them to distrust the results of their liaisons. Unfortunately, in this respect the RIRs have been a victim of their own success.

Just as the consensus model in domains broke down when top- and second-level domains became monetized, so it is likely that the inherent win or loss for any given holder in any policy changes will undermine attempts to build consensus for address policy in a monetized IPv4 world. Absent this consensus, many of the RIR services that we rely upon will be undermined—not least the veracity of the WHOIS database and subsequent reliability of our routing filters, but also the RIR and *Internet Corporation for Assigned Names and Numbers* (ICANN) representations toward governments.

What Are the Problems with Exhaustion?

The biggest problem is the simplest one: existing organizations whose business model or operations are *solely* predicated on an ongoing flow of IPv4 addresses will fail. This premise would seem an extreme, even theoretical, characterization, but the size of this category in the real world is larger than you might think. Numerous organizations are also in trouble, perhaps less predicated upon IPv4 than the others, but that—for example—might have financial or operational difficulty in making the postexhaustion transition happen internally. They would also be placed at risk. Finally, there are those organizations that might rely on others to perform their transition correctly in order for them to continue effective operations: less directly at risk, but still probably affected.

Those who deal with the operation of the Internet on a daily basis are well-aware of the workarounds available that could save organizations from the doomsday scenario. It is unfortunate, then, that many of us have looked to the simplest cases in our immediate experience in order to form our opinions of the scale of the problem. It is indeed true that, in the short term, the client-side problem has largely been solved—provided that your customers or developers never have expectations in line with an end-to-end Internet. (It would seem that address-space pressure is likely to erode whatever end-to-end expectations still remain in today's Internet.)

However, the server-side problem (for example, SSL Website hosting, *IP Security* [IPsec] VPN endpoints, ...) remains unsolved. Workarounds exist[11], but whether they will be ready and deployed in time remains an open question. There are, therefore, organizations operating at this moment that depend upon the continued availability of IPv4 addresses. Adequate workarounds have yet to be developed—never mind proven—for these businesses.

The situation becomes more complicated when we consider the candidate solutions. For example, such organizations as described previously cannot solve their problem by deploying IPv6 alone prior to the end of the transition, because they require universal reachability. Without universal reachability, support costs will rise, the quality of the user experience will decrease, and the credibility of Internet governance will be threatened. The only available evidence shows our position on the IPv6 transition curve being at the very beginning[12].

Therefore it is difficult to emphasize this enough—new entrants providing Internet services *cannot expect to compete equally with existing operations*—because they have a very high barrier to entry formed not by the natural action and development of competitors, but by the resource scarcity of new addresses. Without new addresses, they cannot have an IPv4 *Default-Free Zone* (DFZ) routing-table entry; without a DFZ entry, they cannot be multihomed; without multihoming, they cannot offer sufficiently redundant Internet service; and without sufficiently redundant Internet service, they cannot meaningfully compete with existing operators.

A variety of poor-quality "fudges" are possible, of course: they could use the address space of their upstream operators (and run the risk of having that address space pulled or charged for), or they could outsource any address-requiring services to another organization (and be unable to control their service quality, as well as dependent upon their continuing operation), or they could host through some kind of public proxy network that redirects to their back-end servers through various hard-coded means (and create a fragile, difficult-to-operate network with higher running costs per unit customer than their competitors).

We will examine the other negative consequences of exhaustion in more detail later in the discussion; meanwhile, let us assume that the scenario described previously is undesirable enough for us to ask whether we can actually do anything to forestall it.

Can We Practically Defer Exhaustion?

What we would ideally like is some policy or algorithm that would give us more time—how much time is open to question—without producing its own set of ill effects. (We can certainly defer exhaustion by ceasing to allocate new IPv4 addresses tomorrow, but that solution is hardly practical.) Unfortunately, this problem is very difficult to resolve. Such direct precedents that appear clearly related to the current situation provide no useful guidance. Many resource-exhaustion problems have been faced before, but ultimately the solutions for those can be categorized into three kinds:

- *Make the resource renewable:* In this case, the resource is in danger of running out, but can be replenished by some means. Often this replenishment involves constraining production predicated on the resource to some smaller value, particularly when there is a natural rate of renewal—for example, fishing stocks. In the case of IPv4, it is fundamentally nonrenewable in that the resource is of a finite size. (As we discussed previously, current reclamation efforts[13], although worthy of pursuit as a low-overhead task, cannot be a solution.)
- *Move to another resource:* This solution is already under way in the sense that we are engaged in the transition to IPv6. However, adoption of IPv6 will not happen fast enough to prevent the negative consequences of exhaustion.

- *Divide the resource more fairly:* This solution is useful primarily in the case where hoarding is taking place, causing resource problems for some significant proportion of a resource-using population. We are dividing the resource fairly as it is, and certainly since the emergence of the RIRs. For reasons discussed later, husbanding the resource more carefully is unlikely to actually be a solution.

We have faced other abstract exhaustion problems before as well: for example, phone-number depletion is somewhat similar to our current problem. However, phone-number depletion admits of a simpler solution—the creation of extra digits in the number space—because of the centralization of network knowledge in a comparatively small number of switches. For the Internet, where every deployed host would have to be informed about changes to the number space, such an approach is not operationally feasible. Furthermore, adding extra digits to the number code is not in fact simple, and telecommunications companies have experienced a wide range of problems with such approaches in the past, to say nothing of the loss of revenue and the failure of calls to connect because of customer confusion[14, 15]. We see no historical situation that provides a clear precedent and a clear way forward.

SimLIR

Accordingly, to help answer the question posed in the preceding section, we wrote a tool, *SimLIR*, to explore exhaustion and post-exhaustion scenarios. Rather than being a tool influenced primarily by computations based on growth curves, a "top-down" approach, it is a modeling tool that examines how changes in behavior affect relative consumption rates. Roughly 6,000 lines of Python, the tool is due to be open-sourced at its Google Code page[16] shortly after this article is available. The tool models the whole *Internet Assigned Numbers Authority* (IANA)—>RIR—>LIR hierarchy, and currently maps LIRs to countries; it uses the same publicly available data as Geoff's work. We would appeal to the community to help improve the program, because more research is desperately needed in this area.

Running the tool under various scenarios has produced preliminary results indicating that we cannot meaningfully defer exhaustion, given our current growth rates. It can be used to compare the effect of policy adjustments on known historical and simulated behavior. For example, one simple policy adjustment that has been informally suggested is to decrease the initial allocation size for new LIRs. Modeling this allocation with the tool, we halve the size the LIRs receive at the time of initial membership. If we allow this scenario to run to completion, we have seen that it allows us to defer exhaustion by less than a week. Intuitively, we might expect this assumption to be realistic because startup activity, although important, is relatively small in terms of proportion of allocations. New LIRs numbered approximately 500 in 2006[17], and any scheme that attempted to defer exhaustion based on such a small proportion of overall operations could not practically succeed.

The question then arises whether any other scheme based upon treating some partition of the request-space differently could have a significant positive effect. However, such a scheme necessarily assumes that some set of requests are oversized, and can in fact be shrunk with no ill effects. Even if they are oversized, identifying them without inducing either unworkable bureaucracy or a chilling effect on the operations of the organization would be a significant task, not lightly undertaken. Furthermore, it would be in the self-interest of the current RIR membership not to agree to such a change in policy. With any such scheme, there would be a non-zero chance of their own requests being deemed faulty in some respect, thus leading to significant risk to their own operations. All of this process would of course be happening in the approach to exhaustion, where it would be more critical than ever to receive enough numbering resources! We can assume, therefore, that no such scheme would ever make it past the policy-making apparatus of bottom-up-influenced RIRs. Ironically, the easiest changes to enact are changes governing allocations to startup organizations; the affected organizations are not in the room at the time of policy formation, because they are not members yet. But such changes are highly unlikely to have a positive effect.

Finally, partitioning schemes are similar to other schemes proposed to rework the *End Game* for IPv4 allocation[18, 19, 20] or retain a certain proportion of the free pool for as-yet-unknown future needs, in that we put RIRs in the awkward situation of having to decide that some requests are more legitimate than others, at a time when these requests are likely to be particularly urgent. RIRs should not be in the business of deciding who gets to have new customers, and partitioning the request space invites the possibility of preferential treatment. We can be sure that any preferential treatment at this crucial time, accidental or otherwise, would attract lawsuits. Judicial involvement in the allocation process close to the time of exhaustion would benefit almost nobody.

It is important to note that these risks are mainly specific to partitioning the request space from the RIR to the LIR; in other words, imposing criteria at the time of request. Partitioning the remaining pool per RIR, that is, imposing criteria at the time of division, such as proposed by the $n = 1$ policy[24], does not suffer from "favoritism." Indeed, even if there were blatantly iniquitous division at the IANA-to-RIR level, although various checks and balances exist to ensure there is not, it would be unlikely to affect those with resources sufficient to possess an office in the region in question, or to open one up; it is patently clear that the requests will follow where the space is, and it is highly unlikely that any single RIR with a large amount of space left after others have been exhausted would be in any kind of position to pass a discriminatory policy.

We make these points to highlight that any scheme based upon LIR partitioning presents immense difficulties of principle. Even if these difficulties are worked out, they seem unlikely to meaningfully defer exhaustion: the current run rate for IPv4 address space will exhaust the space within a 5-year timeframe anyway, even if all practically possible measures are taken.

The Consequences of Scarcity

Suppose for the moment that at the time of exhaustion, Internet-connected organizations have to fend for themselves, with no particularly well-defined industry strategy in place. We would then expect to see a broad movement within the industry to conserve precious public IPv4 address space. One obvious way for an organization to obtain more usable IPv4 space is to move previously publicly-numbered resources behind *Network Address Translation* (NAT) gateways. Other, less-legitimate sources of new addresses will probably also be explored, and these actions, combined with the generally uncoordinated changes, may well trigger the following negative consequences:

- *Inability to measure clients, and difficulty of supporting them:* As we see more layers of NAT within networks, it becomes gradually more difficult to establish who is actually connecting to you, and what problems they are having. Cookies are a partial solution for only one important protocol. Measurement becoming harder means that support costs will rise.
- *Address-space hijacking:* As organizations become more desperate for space, it is entirely feasible that they will begin to cast around for space not explicitly unavailable in order to meet their business needs. How widespread this practice would be remains an open question, but effective barriers to this behavior are not currently available. We would expect a general deterioration in the quality of routing.
- *WHOIS database quality down:* Coupled with layers of NAT hiding more and more networks from direct sight, transfers of address space (legitimate or otherwise) will cause the WHOIS database to become gradually less and less accurate, leading to...
- *Distributed denial-of-service (DDoS) tracking trouble:* Problems tracking DDoS attacks and abuse origins of all kinds make law enforcement and network operators equally unhappy.
- *Connection quality down:* Connection quality, in terms of connections that complete successfully and have tolerable latency, will go down as a function of client growth behind gateways.
- *RIR billing model under pressure:* The RIRs will need to find a new way to pay their costs or go out of business—gradually, but inevitably. Of course the RIRs, like every other organization, must serve a need, but they currently provide a large number of ancillary services not directly related to IP allocation, and those services would also be under threat.

- *Consensus undermined:* This consequence is possibly the most dangerous of them all. If a chaotic state of affairs is allowed to continue for too long, our very ability to make decisions as a community will be undermined as organizations abandon the RIR model that has failed them. We will have squandered, in a way, the foundation of trust that allows such ethical codes as we have developed in Internet operations to persist. That foundation will not be easily recovered.

(Note that all of these are effects that are likely to emerge to varying degrees with the onset of scarcity, however it takes place; in other words, if the RIRs engage in a program of scarcity management by partitioning requests, it is highly likely that the scenario described previously will happen no matter what is left in the free pool.)

In any large shock such as we describe, there will be operational turmoil. Organizations will attempt to employ the technologies they need to dig themselves out of trouble, or bend the rules to the same end. There will be financial turmoil as the ability of each business to scale in the new regime is tested. Turmoil for existing businesses and new entrants will no doubt attract increased attention from governmental and quasigovernmental agencies of all kinds. Turnover in the routing table will increase as uncoordinated deaggregation of prefixes takes place. Unwelcome as all these consequences are, we will probably be far too preoccupied with our own individual problems to take care of the broader picture.

Postexhaustion Vision

Although we hope it is clear, given the previous discussion—that IPv4 addresses will still be required after exhaustion—our highest aspiration cannot be an Internet confined in perpetuity to IPv4 alone. If we are to continue in a manner resembling our current operations, we require continued address plenty, even by today's rather restricted standards. The End Game, therefore, is an IPv6 Internet, or at least enough of one to keep off address scarcity for a workable subset of the industry.

So, the problem can then be characterized as the transition toward this state of affairs—the gap between the end of the old allocation model and the emergence of an adequate replacement. Any solution will have to either make the gap shorter, by bringing users to the IPv6 Internet sooner, or make it less painful, by helping IPv4-dependent organizations survive. (Note that a solution that makes the gap less painful may well cause it to lengthen.)

With the problem stated this way, we can evaluate possible solutions in this context. A hurried, stimulated transition of popular services to IPv6 will quite likely shorten the gap, although a mass transition is also likely to be an unstable one and so rather painful.

A voluntary release of unused addresses may help reduce the pain, but is unlikely to service the run rate adequately, given its voluntary nature, and in any event will prolong dependence on IPv4, thus lengthening the gap. Tweaking policies to make remaining IPv4 addresses arbitrarily difficult to get merely introduces the effects of scarcity still sooner, helping neither goal.

That said, our initial examination of the problems of exhaustion indicate that there will be a group of people who will require IPv4 addresses after the exhaustion point, and it is also clear that there are those who have addresses, such as the lucky recipients of class A addresses in the early days, but no particular incentive to give them up. We do not actually want to recycle these prefixes indefinitely, however; that just sustains the current model. Optimally, we should provide whatever opportunity we can to those who require IPv4 addresses, to get them (and us) toward the End Game of an adequate global IPv6 deployment.

We do not require an unlimited IPv4 supply to accomplish this goal. We do, however, require liquidity: the ability to transfer, with incentives to transfer. Although it is very difficult for a centralized system (such as an RIR) to reclaim adequate space, the effort/reward ratio is much more favorable for an individual organization that knows its own network. So we must provide some stimulus for them to increase liquidity, while imposing some realistic restriction on demand. It must of course be scrupulously fair.

Stated in this way, a market-based trading exchange is not just one way of attempting to solve the problem—such an exchange, properly regulated, is arguably the most neutral and fairest way to manage the problem of scarcity.

In the next article we will explore how such a market system should work, discuss what new problems it is likely to create, and consider the potential effect on the routing table.

Remembering Jon: Looking Beyond the Decade

by Vint Cerf, Google

A decade has passed since Jon Postel left us.[0] It seems timely to look back beyond that decade and to look forward beyond a decade hence. It seems ironic that a man who took special joy in natural surroundings, who hiked the Muir Trail and spent precious time in the high Sierras, was also deeply involved in that most artificial of enterprises, the Internet. As the *Internet Assigned Numbers Authority* (IANA)[1] and the *Request for Comments* (RFC) editor, Jon could hardly have chosen more polar interests. Perhaps the business of the artificial world was precisely what stimulated his interest in the natural one.

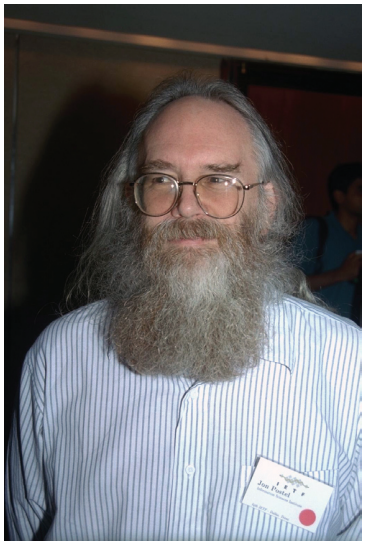

Photo: Peter Löthberg

As a graduate student at UCLA in the late 1960s, Jon was deeply involved in the ARPANET project, becoming the first custodian of the RFC note series inaugurated by Stephen D. Crocker. He also undertook to serve as the "Numbers Czar," tracking domain names, Internet addresses, and all the parameters, numeric and otherwise, that were critical to the successful functioning of the burgeoning ARPANET and, later, Internet protocols. His career took him to the east and west coasts of the United States but ultimately led him to the University of Southern California's *Information Sciences Institute* (ISI), where he joined his colleagues, Danny Cohen, Joyce K. Reynolds, Daniel Lynch, Paul Mockapetris, and Robert Braden, among many others, who were themselves to play important roles in the evolution of the Internet.

It was at ISI that Jon served longest and as the end of the 20th cen-tury approached, began to fashion an institutional home for the work he had so passionately and effectively carried out in support of the Internet. In consultation with many colleagues, but par ticularly with Joseph Sims of the Jones Day law firm and Ira Magaziner, then at the Clinton administration White House, Jon worked to design an institution to assume the IANA re-sponsibilities. Although the path to its creation was rocky, the *Internet Corporation for Assigned Names and Numbers* (ICANN)[2] was officially created in early October 1998, just two weeks before Jon's untimely death on October 16.

In 1998 an estimated 30 million computers and 70 million users were on the Internet. In the ensuing decade, the user population has grown to almost 1.5 billion and the number of servers on the Internet now exceeds 500 million (not counting episodically connected laptops, *personal digital assistants* [PDAs], and other such devices). As this decade comes to a close, the *Domain Name System* (DNS) is undergoing a major change to accommodate the use of non-Latin character sets in recognition that the world's languages are not exclusively expressible in one script[7]. A tidal wave of newly Internet-enabled devices as well as the increasing penetration of Internet access in the world's population is consuming what remains of the current IPv4 address space, accelerating the need to adopt the much larger IPv6 address space in parallel with the older one. More than three billion mobile devices are in use, roughly 15 percent of which are already Internet-enabled.

Jon would take considerable satisfaction knowing that the institution he worked hard to create has survived and contributed materially to the stability of the Internet. Not only has ICANN managed to meet the serious demands of Internet growth and importance in all aspects of society, but it has become a worked example of a new kind of international body that embraces and perhaps even defines a multi-stakeholder model of policy making. Governments, civil society, the private sector, and the technical community are accommodated in the ICANN policy development process. By no means a perfect and frictionless process, it nonetheless has managed to take decisions and adapt to the changing demands and new business developments rooted in the spread of the Internet around the globe.

Always a strong believer in the open and bottom-up style of the Internet, Jon would also be pleased to see that the management of the Internet address space has become regionalized and that five *Regional Internet Registries* (RIRs)[3] now cooperate on global policy, serving and adapting to regional needs as they evolve. He would be equally relieved to find that the loose collaboration of DNS root zone operators has withstood the test of time and the demands of a much larger Internet, showing that their commitment has served the Internet community well. Jon put this strong belief into practice as he founded and served as ex-officio trustee of the *American Registry for Internet Numbers* (ARIN)[4].

As the first individual member of the Internet Society he helped to found in 1992, Jon would certainly be pleased that it has become a primary contributor to the support of the Internet protocol standards process, as intended. The Internet Architecture Board and Internet Engineering and Research Task Forces, as well as the RFC editing functions, all receive substantial support from the Internet Society.

He might be surprised and pleased to discover that much of this support is derived from the Internet Society's creation of the *Public Interest Registry* (PIR)[5, 6] to operate the `.org` top-level domain registry. The Internet Society's scope has increased significantly as a consequence of this stable support, and it contributes to global education and training about the Internet as well as to the broad policy developments needed for effective use of this new communication infrastructure.

As a computer scientist and naturalist, Jon would also be fascinated and excited by the development of an interplanetary extension of the Internet to support manned and robotic exploration of the Solar System. In October 2008, the Jet Propulsion Laboratory began testing of an interplanetary protocol using the Deep Impact spacecraft now in eccentric orbit around the sun. This project began almost exactly 10 years ago and is reaching a major milestone as the first decade of the 21st century comes to an end.

It is probable that Jon would not agree with all the various choices and decisions that have been made regarding the Internet in the last 10 years, and it is worth remembering his philosophical view: "Be conservative in what you send and liberal in what you receive."

Of course he meant this idea in the context of detailed protocols, but it also serves as a reminder that in a multi-stakeholder world, accommodation and understanding can go a long way toward reaching consensus or, failing that, at least toleration of choices that might not be at the top of everyone's list.

No one, not even someone of Jon's vision, can predict where the Internet will be decades hence. It is certain, however, that it will evolve and that this evolution will come, in large measure, from its users. Virtually all the most interesting new applications of the Internet have come not from the providers of various Internet-based services, but from ordinary users with extraordinary ideas and the skills to experiment. That they are able to experiment is a consequence of the largely open and nondiscriminatory access to the Internet that has prevailed over the past decade. Maintaining this spirit of open access is the key to further development, and it seems a reasonable speculation that if Jon were still with us, he would be in the forefront of the Internet community in vocal and articulate support of that view.

A 10-year toast seems in order. Here's to Jonathan B. Postel, a man who went about his work diligently and humbly, who served all who wished to partake of the Internet and to contribute to it, and who did so asking nothing in return but the satisfaction of a job well done and a world open to new ideas.

Letters to the Editor

IPv4 Address Exhaustion

I read with interest your article in *The Internet Protocol Journal* (Volume 11, No. 3, September 2008) regarding the IPv4 address exhaustion problem. It occurs to me that two approaches for encouraging the public and *Internet Service Provider* (ISP) community to migrate to IPv6 are being dismissed somewhat, but used creatively together might offer some hope for pushing us in that direction: government regulation and changing the fact that there isn't a public interest in IPv6.

What if government regulation forced a new or currently existing common service to use IPv6? One obvious possibility is video content. Since the broadcast industry is already regulated by the FCC, further regulation providing for governance of this type of application isn't too much of a stretch. Consumer demand is likely to increase in this area as broadband continues to be widely deployed, and if the public were required to run in dual-stack mode to access it, the likelihood of adoption would be much greater. It would also incent the ISPs to provide connectivity to the IPv6 address space, possibly even with a revenue-generating model behind it.

I reluctantly bring up the pornography industry as another type of content that could be relegated to the IPv6 address space. It is my understanding that this type of traffic as a percentage of the total is quite large. Based on this assumption, it would have the same effect of forcing the large portions of the public and ISPs to provide connectivity to the IPv6 address space. Again, I mention this industry reluctantly, but from a political perspective regulation of this industry and its content is likely to be an easier proposal for the public to support since you could use the "value" of disconnected portions of the Internet to best advantage.

I realize that the global nature of the Internet makes regulation and the subsequent enforcement extremely difficult. But, I also assume that even if our enforcement were controlled only at the perimeter of the U.S. traffic it would have a strong effect on the behavior of the public and ISPs.

Best regards,

—*John Newell, INX Inc.*
jcnewell@gmail.com

The author responds:

Thanks for your response. It is true to say that various efforts have been undertaken across many years to find a "killer-app" for IPv6, if I may be permitted to use that overabused and by now very tired term. To date these efforts have not been successful. That's not because of any lack of trying.

There have been some really quite innovative ideas for IPv6 over the years, and so far most of them have been retrofitted into IPv4 one way or another. From one perspective this retrofit is entirely logical, given that good ideas tend to thrive in locations where audiences are receptive, and today's IPv4 Internet is still a very fertile place for good ideas to flourish.

The other part of the problem is that service providers tend to create innovative services with existing markets in minds, so these days the novel applications and services that appear to gain the attention of significant parts of the user base tend to operate in the IPv4 network, and by necessity such applications and services account for *Network Address Translation* (NAT) devices and various forms of filters and firewalls.

These observations indicate that a certain reinforcing cycle exists that cements the existing role of the IPv4 Internet, and tends to work against the widespread deployment of innovative services that are feasible only in the IPv6 environment.

So if the adoption of IPv6 is a carrot or stick affair, our efforts to find some tempting carrots have, so far, not been overly successful. We've been unable to identify particular goods or services for which there is a compelling case of consumer demand coupled with a set of technology constraints that imply that the service is feasible only across a deployed IPv6 infrastructure with IPv6 endpoints. So if the field we are working in is bereft of carrots, are there any available sticks that we can use instead? In this case there is the same old stick that originally motivated iPv6 in the first place: We are running out of IPv4 addresses. If we believe that there is more to do in the Internet, more people to connect, more devices to add, more conversations to have, more services to deploy, more ideas to realize, and more objectives to achieve, then IPv4 cannot in and of itself sustain that vision for the Internet. The threat here is that the growth of the IPv4 Internet may well cease when the supply of further IPv4 addresses is exhausted.

Is this threat of network stagnation going to be enough to propel us into an IPv6 Internet? Will it be an adequate motivator to encourage the necessary investment in network infrastructure and in the provision of goods and services that first operate in a transitional dual-stack environment, and ultimately in an IPv6 world? I hope that the answers are "yes," as do many others I'm sure.

But I'm also worried that it may not be enough and that we may spin off into an entirely different trajectory that ultimately dismantles most of the attributes of today's Internet. I worry that instead of an open network that fosters innovation and creativity we might end up with "vertical integration" and "transparent convergence" and a network that actively resists new services and applications.

So for me, and I hope many others, IPv6 needs no new "killer-app." IPv6 does not need television or pornography to succeed. IPv6 is an imperative for the Internet simply because the alternatives to IPv6 appear to offer us a leap backward in technology and a leap backward in the elastic ways we've been able to use networks—and in the process we are going to destroy the Internet as we know it!

Regards,

—Geoff Huston, APNIC
gih@apnic.net

Dear Ole,

In his latest IPJ article (Volume 11, No. 3), Geoff Huston highlights the significance of NAT as a mechanism enabling service providers to externalize the costs and risks arising from IPv4 address scarcity. While acknowledging the increased burden and uncertainty borne by end users and NAT-traversing applications, Geoff speculates that the success of this mechanism is likely to inspire the deployment of yet another level of ("carrier grade") address translation, to further prolong if not absolutely preclude the incorporation of IPv6 by incumbent service providers. While entirely plausible, such a move would create the same kind of "double blind" conditions for Internet service delivery that prevailed in financial markets when debt securitization was coupled with the externalization of asset depreciation risks in the form of *Credit Default Swaps* In such cases, the second layer of indirection tends to make it all too easy to maintain self-serving assumptions (and/or plausible deniability) about the true nature and purpose of the first layer, and thus to fuel the perpetuation of unsustainable industry practices unto the point of industry collapse. Given the now inescapable lessons of the recent financial sector collapse, it would be nice if we didn't have to learn this particular one again the hard way.

—Tom Vest
tvest@eyeconomics.com

On Paper

I just received the September issue (Volume 11, No. 3) of IPJ and wanted to make a quick comment about the paper change. Upon reading the section on the change I quickly dug up the previous copy of IPJ and compared the two. I personally like the new paper much better. The main reason I like it is because it is much easier on the eyes, I think mostly because it no longer has a glare from overhead lighting reflecting like the old paper type did. It's a welcomed change from my take.

—David Swafford,
Network Engineer for CareSource, Dayton, OH, US

Book Reviews

A Dictionary and a Handbook

Hundreds of telecom books are published each year, but it is unusual to find a really good one. There must have been a blue moon (I'll have to check my almanac) this month, for I found two new and quite remarkable books by the same author, Ray Horak. One is a dictionary and the other an encyclopedic work, both covering the full range of voice, data, fax, video, and multimedia technologies and applications that comprise contemporary telecommunications. Further, they do so in such a plain-English, commonsense manner that you don't need to be a serious telecom student or professional to benefit from them—any layperson with a serious need to know will find them to be of great value. Finally (and this is rare in a technical book), both are actually relatively easy and certainly interesting reads, with liberal doses of fascinating historical context. In fact, they are even strong on entertainment value, with humorous observations and quotations sprinkled throughout. Horak has written each book in a different style for a different purpose, so they are best acquired together—as a set.

Webster's New World Telecom Dictionary

Webster's New World Telecom Dictionary, by Ray Horak, ISBN-10: 047177457X, ISBN-13 978-0471774570, Wiley Publishing Inc., 2007.

In order to communicate effectively in a contemporary telecom conversation, one must speak a special language rife with technical terminology, much of which is in the form of abbreviations, acronyms, contractions, initialisms and portmanteaux. To add to the confusion, many terms have multiple very precise—and occasionally imprecise—meanings, depending on the context. Writing a telecom dictionary must be a formidable task, one which only either the very brave or very foolhardy would even attempt. I'm not sure into which category Ray Horak falls, but his *Webster's New World Telecom Dictionary* is an excellent piece of work.

Organization

Dictionaries are in alphabetical order, of course, with chapters thrown in for symbols and numbers. Because the introduction of symbols requires special treatment, within each of the 28 chapters Horak organizes the approximately 4,600 definitions in ASCII order, perhaps as an accommodation for the binarians among us. The book includes an appendix of standards organizations and special interest groups, which can be useful if you need more information on a subject or need to know exactly to whom to complain about a *standard* or *specification,* both of which terms are defined clearly in the dictionary, of course.

Comparisons: Comprehensive and Correct

In my opinion, the best telecom dictionary ever written, aside from *Webster's,* is the *Communications Standard Dictionary,* by Martik H. Weik. That book unfortunately is out of print, with the final 3rd edition dated 1996. At 1095 pages, it is a bit overwritten and way too technical for most purposes, reading much like an IEEE dictionary. At this point, it certainly is out-of-date.

A handful of other telecom dictionaries and encyclopedias are currently in print, by far the most popular of which is *Newton's Telecom Dictionary.* Because *Newton's* dominates the market and has done so for many years, any telecom dictionary or encyclopedia is inevitably compared to that work. *Webster's New World Telecom Dictionary* is no exception, particularly because Ray Horak was the contributing editor to Newton's from the 12th through the 22nd editions.

Although *Webster's* defines only 4,600 terms in comparison to Newton's highly dubious claim of some 24,500 terms, *Webster's* definitions are much better researched, much more precise, and much more efficiently worded (that is, there is much less "fluff"). Even if *Webster's* almost certainly will gain in bulk as future editions expand the coverage of the telecom domain, it contains all of the essential telecom and IT terms, and defines them clearly and concisely. *Webster's* includes many humorous definitions but, unlike *Newton's,* they are all relevant and meaningful. For example, Horak lists three types of standards—*de jure, de facto,* and *du jour.* According to him, a *du jour* standard is defined as follows:

> "From French, meaning *of the day.* The popular standard of the day. One day 10 years ago, ATM was really hot and a lot of people made a lot of money talking about ATM and selling products based on ATM. It seemed like only the next day that IP was really cool. (I made this one up.)"

Other humorous definitions include analogue, endianess, Hellenologophobia, hoot 'n' holler, OCD, PC, and WMBTOTCITB-WTNTALI. All of these, and more, serve to lighten the load, so to speak, but none of this humor detracts from what is a serious book on a serious subject. *Newton's,* on the other hand, is so full of personal observations and anecdotes, irrelevant humor (?), and inaccurate definitions as to make you wonder why bother to make the comparison at all. Horak states that he wrote *Webster's* partly to atone for his sins in contributing to *Newton's,* but mostly to put an authoritative reference book in his own hands, and those of others involved in litigation support. He apparently does a fair amount of work as an expert witness in intellectual property (the other IP) cases and on innumerable occasions has been asked to define and opine on terms such as link, circuit, channel, call, connection, switch, router, and PSTN. Now he can testify in court with one hand on the Good Book and the other on *Webster's*.

Recommended

Webster's New World Telecom Dictionary is an excellent piece of work. Ray Horak and his technical editor, Bill Flanagan, have collaborated to create a well-written, authoritative work that clearly sets a new standard for telecom dictionaries. I highly recommend it to anyone serious about telecom.

Telecommunications and Data Communications Handbook

Telecommunications and Data Communications Handbook, by Ray Horak, ISBN-10: 0470041412, ISBN-13: 978-0470041413, John Wiley & Sons, 2007.

Unless you have really big hands, you may wonder how it is that a tome of 791 pages that weighs more than 3 pounds could possibly be called a handbook. Well, the term "handbook" actually is fairly imprecise, but Ray Horak's *Telecommunications and Data Communications Handbook* certainly is not. Actually, it is about as compact as it can be, given its encyclopedic nature, and it is very precise, indeed. The book covers the entire telecom landscape, from wireline to wireless, from copper to radio and fiber, from electrical to optical, and from the customer premises to the cloud. It discusses voice, data, fax, video and multimedia technologies, systems, and applications in great detail, and in the LAN, MAN, and WAN domains. The handbook explores every relevant technology, standard, and application in the telecom and datacom space.

Horak is a well-known telecom consultant, author, writer, columnist, and lecturer. The *Telecommunications and Data Communications Handbook* is based on his best-selling *Communications Systems and Networks* (1997, 2000, 2002), but is considerably more technical and broader in scope. It is exceptionally well-written in Horak's plain-English, commonsense style, making it just as helpful to the neophyte and layperson as to the serious student or seasoned IT professional. Horak makes liberal use of well-constructed graphics to illustrate system and network architectures, topologies, and applications.

Organization

The Handbook begins with an excellent table of contents (20 pages) and ends with an excellent index (29 pages), both of which are crucial to a good book. After all, it doesn't make any difference how good the information is if you can't find it. The book is logically organized into 15 chapters and 2 appendixes.

Chapter 1 is devoted to fundamental concepts and definitions, thereby building a firm foundation of concepts and terminology upon which subsequent chapters build. Terms such as two-wire, four-wire, circuit, link, channel, switch, and router are clearly defined, compared, and contrasted. Chapter 2 explores the full range of transmission systems, including twisted pair (UTP, STP, and ScTP), coaxial, microwave, satellite, *Free Space Optics* (FSO), fiber-optics, *powerline carrier* (PLC), and hybrid systems.

Chapter 3 examines voice communications systems: KTS, PBX, Centrex, and ACD. Chapter 4 discusses messaging systems in detail, including facsimile (fax), voice processing, and e-mail and instant messaging, concluding with a detailed discussion of unified messaging and unified communications. Chapter 5 is dedicated to the *Public Switched Telephone Network* (PSTN) and addresses *Numbering Plan Administration* (NPA), regulatory domains, rates and tariffs, signaling and control systems, and network services. Chapter 6 returns to fundamentals, this time in the data communications domain, with detailed explanations of *Data Communications Equipment* (DCE) such as modems, codecs, CSUs, and DCUs, and then moves on to protocol basics, code sets, data formats, error control, compression techniques, network architectures, and security mechanisms.

Chapter 7 deals with conventional digital and data networks such as DDS, Switched 56, VPNs, T/E-carrier, X.25, and ISDN. Chapter 8 treats *Local-Area Networks* (LANs) and *Storage Area Networks* (SANs) exhaustively, including transmission media, topologies, broadband vs. baseband, equipment, operating systems, and standards. This chapter covers 802.3, 802.11, HiperLAN, Bluetooth, IEEE 1394, Fibre Channel, and iSCSI in considerable detail. Chapter 9 is devoted to broadband network infrastructure, including both access technologies (for example, xDSL, CATV, WLL, PON, and BPL) and transport technologies (for example, SONET/SDH and RPR). Chapter 10 offers an exhaustive study of broadband network services, including Frame Relay, ATM, Metropolitan Ethernet, B-ISDN, and AINs.

Chapter 11 discusses wireless, with an emphasis on mobility, covering both broad concepts and technical specifics of *Specialized Mobile Radio* (SMR), paging, cellular (1G, 2G, 2.5G, 3G, and beyond), packet data radio networks, and mobile satellite networks (GEOs, MEOs, and LEOs). Chapter 12 thoroughly treats video and multimedia networking, including a detailed discussion of video and multimedia standards (for example JPEG, MPEG, and H.320), *Session Initiation Protocol* (SIP), and IPTV. Chapter 13 exhaustively and insightfully explores the Internet and *World Wide Web* (WWW), including a thorough discussion of the IP protocol suite. Chapter 14 briefly examines convergence, and Chapter 15 examines telecom regulation, with a focus on the United States.

Appendix A is something of a decoder for abbreviations, acronyms, contractions, initialisms, and symbols. Appendix B gives a complete listing of relevant standards organizations and special interest groups, including full contact information, in case you need more information or want to offer comments on a particular subject.

Comparisons

It is hard to make a valid direct comparison to this book. *The Irwin Handbook of Telecommunications,* by James Harry Green, is good, but less complete, less technical, and drier, if such a combination is possible. The most recently published 5th edition also is apparently out of print. The *Voice & Data Communications Handbook,* by Regis "Bud" Bates, is written at a lower level; and, the *Essential Guide to Telecommunications,* by Annabel Dodd, at a much lower level. These latter two books are breezy reads and appeal more to a mass market than to a serious student or professional.

The *Telecommunications and Data Communications Handbook* compares more correctly to some of the more seminal works of Gilbert Held or James Martin, but covers a much wider range of subject matter and is a much easier and more pleasant read.

Recommended

The *Telecommunications and Data Communications Handbook* is written for the academic and professional community, but is just as relevant to anyone who needs to understand telecommunications system and network technologies and their meaningful applications. It is an exceptional work that should be on every IT professional's bookshelf…when not in his or her hands.

—John R. Vacca,

Read Any Good Books Lately?

Then why not share your thoughts with the readers of IPJ? We accept reviews of new titles, as well as some of the "networking classics." In some cases, we may be able to get a publisher to send you a book for review if you don't have access to it. Contact us at **ipj@cisco.com** for more information.

Fragments

Itojun Service Award Launched

A new award, providing recognition and support for those progressing IPv6 development on the Internet, was announced in November. The *Itojun Service Award* honors the memory of Dr. Jun-ichiro "Itojun" Hagino, who passed away in 2007, aged just 37[1]. The award, established by the friends of Itojun and administered by the *Internet Society* (ISOC), recognizes and commemorates the extraordinary dedication exercised by Itojun over the course of IPv6 development. Itojun worked as a Senior Researcher at the *Internet Initiative Japan* (IIJ), was a member of the board of the *Widely Integrated Distributed Environment* (WIDE) Project, and from 1998 to 2006 served on the groundbreaking KAME project in Japan as the "IPv6 Samurai." He was also a member of the *Internet Architecture Board* (IAB) from 2003 to 2005.

At the time of his passing, Russ Housley, *Internet Engineering Task Force* (IETF) Chair, and Olaf Kolkman, IAB Chair, issued a joint statement, praising Itojun's service to IPv6 developments, saying that he had "inspired many and will be missed."

The Itojun Service Award will run for 10 years, presented annually to an individual who has made outstanding contributions in service to the IPv6 community. The award includes a presentation crystal, a US$3,000 honorarium, and a travel grant. The Award will honor an individual who has provided sustained and substantial technical contributions, service to the community, and leadership. With respect to leadership, the selection committee will place particular emphasis on candidates who have supported and enabled others in addition to their own specific actions.

The selection committee members for the Itojun Service Award are: Jun Murai, Hiroshi Esaki, Ole Jacobsen, Bob Hinden, Randy Bush, Bill Manning, Tatuya Jinmei, Kazu Yamamoto, and Kenjiro Cho.

Memorial donations to the Itojun Service Award Fund are welcomed and the Internet Society has established an account for donations. Details of the fund, as well as more information about Jun-ichiro "Itojun" Hagino and the Itojun Service Award are available on the ISOC Web site: `http://www.isoc.org/awards/itojun/`

The WIDE Project has also established a Japanese bank account to collect donations in Japanese Yen, the details of which are available here: `http://www.wide.ad.jp/itojun-award`

EsLaRed Receives 10th Annual Postel Service Award

ISOC awarded the *Jonathan B. Postel Service Award* for 2008 to *La Fundación Escuela Latinoamericana de Redes* (EsLaRed) of Venezuela for its significant contributions to promote information technologies in Latin America and the Caribbean.

It is now ten years since the passing of Internet pioneer Jonathan B. Postel, the inspiration for this prestigious award. To mark this event in a special way, ISOC formed a *10th Anniversary Award Committee* including all the past award recipients, which has formally recognised EsLaRed for "its sustained efforts to bring scientific, technical, and social progress in Latin America and the Caribbean through education, research, and development activities on technology transfer."

ISOC presented the award, including a US$20,000 honorarium and a crystal engraved globe, in November during the 73th meeting of the IETF in Minneapolis, USA.

Accepting the award for EsLaRed was its President, Professor Ermanno Pietrosemoli. "We're very excited to be honored in this way," said Professor Pietrosemoli. "In the developing world, having access to the Internet, which gives us access to things like scientific journals and medical information, is not easy and it is not taken for granted. It is wonderful for us to be able to help people improve their conditions and to see first hand how the Internet can change people's lives," he said.

"On behalf of the ISOC community, it is my great pleasure to congratulate Professor Pietrosemoli and his dedicated colleagues at EsLaRed for their achievements over the years," said Lynn St. Amour, President and CEO of ISOC. "EsLaRed's commitment to the Internet has been at the forefront of regional development and their leadership has been an instrumental element in forming today's dynamic Latin American and Caribbean Internet community," said Ms St. Amour. For more information about this year's recipient see:
`http://www.isoc.org/awards/postel/eslared.shtml`

The Postel Service Award was established by ISOC to honor individuals or organisations that, like Jon Postel, have made outstanding contributions in service to the data communications community. The award is focused on sustained and substantial technical contributions, service to the community, and leadership. Previous recipients of the Postel Award include Jon himself (posthumously and accepted by his mother), Scott Bradner, Daniel Karrenberg, Stephen Wolff, Peter Kirstein, Phill Gross, Jun Murai, Bob Braden and Joyce K. Reynolds (jointly), and Nii Quaynor. The award consists of an engraved crystal globe and a US$20,000 honorarium. For more information see:
`http://www.isoc.org/awards/postel/`

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

From The Editor

IP Version 4 address exhaustion and migration to IP Version 6 continues to be the focus of many Internet-related organizations and events. The *Regional Internet Registries* (RIRs), still debating what will happen as the IPv4 address pool runs out, are developing policies for how to manage address-block transfers between address holders. One potential result of the address shortage is that a *market* (official or otherwise) will develop for the buying and selling of IPv4 addresses. In our last issue, we brought you the first in a two-part series of articles entitled "The End of Eternity," by Niall Murphy and David Wilson. Part Two, included in this issue, discusses what a market-based IP trading exchange might look like.

IP address allocation, transfers, and even the potential trading market for addresses is ultimately dependent on a reliable and trusted registry for this information. The RIRs have been working on a way to ensure that information about *IP Number Resources* (that is, IPv4 addresses, IPv6 addresses, and *Autonomous System* [AS] numbers) are securely stored and distributed so that users of such information can be assured that it is authentic. The underlying technology is a *Resource Certificate Public Key Infrastructure* (RPKI), and it is described in our second article by Geoff Huston.

The Internet technical community is discussing the so-called *identifier/locator split* as a major change to the Internet architecture. The IETF is developing several proposals, including the *Locator Identifier Separation Protocol* (LISP) discussed in our March 2008 issue. In this issue we look at another proposal, the *Host Identity Protocol* (HIP). The article is by Andrei Gurtov, Miika Komu, and Robert Moskowitz.

You will notice that our back cover has a new look. This layout is not the result of any creative design urges, but rather a change in U.S. Postal Service regulations regarding the placement of the subscriber address label. I guess the Internet isn't the only place where addressing is a major topic.

As always, your comments, suggestions, and contributions are welcome, including Letters to the Editor, Book Reviews, and of course full-length articles. Our Call for Papers is included on page 35. Contact us by e-mail at ipj@cisco.com

—Ole J. Jacobsen, Editor and Publisher
ole@cisco.com

The End of Eternity
Part Two: Address Space Trading and the Routing Table

by Niall Murphy, Google, and David Wilson, HEAnet

In our last article[0], we wrote about the onset of scarcity and the problems that are likely to ensue as a result. We characterized the problem we face as the *gap*, the length of time between the end of IPv4 plenty and the beginning of a universally reachable IPv6 Internet. Noting that any solution should either make the gap shorter, by bringing forward full IPv6 deployment, or make it less painful, by reducing the pressure of IPv4 scarcity, we propose that the fairest, most neutral way to encourage networks out of IPv4 while providing help for those who need it is to introduce a market-based IP address trading exchange. Let us explore now how such a system could work.

Possible Market Structures: Advantages and Drawbacks

An exchange could be set up and operated in many ways. Our preference, however, is for such a service to be run by the existing, trusted, and stable *Regional Internet Registries* (RIRs). Not only are they experienced in maintaining the values that the community as a whole wants to see maintained—fairness and neutrality, transparency, etc.—the RIRs are also in an excellent position to establish the *quality* of prefixes traded in an exchange, having excellent service contracts and history with members. Furthermore, the RIRs are unlikely to be made available for onward sale or transfer to other organizations with "different values," and would maintain their traditionally community-focused policy-making apparatus. They would also be in a position to act quickly to coordinate and assume responsibility if given sufficient authority by the membership.

It does not have to be an RIR, of course: we *could* set up another industry body, but it would take valuable time and require a new governance model. We could also outsource the whole thing to any professionally run auction-handling site, but for such a fundamental change in how we do things, it seems wise to keep it under direct control. Finally, the psychology of continuity is important; if organizations are used to dealing with the RIRs, it provides an important perception of stability to keep them as the interface to getting new addresses.

As with our previous article, we emphasize again that the RIRs have provided excellent service in focusing the consensus of the community in a form that can be passed back to governments and other stakeholders, both external and internal.

The shield provided by the RIRs, protecting the members from the outside and protecting the members from themselves, has worked well for three reasons:

- First, RIR consensus is widely seen to broadly reflect the wishes of their communities as a whole because of the extremely low barrier to representation—in essence anyone who cares can attempt to influence policy, and no formal attempt is made to weigh one set of opinions over another. As a result, RIR policy is a lowest common denominator that is in general free from many of the more partisan stances usually found in the telecommunications arena, leading to greater credibility outside the RIR system, and greater credibility within, because the oppression of a minority by the majority within the context of policy formation is very difficult.
- Secondly, possessing that credibility has led to repeated success for the RIRs in the arena of disseminating and explaining policies outward, and they have therefore reinforced the confidence their members have in them.
- Finally, the RIRs are also comparatively financially easy to run; in the *Réseaux IP Européens* (RIPE) region, fees are by no means excessive given the ratio of customers to addresses; they are observed and validated by RIPE *Network Coordination Centre* (NCC) members, and any competing industry body would have to duplicate not only all the previously mentioned activities, but also the large working surplus that allows the RIRs to ensure stability through more turbulent times. Or to put it another way, "it's open, it works, and it's cheap." We would recommend that any significant extension to the RIR authority, such as running an exchange as proposed, should endeavour to preserve as many of these properties as possible.

So if RIRs are to be the point of contact and policy making, how might such an exchange operate? We have a few guidelines from a relatively new field of economics, called *Market Design Theory*[21], that might help to inform our choices. Firstly, we must have *thickness*: we must have enough traders (both buyers and sellers) entering the market, such that the populace at large can be assured that if they need to perform a transaction, the exchange is the place to do it, rather than private trades. (Private trades, although they enable liquidity, have the disadvantages that the WHOIS database is not maintained, that policy cannot be centralized, that prefix de-aggregation can occur arbitrarily, and so on.) We should avoid *congestion:* so many participants that it becomes difficult to trade. Finally, we must have *safety:* the assurance that if a transaction is engaged in, it will complete, and buyers will receive what they want.

Although other properties exist, those are the main ones required for the exchange to operate successfully. On thickness, we think it is clear that attracting buyers in a time of scarcity will not be a problem. The problem will be attracting sellers from such constituencies as have them available (old *Internet Assigned Numbers Authority* [IANA]-allocation holders, dot-com failures, and so on). An open question is whether the exchange can do more to attract sellers than the monetary reward for selling would do on its own; more meaningful incentives for them are difficult to determine. Overall, congestion does not seem likely to be a concern, given that the RIR model most usefully supports only membership-based participation initially. (Furthermore, our guess is that the "product" will be quite homogenous, so performing trades will presumably be mostly a matter of determining price.)

Let us return to the question of prefix *quality*. The single most important measure of quality of a prefix, the attribute without which the prefix is useless, is *uniqueness*. One must be assured that the prefix one holds is acknowledged as being held by oneself, and that *Internet Service Providers* (ISPs) will accept its announcement from *no other* parties.

From a plentiful pool, where prefixes have no cost other than the service charge of the registry, ensuring uniqueness is perhaps not a simple task, but it is a relatively uncontroversial one. When scarce, prefixes become valuable and will be given a cash value, either officially or by other means. ISPs will then have a business reason to break with consensus on routing filters, as we discuss later in more detail; but regardless, prefixes allocated from the IANA free pool generally have an impeccable heritage and do not vary greatly in usability. There are, of course, the natural delays in having new /8s incorporated into routing filters across the world. Those delays do have real effects, but the recipient of these prefixes usually has good reason to believe that a) these problems will be corrected over time, and b) everyone else in the same /8 will have the same problem.

In the new paradigm, each prefix must be carefully examined by the recipient to test that it is uniquely held by the proffering organization, and the recipient will presumably have a further interest in its routability and membership in blacklists. The quality problem arises in both private and public trades; if the RIRs implemented a quality test, that would be yet another advantage of centralization to the benefit of everyone.

Closely associated with prefix quality is the question of *safety*. Again the RIRs are in an excellent position to provide the necessary support for good-faith transactions, certification of prefixes being the primary mechanism, although various other possibilities (such as membership controls) might also exist.

More pertinently, pricing of the goods traded in such an exchange is an important question. Various natural calculations might support the calculation of address costs, including but not limited to average revenue per address, operational costs averaged over all addresses held, and so on. Our primary contention here is that the RIRs should not engage in price setting directly. Doing so would at the very least invite regulation. There may be a case for placing caps on trades as an antispeculation measure, but that requires further analysis.

What exactly the "goods" are in this case also needs consideration. Our preference is that what is traded is the right to use a prefix, rather than a prefix itself. Quite apart from the inherent oddness in selling a 32-bit integer (with 5-bit netmask), we should avoid the land registry model, where all the previous history of a prefix must be checked before sale. We need the RIR to intermediate itself and provide quality evaluation services rather than leaving it up to the end buyer. We should also not be selling rights to use prefixes of fixed sizes. The exchange needs to offer a spread of lengths in order to meet the needs of all potential customers.

You Say You Want a Revolution

To be sure, a change in the perceptual or legal status of IP addresses is a revolution in how we do things. The ramifications of IP addresses becoming property, or even acquiring intermediate states with property-like title rights, are manifold and they involve sweeping changes. Suddenly things that had no value have a clear public worth. Will organizations then be compelled to list addresses on their books as an asset? Could they then be taxed on them? What would such a tax rate be? Could organizations not actually using the asset (say, the RIRs) avoid this charge? Would transfers entail a taxable operation? These questions are significant and difficult. The right thing for the community is almost undoubtedly that IP addresses do not become simple property, but rather have (at a minimum) transfer and sale rights associated with them. In this way we could enable liquidity without complications, and avoid introducing extra complications at a difficult time. But it is unclear whether regulatory authorities will see it this way without the correct guidance.

The change in legal status of IP addresses is not the only violent change that could be unleashed by exhaustion. Consider, for example, the potential for litigation led by both new entrants unable to acquire an allocation to fulfill their business plan and incumbents seeking to either cause confusion (as an anticompetitive measure against just about anyone) or to try to disrupt any fragile consensus about how the last allocations play out. Leaving aside the question of whether simple prudence would recommend or deprecate such a move, there is a very clear risk of attempted litigation affecting the outcome of the end game.

However, one of the major benefits of a market is that it allows the RIRs to maintain a hands-off approach while still making it at least theoretically possible for an organization to get an independent allocation. The community can be doing all that it realistically can to continue the flow of IPv4, in terms of creating conditions fostering its dissemination, while being seen to be doing such, rather than simply running out of ideas and giving up. It could, of course, be seen—not unfairly—that participating in the transition to a market mechanism might amount to the effective transference of title to those who happened to be in the room at the time of exhaustion, an effective "insider privatization."

Yet, if a market does not emerge, it is hard to see how any new entrants can have a business plan not directly dependent on incumbents. Although there are plenty of incumbents who would value having more address space to continue their business over the cash value of their addresses, so rendering entrance to the market impossible, there are plenty of other organizations that have only ever used a portion of their first allocation and would theoretically be well motivated to disburse these addresses accordingly.

To avoid exceptional attention from regulatory authorities, and to prevent the exchange from failing, we should design the exchange to deter in a systematic way the misbehavior of markets: speculation, hoarding, cartels, price fixing, and regional disadvantage should all be made as difficult as possible within the context of running a limited-membership market.

If we define *speculation* as short-term dealing with no expectation of use, we may be able to limit this kind of behavior naturally as a consequence of the membership-based participation inherent in the RIR model, and as a function of the periodic nature of routing filter generation. Increasing the price with short-term speculation disincentivizes the end purchaser with a use expectation from actually buying the prefix, because there will be a time delay before it can be used; therefore the purchaser with no use expectation will find it more difficult to find a buyer if the price rises to unreasonably high levels.

Hoarding, defined as long-term speculation with no use expectation, is bad for the exchange in that thickness is reduced, but also bad for the hoarder because the long-term value of the asset should decrease, in line with the increase in deployment of IPv6.

The formation of *cartels* would actually be quite a practical difficulty, especially under the closer attention likely to be paid to the exchange by competition authorities. Notwithstanding the coordination difficulties, we are inclined to say again that enough buyers should help to control this problem sufficiently to make the exchange work.

Regional disadvantage is, however we look at this situation, a problem. If scarcity is likely to lead to some monetary value being placed on address space, we face a vista where regional disadvantage can only be reduced, not eliminated. The inequality is, ultimately, one of the most compelling reasons to minimize the length of the transition period, and it would benefit us all to do so. Some measures go part way toward alleviating the problem. For instance, regional cooperation can help—in a market, if buyers cooperate and bulk buy, the threshold for organizations that would otherwise be facing a prohibitive barrier to entry would be reduced.

If we do not have a globally accessible exchange, it does not necessarily mean that the organizations will simply fail, entrenching the regional inequality, but they may respond by trying to fulfill their customer requirements by means of private, uncoordinated trading, with all the problems that entails.

We note that it is probably best to structure the actual trades as *auctions,* rather than facilitated marketplace transactions. When quality is asserted, one prefix is much like another—at least compared to prefixes of a similar size—and treating them as a commodity in this way facilitates the enforcement of policies on a centralized basis.

Drawbacks of a Market

Many cautionary tales about the operation of markets exist. Irrational exuberance, long-lasting depressions, fraudulent or exploitative behavior of all kinds—all of these effects, either enabled or supported by market mechanisms, are well known. Do we have any reason to believe either that these consequences will be not serious in our particular domain or that we have any new way of preventing them from happening?

In truth, we have no particular reason to believe that they won't happen, but there is a structural reason to believe that they might not matter to the exclusion of all else: the worse the situation becomes in the IPv4 marketplace, the more incentive there is to move to IPv6. To that extent, the market might be considered as providing a somewhat self-regulating reason for transition. Of course, we can put various mechanisms in place to help mitigate unstable behavior, as we suggested previously, but ultimately this is a fundamentally new way of doing things that we are ill equipped to understand the full consequences of.

Perhaps the largest drawback, outside of the practical difficulties in getting IPv4 addresses to organizations, is the philosophical impediments that come inherent with switching to a market-based model for allocation. Although a market cannot be said to rule out the consensus model that has turned out well for the Internet community, it also cannot be said to fully support it. This change may be a cultural one we find difficult to reverse, and it might undermine any future attempt by the community to try to differentiate itself on governance model.

Even though we have proposed the market model in good faith, as an attempt to meet the needs of new entrants and existing organizations—and as a boost to the faster deployment of IPv6—if it proves to be a failure in meeting those needs, there may be no more credible strategies left if governments insist on action. That in itself might represent even larger, more unpredictable change for the industry.

Effects on the Routing Table

Another inescapably important question is what will happen to the *Default Free Zone* (DFZ) routing table. A world in which address blocks transfer without the aggregating procedures of the RIRs is naturally a cause for concern, and when needs-based allocation comes to an end, a change in the rate of growth does seem inevitable. We can, however, make some observations that might reassure us, to some extent, that the rate of growth will not be calamitous.

First, as we go from a time of address plenty to address scarcity, one can assume that the ongoing fulfilled demand for address space will be no greater than it is now. Hence, the future growth in the number of prefixes in the routing table—regardless of prefix length—would seem to have an upper limit consistent with the number of allocations by RIRs to *Local Internet Registries* (LIRs) at the moment. This limit is still a multiple of the current curve, because we lose the benefit of the aggregation function performed by LIRs, but it suggests that we will at least not face an order-of-magnitude step change as a result of a disorderly competition.

Then there is the question of the routability of smaller prefixes. There is, at the moment, a *de facto* longest prefix size of around /24 that has close to universal reachability on the general Internet. One might assume that this prefix size will grow inexorably during and after exhaustion, as existing space is broken up into smaller and smaller blocks. Implicit in that assumption is the notion that such block sizes will be adequate for users and worthwhile for ISPs to route; we should probably not rely on networks "making do" with smaller and smaller chunks of address space.

Simultaneously, inexorably growing prefix lengths in the DFZ can only come about because of operator action. In particular, although there is a rough consensus in DFZ operators at the moment that /24 is routable and /25 is not, this policy is not a consensus-approved policy of the RIRs or the IETF. Each operator makes its own decision, based on its own customer needs, its own network, and the expectation of routability with other networks.

Reachability, therefore, depends on ISPs cooperating, and universal reachability depends on ISPs cooperating universally. An ISP may well choose to carry smaller prefixes on behalf of its customers, but unless this practice becomes widespread, no expectation can be made of universal reachability, and the practice will remain a minority one conducted by cooperating ISPs, as occasionally happens from time to time today, and this situation will little affect the size of the routing table for those involved.

Is there a competitive advantage to the largest of the ISPs in investing in very large routers that can carry many millions of prefixes, more than the smaller ISPs can support? If there were, it could perhaps lead to a concentration of power in the tier-one providers (who, as inevitable parts of any lengthy path across the Internet, have the greatest influence on the *de facto* longest routable prefix.) This situation could perhaps be true if routers are price-limited by the supportable number of prefixes, but this characteristic is typically a secondary one at worst. Routers are grouped by the bandwidth they can support, and priced accordingly; a 100-Mbps router that can support a million prefixes will certainly be more expensive than a 100-Mbps router that can support only ten thousand, but there is an order of magnitude step from either router to a router that can support 10 Gbps.

Inaction Leads to Harm

In fact the argument that the effect on the routing table will be unsustainable is opposed to the argument that there may not be adequate liquidity to sustain the market. It is true that we could find ourselves in the latter position, and so the effect of this system on reducing the problem (characterized as "the gap") will be smaller than we might like—but, as a best-effort scenario, not negligible, particularly in regard to showing good stewardship of the resource to potential outside influence. Compared to any other proposal, and particularly compared to voluntary release or a locking down of the address space, we think that this way is the best way to assure that we make available what liquidity there is.

It is difficult to see any model—even an idealized one—that could possibly service the run rate while maintaining aggregatability. The sparse allocation model used by the RIRs is dependent upon the continued availability of large, clean blocks of space, that is, /8s from IANA. With this address plenty comes freedom in our choice of policies, and with that freedom comes relatively quick consensus.

Post-exhaustion, the space will not be plentiful, and regardless of whether a monetary cost is attached, it will no longer be free. At this point, the legitimacy of the consensus of the RIR fora becomes critical. It is a fiercely defended bottom-up process. As the legitimacy of policies in the *Domain Name System* (DNS) world comes from consensus to abide by a single `root.cache`, so the legitimacy of policies in routing comes from general agreement on route filters and the authenticity of data in the RIR WHOIS databases.

We have also learned from the DNS world what happens to operational consensus when the resource becomes in some way valuable. Although the current RIR meetings are able to come to decisions that roughly reflect the consensus of the operational Internet, the necessarily tougher decisions forced upon us will challenge those who participate directly in policy making to reach conclusions that will satisfy operators who are not present. In principle it should not be necessary to account for those who do not represent themselves, but when the legitimacy of our policies is derived from their operational choices, the burden rests on us to ensure that our processes are truly representative.

If we are unsuccessful in doing so, or indeed if we choose to maintain the status quo, we cannot assume that the policies implemented on the operational Internet will themselves remain static. It is already the case that ISPs will work together, as is their entitlement, to agree to route prefixes for the benefit of their mutual customers. It is not unusual for one ISP to accept the announcement from a customer of a subnet of another ISP's address space. This decision is one for those ISPs to make about their own operational environments.

If we choose not to endorse a particular short-term solution to depletion, it falls upon ISPs themselves to find a way to continue their business operations, and resolve their customers' problems. If they cannot get address space from themselves, it will be their *duty* to their customers to get routable address space from somewhere—by negotiating, if necessary, with their peers and upstream providers to change the definition of "routable address space." Ultimately we may assume that if we do not provide a solution to the industry, the industry will invent one—or several competing ones.

Because we assert that the solution that best solves this problem is an address space trading exchange, we may well end up getting one—but one (or more) that is private, and out of sight of our existing policy-making structure. Worse still, competing exchanges would not have access to the RIRs data, and so would not be in a position to assure the quality of a prefix—a situation that could threaten all transactions.

Without exaggerating, it is likely that what we do in response to this crisis will determine the architecture of the Internet for a long while to come. Although we are reminded of Woody Allen's quote wherein he "... hope[s] mankind has the wisdom to choose correctly... between utter hopelessness and total extinction[22, 23]," there are, as we have outlined, measures we can take to survive the coming storm. They are not beautiful solutions. They are not how we have traditionally done things, or even how we would like to do things. Adopting them will almost certainly result in someone being worse off than if we had simply done nothing. But they represent, to our minds, the best, most realistic chance to avoid widespread difficulties and the loss of many of the principles we in the networking community hold dear, to ourselves and in our institutions. Let us begin this process now.

Resource Certification

by Geoff Huston, APNIC

Opinions vary as to what aspect of the Internet infrastructure represents the greatest common vulnerability to the security and safety of Internet users, but it is generally regarded that attacks that are directed at the network infrastructure are the most insidious, and in that case the choice is probably between the *Domain Name System* (DNS) and the interdomain routing system.

The question of how to improve the robustness of these functions has been a longstanding topic of study. For the DNS it appears that there is convergence on *Domain Name System Security Extensions* (DNSSEC) as the technical solution to securing DNS resolution operations, and the focus of attention in this space has shifted from technical behavior to topics relating to operational deployment. It has been a difficult time for DNSSEC and to say that there is an end in sight may well be premature at this stage, but there are definite signs of progress in this space. The same cannot be said of progress with securing routing, and particularly in securing interdomain routing. Here much remains to be done in order to achieve reasonable consensus on what technical measures to adopt, let alone the second step of study of how such measures could be deployed across the Internet.

The IETF's approach to addressing the topic of securing interdomain routing has followed a conventional IETF path. The first step has been to consider the nature of various vulnerabilities that exist within today's interdomain routing system and then develop a set of requirements that should be addressed in any solution space, without necessarily defining what such a solution may be. When the enumeration of requirements achieves a suitable level of consensus from the community, it is then possible to commence work on standardizing solutions. In the case of securing interdomain routing, the first steps were undertaken in *Birds of a Feather* (BOF) sessions and in the subsequently formed *Routing Protocol Security Requirements* (RPSEC) Working Group. This work is almost complete, and apart from some definitive statement relating to a requirement for securing the *Autonomous System* (AS) Path attribute in *Border Gateway Protocol* (BGP), the set of requirements for securing interdomain routing is now in an almost final state[1]. The task of the *Securing Inter-Domain Routing* (SIDR) Working Group is to standardize technologies that can meet these requirements.

So where does "Resource Certification" fit in?

Public Key Cryptography

One commonly used security technology is *Public Key Cryptography,* a technique that is easily explained. The approach uses a pair of keys, A and B. Anything enciphered with key A can be deciphered only with key B, and conversely, and knowledge of the value of one key does not lead to discovery of the value of the other key. Key A is kept as a closely guarded secret, whereas key B is openly published. If I want to send you a message that only you can decipher and read, I should encrypt it using your public key. If I want to send you a message that only I could have sent (nonrepudiation), then I will generate a digital signature of the message using my private key. That way any attempts to alter the message will also be detectable.

This latter approach, of using keys to generate digital signatures of messages, lies at the heart of DNSSEC, because DNSSEC adds public keys and digital signatures to the DNS. A DNS query can generate a response that lists both the DNS answer and the digital signature of that answer. The DNS can also be queried to retrieve the public key used to sign all the components of that zone, so that the digital signature can be verified and the query agent can be assured that the response is a genuine one. But how can the key itself be verified? In DNSSEC the hierarchical nature of the DNS itself is exploited by having each zone "parent" sign the keys of its delegated "children." So the zone key can be verified by retrieving the parent's signature across that zone key, and so on to the root of the DNS. As long as the query agent knows beforehand the value of the public key used to sign the root zone of the DNS, and as long as DNSSEC is used universally, all DNS responses can be verified in DNSSEC.

Although this approach works in the interlocked hierarchical structure of the DNS, when we turn our attention to securing the use of IP addresses and AS numbers in the context of interdomain routing, there is no comparable hierarchy to exploit. In such cases a common solution is to turn to *Digital Certificates*.

Digital Certificates are digitally signed public attestations by a certification authority that associate a subject's public key value with some attribute of the subject. A typical application is in identity certification, where the certification authority is attesting that the holder of the private key whose matching public key is provided in the certificate has met the authority's certification criteria to be identified by a particular name. Digital certificates are useful in that they can reduce the number of trust points in a security domain, so that each member of the domain does not have to validate identity and exchange public keys with every other member of the domain, but can undertake a single transaction with a certification authority that is trusted by all the members of the domain. As long as every member of the domain carries the public key of the certification authority and can access all issued digital certificates, then the members of the domain can verify each other's attestations and digital signatures.

Of course digital certificates are used for far more than attestations of identity, and can encompass the authority to perform specific tasks, undertake particular roles, or grant permissions and right-of-use authorities. It is this latter use case that is relevant to resource certification.

Resource Certificates

A Resource Certificate is a conventional X.509 certificate that conforms to the *Public Key Infrastructure Working Group* (PKIX) profile (RFC 5280) with one critical component, namely a certificate extension that lists a collection of IP number resources (IPv4 addresses, IPv6 addresses, and AS numbers)[17].

These certificates attest that the certificate issuer has granted to the entity represented by the certificate subject a unique "right-of-use" of the associated set of IP number resources listed in the certificate extension, by virtue of an associated resource allocation. The unique "right-of-use" concept mirrors the resource allocation framework, where the certificate provides a means of third-party validation of assertions related to resource allocations[2].

By coupling the issuance of a certificate by a parent *Certification Authority* (CA) to the corresponding resource allocation, a test of the validity of a certificate, including the IP number resource extension, can also be interpreted as validation of that resource allocation. Signing operations that descend from that certificate can therefore be held to be testable, under the corresponding hierarchy of allocation. In other words, if you received your address block from a particular *Regional Internet Registry* (RIR), then only that RIR can issue a Resource Certificate for you that includes your public key and the allocated number resources. Anything you sign using your private key can be verified through the RIR's issued certificate.

Unlike certificates that relate to attestations of identity, Resource Certificates are not necessarily long-lived. When an additional allocation action occurs, the associated Resource Certificate is reissued with an IP number resource extension that matches the new allocation state. In the case of a reduction in allocated resources, the previously issued certificates are explicitly revoked when the new certificate is issued. In other cases there is no explicit revocation of the older certificates.

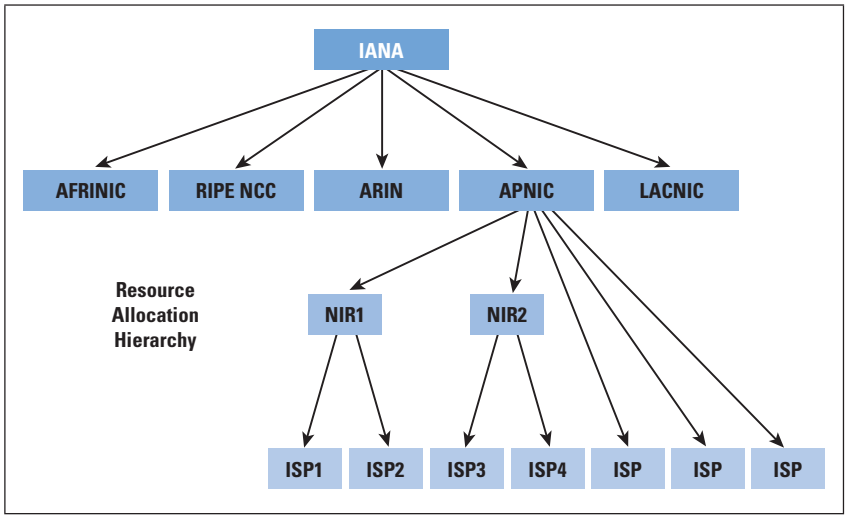
The intention here is that any instrument signed by the subject's private key that relates to an assertion of resource control, whether it is a protocol message in a routing protocol or an administrative request to an *Internet Service Provider* (ISP) to route a prefix or as assertion of title over the "right-of-use" of a number resource, can be validated through the matching public key contained in the certificate and the IP number resource that is enumerated in this certificate. The Resource Certificate itself can be verified in the context of a Resource Certificate *Public Key Infrastructure* (PKI).

The Resource Certificate Public Key Infrastructure

The *Resource Certificate Public Key Infrastructure* (RPKI) describes the structure of the certification framework used by Resource Certificates. The intent of the RPKI is to construct a robust hierarchy of X.509 certificates that allows relying parties to validate assertions about IP addresses and AS numbers, and their use.

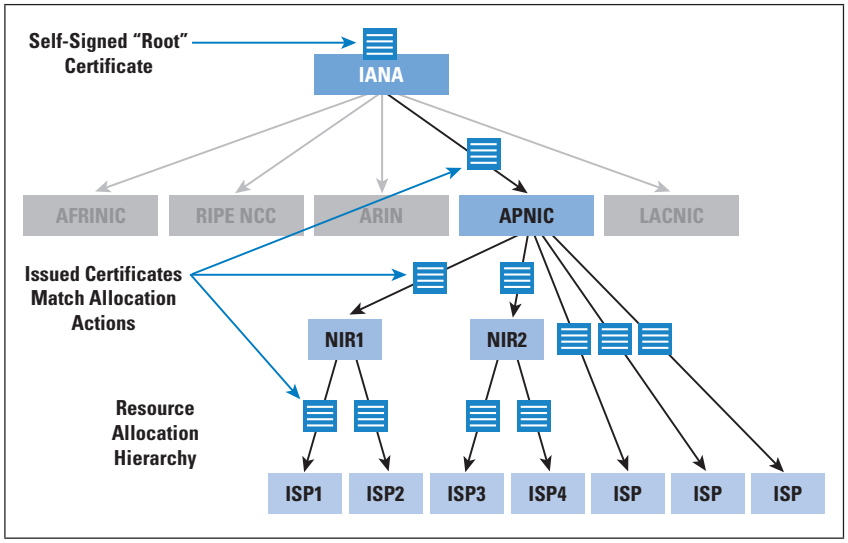
The structure of the RPKI as it relates to public use of IP number resources is designed to precisely mirror the structure of the distribution of addresses and ASs in the Internet, so a brief description of this distribution structure is appropriate. The *Internet Assigned Numbers Authority* (IANA) manages the central pool of number resources. The IANA publishes a registry of all current allocations. The IANA does not make direct allocations of number resources to end users or *Local Internet Registries* (LIRs), and instead allocates blocks of number resources to the RIRs. The RIRs perform the next level of distribution, allocating number resources to LIRs, *National Internet Registries* (NIRs), and end users. NIRs perform allocations to LIRs and end users, and LIRs allocate resources to end users (Figure 1).

Figure 1: Address Distribution Hierarchy for the Internet



The RPKI mirrors this allocation hierarchy. One interpretation of this model would send the IANA manager a root RPKI key, and using this key the IANA would issue a self-signed "root" certificate, and also issue subordinate certificates to each of the RIRs, describing in the resource extension to the certificate the complete set of number resources that have been allocated to that RIR at the time of issuance. The certificate would also hold the public key of the RIR and would be signed by the private key of the IANA. Each RIR would issue certificates that correspond to allocations made by that RIR, where the resource extension to those certificates lists all the allocated resources, and the certificate includes the public key of the recipient of the resource allocation, signed with the private key of the RIR. If the recipient of the resource allocation is an LIR or an NIR, then it too would also similarly issue resources certificates (Figure 2).

Figure 2: RPKI Resource Certificate Hierarchy



The common constraint within this certificate structure is that an issued certificate must contain a resource extension that contains a subset of the resources that are described in the resource extension of the issuing authority's certificate. This requirement corresponds to the allocation constraint than a registry cannot allocate resources that were not allocated to the registry in the first place. One implication of this constraint is that if any party holds resources allocated from two or more registries, then it will hold two or more Resource Certificates in order to describe the complete set of its resource holdings.

Validation of a certificate within this RPKI is similar to conventional certificate validation within any PKI, namely establishing a chain of valid certificates that are linked by issuer and subject from a nominated trust anchor CA to the certificate in question. The only additional constraints in the RPKI are that every certificate in this validation path must be a valid Resource Certificate, and the IP number of resources described in each certificate must be a subset of the resources described in the issuing authority's certificate.

Within this RPKI all Resource Certificates must have the IP addresses and AS resources present, and marked as critical extensions. The contents of these extensions correspond exactly to the current state of IP address and AS number allocations from the issuer to the subject.

Any holder of a resource who can make further allocations of resources to other parties must be able to issue Resource Certificates that correspond to these allocations. Similarly, any holder who wishes to use the RPKI to digitally sign an attestation needs to be able to issue an *End Entity* (EE) certificate to perform the digital signing operation.

For this reason all issued certificates that correspond to allocations are certificates with the CA capability enabled, and each CA certificate is capable of issuing subordinate CA certificates that correspond to further sub-allocations and subordinate EE certificates that correspond to a generation of digital signatures on attestations.

The RPKI makes conventional use of *Certificate Revocation Lists* (CRLs) to control the validity of issued certificates, and every CA certificate in the RPKI must issue a CRL according to the nominated CRL update cycle of the CA. A CA certificate may be revoked by an issuing authority for numerous reasons, including key rollover, the reduction in the resource set associated with the subject of the certificate, or termination of the resource allocation. To invalidate the authority or attestation that was signed by a given EE certificate, the CA issuing authority that issued the EE certificate simply revokes the EE certificate.

Resource Certificates are intended to be public documents, and all certificates and objects in the RPKI are published in openly accessible repositories. The set of all such repositories forms a complete information space, and it is fundamental to the model of securing the public Internet interdomain routing system that the entire RPKI information space is available. Other uses of the RPKI might permit use of subsets, such as the single chain from a given end-entity certificate to a trust anchor, but routing security is considered against all known publicly routable addresses and AS numbers, so all known resource certification outcomes must be available. In other words the intended use of the RPKI in routing contexts is not a case where each relying party may make specific requests for RPKI objects in order to validate a single object, but one where each relying party will perform a regular sweep across the entire set of RPKI objects in order to ensure that the relying party has a complete picture of the RPKI information space.

This aspect of the RPKI represents some interesting challenges, in that rather than having a single CA publish all the certificates produced in a security application at a single point, the RPKI permits the use of many publication points in a widely distributed fashion. Each CA can issue RPKI objects and publish them using a locally managed publication point. It is incumbent upon relying parties to synchronize a locally managed cache of the entire RPKI information space at regular and relatively frequent intervals.

For this reason the RPKI has introduced an additional mechanism in its publication framework, namely the use of a "manifest" to allow relying parties to determine whether they have been able to retrieve the entire set of RPKI published objects from each RPKI repository publication point, or if there has been some attempt to disrupt the relying party's access to the entire RPKI information set.

It also implies that the RPKI publication point access protocols should support the efficient function of a synchronization comparison, so that a locally managed cache of the RPKI need only call for the uploading of those objects that have been altered since the previous synchronization operation.

Signed Attestations and Authorities

The underlying intent of digital certificates, and Resource Certificates in particular, is in terms of supporting a transitive trust relationship that allows a relying party to verify the authenticity of a signed artefact through verification of the signer's key using the PKI. So the obvious question is: what artefacts are useful to sign?

Much of the motivation for Resource Certificates has come from a desire to underpin efforts in securing aspects of interdomain routing. This effort goes well beyond securing the individual point-to-point connection used between BGP speakers, and refers to the matter of verifying the authenticity of the payload of the BGP protocol exchange. The specific question that may be posed is: how can a BGP speaker validate the authenticity of the route object being presented to it?

The approach being studied by the SIDR Working Group is to use structured attestations, where, like the digital certificate itself, the attestation is structured in an ASN.1 digital object, and this object is signed using a signing formation that is itself a piece of structured ASN.1, namely the *Cryptographic Message Syntax* (CMS)[18].

The first of these attestations relates to the ability to verify the authenticity of the "origination" of an interdomain routing object. This verification refers to the address prefix and the originating AS, and the questions that this verification function is intended to answer include:

- Is this a valid address prefix and AS number? Have these resources been allocated through the IP number resource allocation process?
- Has the holder of the title of "right-of-use" for the address prefix authorized the AS holder to originate a routing advertisement for this prefix?

Here an address holder is authorizing a particular ISP to generate a route announcement for its particular address prefix. In this case the prefix holder would generate an EE Resource Certificate with the IP number resource extension spanning the set of addresses that match the address prefixes that are the intended subject of the routing authority, and place validity dates in the EE certificate that correspond to the intended validity dates of the routing authority.

The signed authority document would contain the AS number that is being authorized in this manner, a description of the range of prefixes that the prefix holder has authorized, and the EE certificate. The document would be signed by the EE certificate private key using a CMS signing structure. The resultant object is published in the RPKI distributed publication repository as a *Routing Origination Authorization* (ROA). A relying party can validate the ROA by checking to ensure that the digital signature in the ROA is correct, indicating that the authority document has not been tampered with in any way since it was signed, that the resources in the associated EE certificate encompass the prefixes specified in the document, and the EE certificate itself is valid in the context of the RPKI by verifying that there is an issuer-subject chain of valid certificates that link one of the relying party's nominated trust anchors to the EE certificate.

The ROA itself is valid as long as the signing EE certificate is valid. To withdraw the authority prior to the expiration of the EE certificate, the ROA publisher can simply revoke the EE certificate, leading to the concept of "one-off-use" EE certificates in the RPKI, where a key pair and a corresponding EE certificate are generated in order to sign a single attestation or authority. If the authority's lifetime is extended, the authority is reissued with a new EE certificate and a new digital signature, and, as noted, the authority can be prematurely terminated through revocation of the EE certificate, so at no stage is there a need to reuse the original signing private key. After the private key is used to sign this object, the key is destroyed, alleviating to some extent the key management load.

In any security system knowledge of what is authorized is helpful, but knowledge of what has not been authorized is perhaps even more helpful. For ROAs there is an analogous situation to DNSSEC, where DNSSEC is most effective from a client's perspective after the entire DNS space is DNSSEC signed. Where there are gaps in the DNSSEC signing chains the client is left in an uncertain state regarding the verification outcomes of the unlinked DNS sub-hierarchies. The same could apply to ROAs, in that in an environment where not every originated route object has a published ROA, the absence of a ROA does not necessarily indicate an unauthorized route origination. If one of the objectives of this study is to define a framework that can unambiguously identify the unauthorized use of IP number resources in routing (route "hijacks") even in a world where ROAs are used in a piecemeal fashion, then one possible refinement to the ROA model is the introduction of a comparable negative authority, the *Bogon Origination Attestation* (BOA).

In this case the prefix holder generates a signed attestation, or BOA, in a similar manner to the ROA, but does not provide any originating AS. Instead the BOA refers to "all originating ASs," and has the semantic interpretation that any use in the routing space of this address prefix described in the BOA, or any more specific address prefix, should be regarded as unauthorized and the route should be discarded.

Although this process makes the detection of route hijacks more direct in a world of piecemeal use of ROAs, there is now the added complication of having both "positive" and "negative" authorities. The proposed resolution of this dilemma is to use a relative priority rule that ROAs take precedence over BOAs, so that if a valid ROA and a valid BOA both exist that describe the origination component of a route, then the route can be regarded as authorized.

It should be noted, however, that at this stage these concepts are "work in progress," and are part of the SIDR Working Group's agenda of study, and the working group has not as yet reached any consensus regarding the decision to advance these proposals onward along the Internet Standards Process.

Also on the near-term horizon for SIDR is examining approaches to secure the AS path in BGP updates. The RPSEC Working Group has explored two approaches in this space. One involves an incremental multiple signature technique that allows a receiver of a BGP update to verify that the AS path described in the update is matched by a sequence of interlocking AS digital signatures using the RPKI. At the same time that an AS adds its own AS to the AS path prior to further *External Border Gateway Protocol* (eBGP) propagation of the route update, the AS would digitally sign over an analogous sequence of AS signatures. This approach allows a receiver to perform a match of the AS sequence in the AS path with the AS number sequence identified in the AS signature block. A match here would indicate that the BGP update has indeed been sequentially passed along the sequence identified by the AS path. This approach was originally proposed in the *Secure BGP* (sBGP) design[21] and has attracted some comment related to the computation overhead associated with the application and validation of these AS path signature sequences. An alternative approach has been one that is described by RPSEC as being less rigorous, and refers to a "feasibility" check, which checks to ensure that each pair of ASs represented in the AS path has an associated verifiable assertion of inter-AS adjacency that is digitally signed by both ASs.

It should also be noted that this activity of addressing aspects of improving the robustness of interdomain routing has some previous context. In many parts of the Internet, some degree of routing integrity is managed through the use of *Internet Routing Registries* (IRRs) and the publication of routing policies through the use of *Routing Policy Specification Language* (RPSL) objects.

Although opinions vary as to the robustness of the security offered by the IRR approach, at the very least it can mitigate some weakness in the routing system through the use of a "second check" that can be used to filter the information that is being provided in a BGP feed.

The weaknesses in the IRR system tend to relate to the consistency, completeness, and authenticity of the IRR data, and in many cases the trust in the integrity of the data relies on the admission practices of the IRR itself, and individual data objects cannot be verified by clients of the IRR. One possible way to address this situation has been through the use of *Routing Policy System Security* (RPSS) measures, but the adoption of these measures has not been widespread, and the question still remains for the client that even if an IRR object was authenticated upon admission, it does not mean that when the object is subsequently used by an IRR client the information reflects the current situation, and the information could well be invalid or not reflect the current policies of the author of the IRR object.

One possible approach being considered by the SIDR Working Group is to implement the RPSS authentication models using object signing in the context of the RPKI. For example, the RPSS assumption that routes should be announced only with the consent of the holder of the origin AS number of the announcement and with the consent of the holder of the address space implies in RPSS that both parties should authorize the entry of a *route object* into the IRR. Translating this stipulation into an analogous model using the RPKI would require that a route object be signed with the digital signatures of both the AS holder and the address space holder, and a IRR client can verify this route object at the time of use by verifying both digital signatures. Either the address space holder or the AS holder can revoke authorization by revoking the EE certificate used to sign the route object, and the verification is independent of the particular IRR that has published the route object. It is also a possibility that the IRR itself can be folded into the RPKI distributed publication repository framework, because there is no particular requirement in such an environment for a disparate collection of IRRs with their own partial collections of routing policy information, although at this stage this discussion is heading into the realm of more advanced speculation about the potential for application of Resource Certificates and digital signatures to RPSL and the IRR framework.

Putting Resource Certificates into Context

Resource Certificates and the associated RPKI represent a major part of any effort to construct a secure interdomain routing framework. An RPKI, even partially populated with signed information, allows BGP speakers to make preferential selections to use routing information where the IP address block and the AS numbers being used are recognized as valid to use, and the parties using these IP addresses and AS numbers are properly authorized to so do. The RPKI can also be used to identify instances of unauthorized use of IP addresses and attempts to hijack routes.

However, the RPKI represents only one part of a larger framework of securing interdomain routing, and the next step is that of applying the RPKI to the local BGP processing framework. There is also the need to move beyond validation of route origination and look at the associated topic of validation of the AS path, and potentially to consider the most challenging task, of attempting to validate whether the initial forwarding decision associated with a route object actually represents the correct first hop along a usable forwarding path for packets to reach the network destination.

The concerns here include not only a consideration of what can be secured and validated, but matters of scalability and efficiency in terms of deployment cost. The various approaches to routing security studied so far offer a wide variety of outcomes in terms of the amount of routing information that is validated, the level of trust that can be placed in a validation outcome, and the overheads of generating and validating digital signatures on routing information. The next step appears to include the task of establishing an appropriate balance between the overheads of operating the security framework and the extent to which efforts to disrupt the routing system can be successfully deflected by such measures.

The RPKI has been designed as a robust, simple framework. As far as possible existing technologies and processes have been exploited, reflecting to some extent a level of conservatism of the routing community and the difficulty in securing widespread acceptance of novel technologies.

References and Further Reading

The following documents provide further detail about the IETF work on resource certification. The Internet Drafts listed here are still a "work in progress," and although they are reflective of the areas of activity of the SIDR Working Group, they do not necessarily represent finished work.

Host Identity Protocol: Identifier/Locator Split for Host Mobility and Multihoming

by Andrei Gurtov and Miika Komu, Helsinki Institute for Information Technology, and Robert Moskowitz, ICSAlab

A host and its location are identified using *Internet Protocol* (IP) addresses in the current Internet architecture. However, IP addresses can serve only as short-term identifiers because a considerable amount of hosts are *portable* devices and they change their IP addresses when moved from one network to another. Short-term identifiers disrupt long-term transport layer connections, such as Internet phone calls, and make locating the peer host more difficult. Therefore, mobility and multihoming are hard to implement securely in the present Internet. Upon changing an IP address, the host must prove to its peers that it is the same entity they communicated with before, requiring the use of cryptographic identities.

Another challenge the Internet faces is due to the fact that deployed protocols in the Internet are prone to *Denial-of-Service* (DoS) attacks. Substantial memory state can be created before the communicating peer is authenticated. Impersonation attacks are possible because IP addresses are relatively easy to forge. Because of difficulties in configuring *IP Security* (IPsec) for users, most Internet traffic is still transmitted in plaintext, making it easy for attackers to collect passwords or lists of visited websites, for example, in public *Wireless Local-Area Networks* (WLANs). As the IPv6 protocol is seeing gradual deployment, interoperating traditional IPv4 applications with new IPv6 applications remain a challenge.

The so-called *identifier/locator split* is recognized by the *Internet Engineering Task Force* (IETF) community as a next big change in the Internet architecture. Although the problem has been known for a long time[17], it has only recently started to get sufficient attention. Developments in public key cryptography and increased computational resources of hosts enables the use of cryptographic mechanisms to securely handle identities. Several proposals are under consideration in the IETF, including the *Locator Identifier Separation Protocol* (LISP)[16] for the network-based and the *Host Identity Protocol* (HIP) for the host-based approach. LISP focuses on improving scalability of the routing system, whereas HIP provides secure end-to-end mobility and multihoming. Therefore, the two proposals are complementary rather than competing.

HIP Architecture

The HIP architecture[1,2] uses the identity/locator split advantage to address Internet architecture challenges in an integrated approach. HIP was proposed by Bob Moskowitz in 1999 and since then has been under active development in the IETF Working Group and *Internet Research Task Force* (IRTF) Research Group.

HIP enables host mobility and multihoming across different address families (IPv4 and IPv6), offers end-to-end encryption and protection against certain DoS attacks, allows moving away from IP address-based access control to permanent host identities, and restores end-to-end host identification in the presence of several addressing domains separated by *Network Address Translation* (NAT) devices.

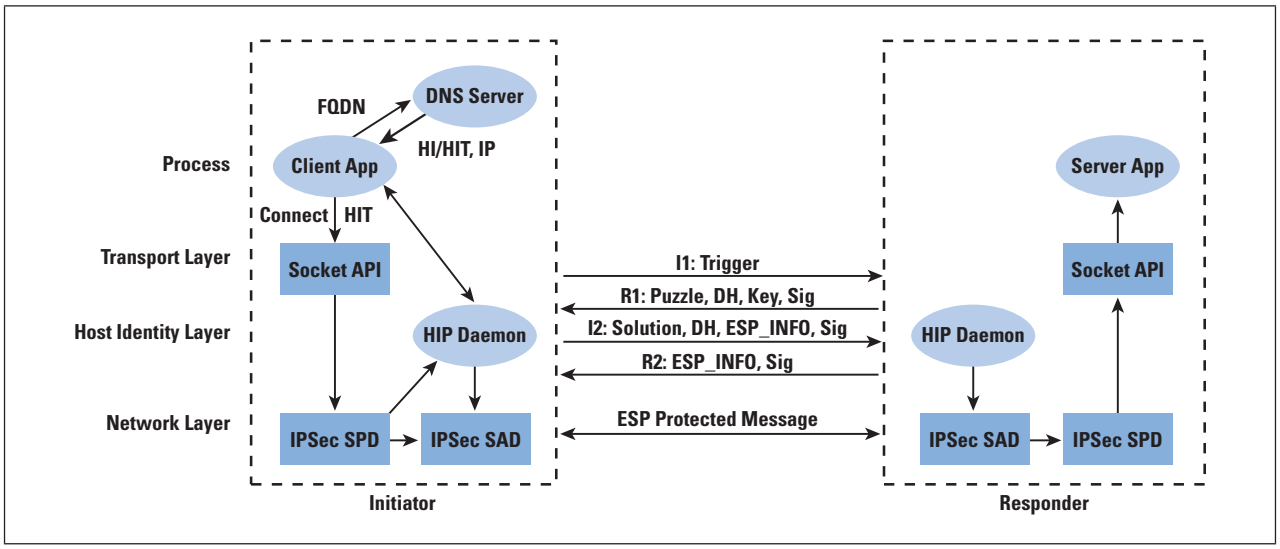
HIP separates the identity of a host from its location. The location of the host is bound to IP addresses and used for routing packets to the host in the same way as in the current Internet architecture. However, transport and application layers use *host identity,* consisting of the public key component of a private-public key pair. Each host is responsible for creating one or more public/private key pairs to provide identities for itself. Because the host identities are based on public key cryptography, they are computationally difficult to forge. Host identities are location-independent identifiers that allow a mobile host to preserve its transport layer connections upon movement. On the other hand, the host identity can be used for looking up the current location of a host because the host identity is a long-term identifier. A client host obtains the host identity of a server typically from the *Domain Name System* (DNS)[7] or a *Distributed Hash Table* (DHT). However, the infrastructure may not support this DHT in certain scenarios, such as in peer-to-peer and temporary environments. In such cases, *opportunistic* HIP can be used for contacting a peer without prior information of the identity of the peer. Opportunistic HIP is based on a "leap-of-faith," meaning that it is prone to man-in-the-middle attacks for the initial connection. It is similar to the *Secure Shell* (SSH) *Protocol,* where the public key of the server is added to the known host list after the first connection.

The problem of certifying the keys in *Public Key Infrastructure* (PKI) or otherwise creating trust relationships between hosts has explicitly been left out of the HIP architecture, because it is expected that each system using HIP may want to address it differently. For mere mobility and multihoming, the systems can work without any explicit trust management, in an opportunistic manner.

All other parties use the host identifier, that is, the *public key,* to identify and authenticate the host. Typically, a host identifier is a 128-bit-long bit string, the *Host Identity Tag* (HIT), as shown in Figure 1. A HIT is constructed by applying a cryptographic hash function over the public key. The introduction of new endpoint identifiers changes the role of IP addresses. When HIP is used, IP addresses become pure topological labels, naming locations in the Internet. One benefit of this identity/locator separation is that hosts in private address realms (behind NATs) can name each other in a unique way with HITs. A second benefit is that the hosts can change their IP address without breaking transport layer connections of applications and rely on HIP to manage host mobility; the relationship between location names and identifiers becomes dynamic.

To start communicating through HIP, two hosts must establish a HIP association. Known as the HIP *Base Exchange* (BEX)[3], this process consists of four messages (I1, R1, I2, and R2) transferred between the initiator and the responder. After BEX is successfully completed, both hosts are confident that private keys corresponding to host identifiers (public keys) are indeed possessed by their peers. Another purpose of the HIP base exchange is to create a pair of IPsec *Encapsulated Security Payload* (ESP) *Security Associations* (SAs), one for each direction. HIP uses IPsec ESP *Bound End-to-End Mode* (BEET)[4,9] to provide data encryption and integrity protection for network applications.

Figure 1: HIP Architecture



Because neither transport layer connections nor security associations created after the HIP base exchange are bound to IP addresses, a mobile client can change its IP address (that is, upon moving, because of a *Dynamic Host Configuration Protocol* [DHCP] lease or IPv6 router advertisement) and continue to transmit ESP-protected packets to its peer. HIP supports such mobility events by implementing an end-to-end three-way UPDATE signaling mechanism[8] between communicating nodes. HIP multihoming uses the same mechanisms as mobility for updating the peer with a current set of host IP addresses.

A rendezvous server[6] provides a mechanism to locate a host, for example, when two communicating hosts move simultaneously. To employ a rendezvous mechanism, a host first must perform a registration procedure[5], which is an extended version of the HIP base exchange.

The HIP control packets as well as ESP-encapsulated data packets have difficulties in going through NAT applications and firewalls. To traverse NAT, HIP uses *User Datagram Protocol* (UDP)-based encapsulation provided by the *Interactive Connectivity Establishment* (ICE) protocol.

It enables two hosts located behind NAT to communicate through a Rendezvous server. Bob Moskowitz suggests an alternative approach, where HIP always uses IPv6 for end-to-end communication and the *Teredo* protocol is employed to traverse NAT instances in IPv4 networks if native IPv6 connectivity is not available.

Most Internet applications can run unmodified over HIP[10], although only HIP-aware (new) applications using the extended socket interface can take better advantage of the new features that HIP provides. As HIP secures application data traffic with IPsec that is located logically "deep" within the networking stack, the challenge is to provide proper and understandable security indicators to the user to convince the user that the connection, for example, to a banking website, is secured. Such indicators can be developed as extensions to applications (for example, a security plug-in to the *Firefox* browser) or within a hostwide HIP management utility that controls all applications.

HIP provides a network layer alternative to using *Secure Sockets Layer/Transport Layer Security* (SSL/TLS) for application security, which has its benefits and drawbacks. HIP is a generic solution that should work for any transport protocol, whereas until recently TLS supported only TCP. HIP enables host mobility and multihoming, which is not supported by TLS. TLS runs on top of TCP, leaving it vulnerable to various TCP attacks; for example, using spoofed *reset* (RST) packets or DoS attacks with SYNs. Applications must be designed explicitly to use TLS, whereas HIP can provide security as an add-on to existing traditional applications. On the other hand, TLS does not have a problem with traversing traditional middleboxes such as NATs and firewalls that need special attention for HIP. Both protocols share the characteristic of endorsing host identity. TLS relies on certificates issued by one of the known Certification Authorities, whereas HIP can use *Domain Name System Security Extensions* (DNSSEC)[18] or a PKI infrastructure.

There are currently three open-source interoperating HIP implementations. *OpenHIP* from Boeing runs on Linux, Windows, and Mac OS, whereas *HIP on Linux* (HIPL) runs on Linux and Symbian, and *HIP for Inter.net* from Ericsson runs on FreeBSD and Linux. Several testbeds are deployed based on HIP, including the Everett Boeing factory[11], the P2PSIP pilot in Finland[14], and Wi-Fi P2P Internet Sharing Architecture in Germany[12]. Ericsson NomadicLab and TeliaSonera have demonstrated using HIP for transparent IPv4 and IPv6 handovers, mobile router, simultaneous multiaccess, and the use of proxy for traditional hosts[13,15].

Acknowledgements

We are grateful to Pekka Nikander, Tom Henderson, and others in the IETF and the *Internet Research Task Force* (IRTF) community who were encouraging and contributing to the development of HIP. We thank Andrey Khurri for the figure on HIP architecture and Henry Sinnreich for encouraging us to write this article.

We also thank members of InfraHIP II project for comments helping to improve this article.

Allocation Policy for the Remaining IPv4 Address Space Ratified by ICANN

On 6 March 2009, the *International Corporation for Assigned Names and Numbers* (ICANN) Board ratified the *Global Policy for the Allocation of the Remaining IPv4 Address Space*. The policy requires ICANN to reserve one /8 for each *Regional Internet Registry* (RIR) from the *Internet Assigned Numbers Authority* (IANA) free pool. This has been done. The remainder of the implementation will be done once the IANA free pool has been fully allocated to RIRs. There are currently 32 unallocated unicast IPv4 /8s. 27 are in the IANA free pool and five are reserved under the Global Policy for the Allocation of the Remaining IPv4 Address Space.

On 4 February 2009, the Chair of the *Address Supporting Organization Address Council* (ASO AC) forwarded the Proposed Global Policy for the Allocation of the Remaining IPv4 Address Space for ratification by the ICANN Board. On 5 March 2009, the ASO AC submitted advice in full support of the proposal to the ICANN Board. This proposed global policy had been submitted to the ASO AC by the Executive Council of the *Number Resource Organization* (NRO) on 3 December 2008, and adopted by the ASO AC on 8 January 2009. Each RIR community individually discussed the policy and approved its adoption via its own policy development process. The policy text is published on the ICANN web site at:

`http://www.icann.org/en/general/allocation-remaining-ipv4-space.htm`

ISOC's Trust and Identity Initiative

The Internet Society's *Trust and Identity Initiative* recognizes that in order to be trusted, the Internet must provide channels for secure, reliable, private, communication between entities, which can be clearly authenticated in a mutually understood manner. The mechanisms that provide this level of assurance must support both the end-to-end nature of Internet architecture and reasonable means for entities to manage and protect their own identity details.

A *trusted* Internet takes into account security, transaction protection, and identity assertion and management. Given the network dependence on unique numbers and the escalating amount of geolocation data being gathered, the privacy implications of the current Internet represent a significant and growing concern. Trust must be a primary design element at every layer of the architecture, and in some cases, existing elements may need to be redesigned or improved to meet emerging requirements.

In late 2007, the ISOC Board of Trustees held an intensive retreat to consider ISOC's role in identifying and pursuing trust and identity issues. The report arising from that meeting, "Trust and the Future of the Internet,"[1] forms the basis of ISOC's current long term strategic initiative.

The Trust and Identity initiative focuses on the following major research programs:

- *Architecture and Trust:* This research program investigates the implementation of open-trust mechanisms throughout the full cycle of Internet research, standardization, development, and deployment.
- *Current Problems and Solutions and Trust:* This research program investigates the mitigation of the social, policy, and economic factors that may hinder development and deployment for trust-enabling technologies.
- *Identity and Trust:* This research program investigates the elevation of identity to a core issue in network research and standards development. ISOC is taking a lead role in reviewing the current Internet architecture and the model of Internet development and deployment. This includes active engagement with participants within the traditional ISOC sphere, as well as with the research, enterprise, and end-user communities. We offer the kind of support for research that enhances and facilitates trust and collaboration with the standards community and that advances the most interesting outcomes of that research.

ISOC is reaching out to the businesses and end users that rely on the Internet to exchange sensitive data. Their needs and concerns inform both our baseline research agendas and ongoing standards and development work. ISOC continues to support the advancement of current technical solutions and best practices through our existing programs.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ contains standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

From The Editor

After many years of using DSL as my only Internet access option from home, I recently upgraded to a broadband solution provided by a cable modem. As a result, I faced the task of renumbering (and partially rewiring) my home network. As you might have guessed, the addressing scheme provided by my new ISP offers *Network Address Translation* (NAT), as well as a small number (5) of fixed IPv4 addresses, the latter at an extra cost as you might expect. I probably should have tried to enable IPv6 just as an experiment, but this task will have to wait for another day. In the meantime, I was pleased to find a relatively user-friendly web interface to the cable modem that allows me to configure numerous parameters, including the range of the *Dynamic Host Configuration Protocol* (DHCP) pool so that certain devices (printers and wireless access points in particular) can have fixed IP addresses for ease of use and configuration. The entire exercise, which took a couple of hours on my very small network, reminded me of what network managers face every day, particularly as they consider the inevitable migration to IPv6. Let me take this opportunity to invite you to share your network management and operations experience, plans for IPv6 migration, and so on. You can send us Letters to the Editor or article proposals. The address, as always, is **ipj@cisco.com**

The *Domain Name System* (DNS) has been the target of attacks over its many years of existence. In recent years, new attacks have emerged that exploit some of the attributes of the DNS protocol and its implementation. One of the corrective measures is to improve the security of DNS caches. There are several ways to improve cache security, most of which involve changing the protocol. Another way, without changing the protocol, is to reduce the attack surface of your cache by shrinking the number of users of any given cache. Our first article, by Bill Manning, explores this view in more detail.

This journal has covered numerous current and emerging *wireless* technologies such as Bluetooth, Wi-Fi, WiMAX, and mobile cellular systems. In this issue, Esa Piri and Kostas Pentikousis describe *Media-Independent Handovers* (MIH), which allow mobile devices to use different wireless and wired network infrastructures transparently. The protocols associated with operation across such diverse access networks are being standardized by the IEEE 802.21 working group.

Intermediate DNS Caching as an Attack Vector

by Bill Manning

The *Domain Name System* (DNS) specification calls for the use of *caching*. Caching is expected to improve the overall responsiveness of the system by ensuring that answers to questions are known and stored locally and that the query load placed on the authoritative servers is minimized. Certain presumptions are associated with caches that may no longer hold. This article looks at some of these presumptions and explores some of the problems that emerge when they are violated. Based on our observations, we offer some recommendations on DNS cache best practices and show our results of testing these practices.

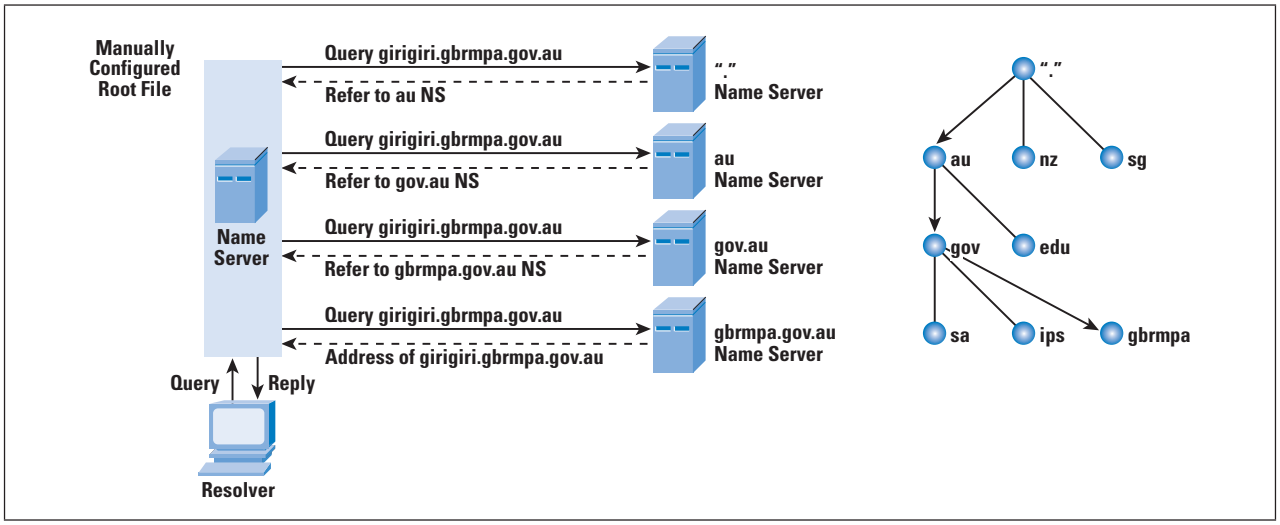
The Problem

A DNS resolver can no longer trust the data it gets—because the data generally comes from nonauthoritative nodes or caches operated by third parties, most of whom have no vested interest in providing accurate data. Removing or bypassing caching from the DNS and going directly to the authoritative servers is considered a fatal flaw because authoritative servers are presumed to have neither the bandwidth nor the processing power to accommodate the perceived demand from a cacheless service. This article looks at the bandwidth and processing capabilities of modern authoritative servers to ascertain the viability of these presumptions. We start by looking briefly at the DNS.

The DNS

The DNS namespace is made visible and useful by nodes publishing authoritative information about the namespace and *resolvers* that send queries about the namespace to these servers. As an optimization, other nodes may act as intermediates or proxies for the authoritative servers for one to many resolvers. These intermediate nodes are called *caching nameservers* or *iterative mode resolvers*. This flow is shown in Figure 1.

Figure 1: DNS Query Flow



Several assumptions about the use and placement of caches have been questioned recently. The simplest is one of placement. A cache works best when the *Round-Trip Time* (RTT) between the resolver and the cache is low. Historically, a cache was placed at traffic aggregation points such as an *Internet Service Provider* (ISP) operating a cache for its clients. With increased mobility of nodes, this presumption is no longer as firm. There are reported cases where resolvers continue to use caches 300 ms away, while an authoritative server is 15 ms away. So if the intent is to reduce network bandwidth, then a cache presuming its client resolvers are all "local" might be misconstrued.

Fixing a resolver to a specific cache does have the benefit of being tied to a known business relationship; for example, using your ISP's caching service. In contrast, mobile nodes often get an IP address from a provider's *Dynamic Host Configuration Protocol* (DHCP) servers, which also hand out more "local" caching servers to be used by the mobile node.

This scenario would be fine—as long as the DNS namespace was in fact a coherent, single space. Unfortunately it is not. So-called *Walled-Garden* networks that have their own versions of DNS namespace have been and remain common. In the Internet, there are more and more alternate root hierarchies that diverge from what most think of as "the" root namespace in either subtle or wildly divergent ways. To date, there is no deployed way for a resolver to determine the origin of the data stored in a cache. A resolver then has no way other than verification of the data to know that the locally assigned cache is in fact using the namespace desired. This situation represents one important reason for going back to a well-known cache, even if it is topologically remote. But this assumption may no longer be valid.

ISPs and even some caching service providers are starting to manipulate caches as a means to monetize their operations.[1] Numerous techniques are in use, from the nominally benign method of using wildcards to more insidious capture and rewrite of NXDOMAIN replies, to outright intentional cache pollution.

In this climate, a resolver should choose its cache carefully. We argue that it is reasonable, in many of today's environments, to place the cache within 1 ms of the resolver; for example, run a cache on the local node. This argument is an extension of the assertion[2] that claims that caches are effective for client populations that are about 10 or fewer.

This technique has the added advantage of reducing the "attack surface" by reducing the effect of cache poisoning or rewriting replies to a small handful of nodes. The perceived disadvantage is the increased load on network bandwidth and query load on authoritative servers as the number of caches increases.

The Experiment

Our experiment has two parts: first we looked at authoritative server processing capabilities and then at the bandwidth effects of a larger number of caches.

Authoritative service is generally run on systems with modern software, supporting threading or precomputed responses. Independent testing shows that these stock software solutions can, on current hardware, support query rates in the hundreds of thousands of queries per second.[3]

A brief survey of authoritative server operators indicates that normal query rates range from 12,000 to 64,000 queries per second.[4,5,6]

On the surface, this result would indicate that there is enough overhead to be able to process more queries, regardless of how they are originated. Regarding bandwidth, a survey of *Top-Level Domain* (TLD) operators has shown that 92 percent of the delegations have two or more authoritative servers for that data on networks with a minimum uplink bandwidth of 100 Mbps. Selected path characterization from clients to target authoritative servers seems to support our presumption that bandwidth is not of concern.

The DNS was designed to function as a roughly symmetrical transfer of information: a request or query is sent and the reply reflects the query and supplies the answer and additional data. Historically, the request and reply were within the same order of magnitude. Into the future, this model may no longer be valid. With *Domain Name System Security Extensions* (DNSSEC), *IP Version 6* (IPv6), and *Naming Authority Pointer* (NAPTR) records being possible candidates in the *Resource Record set* (RRset), the traffic profile more resembles an HTTP request/response, with a significant amount of data being returned from a simple question.[7]

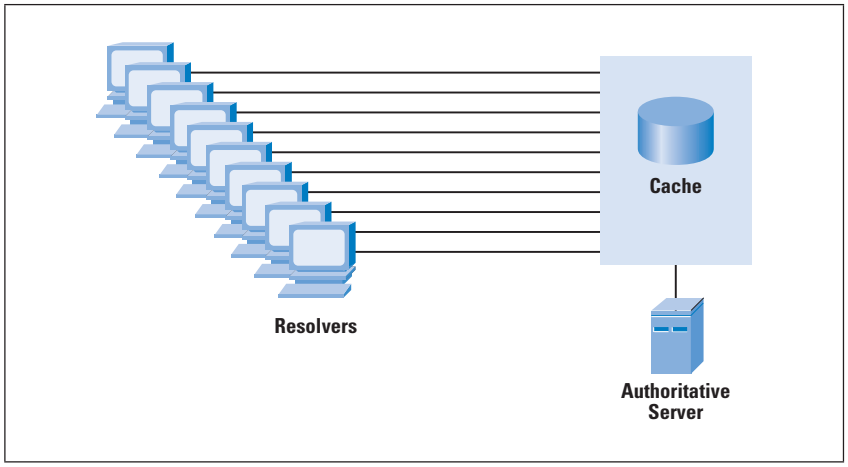
With this information, we can project a worse case in today's environment where a query/reply is about 260 bytes to a worst case in a future environment where a query/reply is about 9 KB, clearly indicating that the amount of bandwidth to authoritative servers needs to grow as new DNS capabilities are deployed, but for the nonce, most have a bandwidth overhead sufficient to absorb a modest change in the number of queries presented.

Modification of the Number of Caching Servers

We began with a cache that serviced 140 stub resolvers on the *University of Southern California's Information Sciences Institute* (USC/ISI) campus in a "normal" dense cache mode (Figure 2).

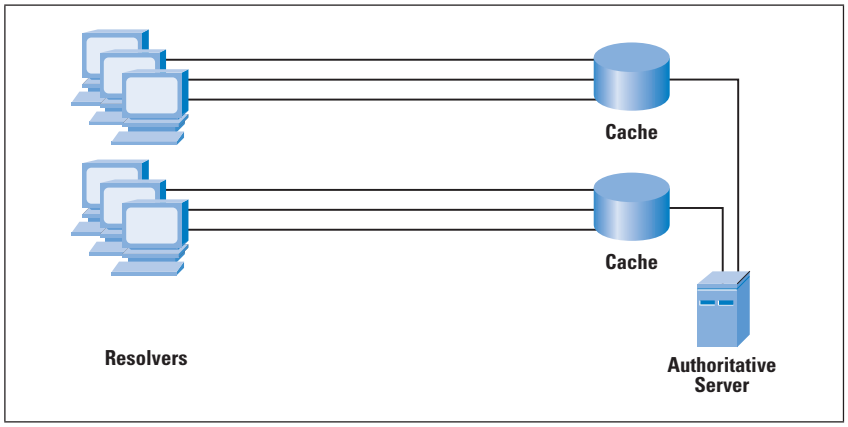
Traffic traces show a distribution of priming queries to 534 authoritative servers in the first 15 minutes of clearing the cache.

Figure 2: Dense Cache



We then added 9 new caches and redistributed the 140 stub resolvers among the 10 caches into a sparse cache mode (Figure 3) and restarted all the caches. In the first 15 minutes, the number of priming queries from each of the caches averaged 61, with a total of 622 unique priming queries for all caches. The number of "duplicate" queries between caches averaged 45. Although the number of queries to the authoritative servers was slightly higher, the results seem to indicate that there is a small but significant difference in each of the caches[8].

Figure 3: Sparse Cache



Conclusions

Reducing the size of the user population for each cache reduces the attack surface for the DNS overall because we have effectively compartmentalized the threat to a small number of nodes. Generally, restarting a cache for a small number of nodes is considered acceptable, whereas restarting a cache for 10,000 or 100,000 nodes would significantly affect operations.

Moving the cache closer to the resolver increases overall response time and may support better mobility of the node. If validation is also placed with the cache, it is possible to increase the confidence of validation because that information may not have to use DNS protocols to send validation data over untrusted, open networks.

The concept of supporting larger numbers of full DNS servers on more nodes raises concerns, but most systems these days have enough processing power and bandwidth to support this application. Administrative and management processes can be fully automated. Overall, this design complements other, protocol-based attempts to increase DNS integrity.

IEEE 802.21: Media-Independent Handover Services

by Esa Piri and Kostas Pentikousis, VTT Technical Research Centre of Finland

Popular mobile devices now ship with several integrated wired and wireless network interfaces. *Personal Digital Assistants* (PDAs) and smartphones, for example, are increasingly supporting communications through both cellular technologies and *Wireless LANs* (WLANs); laptops typically come with built-in Ethernet, Wi-Fi, and Bluetooth[1]. As multiaccess devices proliferate, we move closer to a network environment that is often referred to as "*beyond 3G*" (B3G). Key success factors for cellular *third-generation* (3G) communications include better cell capacities, increased data rates, transparent mobility within large geographical areas, and global reachability. For B3G, the next frontier lies beyond transparent mobile connections within the same access technology because users will expect to be globally reachable anytime, anywhere, and remain "*always best-connected*" (ABC)[2]. In order to select the best possible connectivity option (anytime, anywhere), mobile devices and access networks will have to work together in order to enable users to take full advantage of all available options.

The IEEE 802.21 working group (see `www.ieee802.org/21`) recently finalized the first standard for dealing with handovers in heterogeneous networks, also called *Media-Independent Handovers* (MIH)[3]. The standard is expected to allow mobile users (and operators) to take full advantage of overlapping and diverse access networks. It provides a framework for efficiently discovering networks in range and executing intelligent heterogeneous handovers, based on their respective capabilities and current link conditions. This article aims to serve as a primer for those interested in the IEEE 802.21 standard. After introducing the IEEE 802.21 reference model, we present the MIH services and provide illustrative use cases that highlight the benefits of employing the Media-Independent Handover Services standard in heterogeneous networks.

Mobile and Wireless

The widespread success of 3G technologies[4, 5] is evidenced by the rapid increase in the amount of data traffic over cellular networks in recent years. In Sweden, for example, the total amount of mobile data traffic leapt tenfold from just over 203 TB in 2006 to 2191 TB in 2007[6]. This trend is expected to continue unabated with the deployment of *High-Speed Packet Access* (HSPA) and *Long-Term Evolution* (LTE) in the coming years. Of course, the amount of traffic over cellular networks is only a proportion of the traffic that originates from or terminates at WLANs worldwide. Campuswide deployments of WLANs are becoming the norm in developed countries, and we even find citywide WLANs, as in the case of the city of Oulu, Finland (see `www.panoulu.net`).

Finally, many anticipate that mobile WiMAX[7] deployments will significantly affect telecommunications markets. In short, we are moving toward a far more heterogeneous network access environment than the one users and operators face today, with multiple overlapping mobile and wireless networks with diverse characteristics.

Multiaccess Devices in Heterogeneous Networks

As communication environments become more complex because of the diversity of network access technologies that support, for example, different access rates and *Quality of Service* (QoS) levels, users expect more from their wireless operator. Mobile devices, once featuring tiny screens, extremely limited processing and storage capacities, and narrowband connectivity[8], now pack capabilities that just a few years ago were typical of high-end laptops. This scenario has allowed users to increasingly depend on mobile devices for e-mail and *Instant Messaging* (IM), but also for making *Voice over IP* (VoIP) calls, listening to streaming Internet radio, and watching online videos.

With respect to user mobility patterns, campuswide Wi-Fi users typically spend most of their connection time attached to a small set of access points located within a small radius[9, 10]. This situation is not surprising, because Wi-Fi was originally designed and subsequently deployed mainly as an extension to wired infrastructures. In the future, however, we anticipate that multiaccess devices will employ different network interfaces to attach to different access networks, establishing multiple parallel connections over 3G/*Universal Mobile Telecommunications Service* (UMTS) and Wi-Fi, for example. With global reachability and ABC mechanisms in place, mobile devices will be able to selectively connect to different access networks depending on certain criteria. Keep in mind that from a conventional, IP-centered point of view, changing the *Point of Attachment* (PoA) calls for mobility management actions[11, 12, 13], although in practice there may be no physical mobility whatsoever.

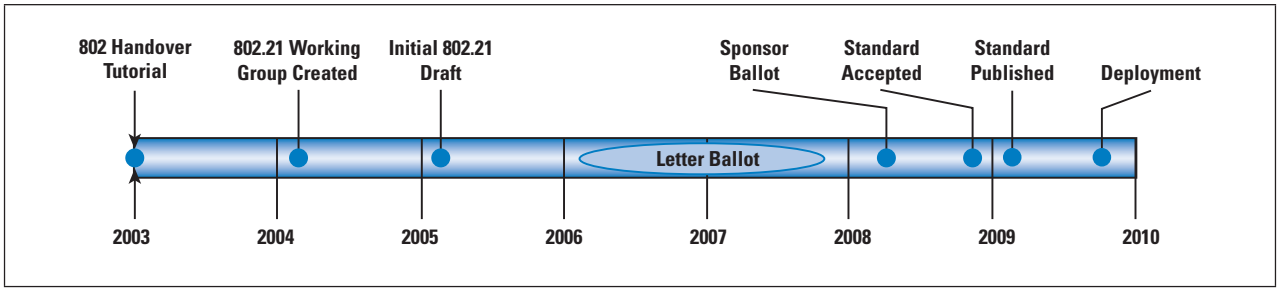
Given the diversity of networked applications running on mobile devices, knowledgeable network resource planning and operation is needed, in turn calling for a framework that allows users and their applications to state their network access preferences. This framework should also allow operators to steer terminal access patterns aiming at maximizing resource usage and increasing user satisfaction. For instance, podcasts can be downloaded only when connected to an uncongested WLAN, but web, map/navigation, and e-mail clients can use the cellular network or WLAN access on demand. Currently, this process can only be done manually: users need to be watchful for available access networks and choose which one to attach to based on very rudimentary information such as signal quality. If mobile nodes could collect timely and consistent information about the state of all available networks in range and were given the means to control their network connectivity, then a whole range of possibilities would become available.

In order to optimize the use of available network resources, mobile nodes need to be able to collect information about numerous heterogeneous networks in a generic and standardized way, irrespective of the underlying network access technology. The collected information, both dynamic and static, can then be used by handover decision-making processes, such as, say, mobility managers. Mobility managers can be enhanced versions of *Mobile IP* (MIP)[11, 12, 13], proprietary solutions, or other proposals stemming from recent research, such as [14]. Researchers in the area have proposed several cross-layer frameworks for enhancing the efficiency of handover decision makers (see [14, 15] and the references therein), but none of them has been formally standardized or is widely accepted so far. What is needed is a standard framework that can attract ample support from major vendors and operators, and can be deployed incrementally.

Introducing IEEE 802.21-2008

Figure 1 illustrates the progress toward the IEEE 802.21-2008 standard. The working group was initiated in 2004, and the latest draft version of the standard was accepted as a new standard by the IEEE-SA Standards Board in November 2008[3]. The standard was published in January 2009. It is anticipated that actual deployment of the standard will take place at the earliest in late 2009–2010.

Figure 1: Timeline of the IEEE 802.21-2008 Standardization Effort



IEEE 802.21-2008, also known as *Media-Independent Handover Services*, features a broad set of properties that meet the requirements of effective heterogeneous handovers. It allows for transparent service continuity during handovers by specifying mechanisms to gather and distribute information from various link types to a handover decision maker. The collected information comprises timely and consistent notifications about changes in link conditions and available access networks.

Note that the scope of IEEE 802.21-2008 is restricted to access technology-independent handovers. Intratechnology handovers, handover policies, security mechanisms, media-specific link layer enhancements to support IEEE 802.21-2008, and *Layer 3* (L3) and upper-layer enhancements are outside the scope of IEEE 802.21-2008. This article summarizes the salient points of [3], which henceforth is referred to as IEEE 802.21.

The IEEE 802.21 Reference Model

IEEE 802.21 facilitates a variety of handover methods, including both *hard handovers* and *soft handovers*. A hard handover, also known as "break-before-make" handover, typically implies an abrupt switch between two access points, base stations, or, generally speaking, PoAs. Soft handovers require the establishment of a connection with the target PoA while still routing traffic through the serving PoA. In soft ("make-before-break") handovers, mobile nodes remain briefly connected with two PoAs. Note, however, that depending on service requirements and application traffic patterns, hard handovers may often go unnoticed. For example, web browsing and audio/video streaming with prebuffering can be accommodated when handing over between different PoAs in the range of one network by employing mechanisms that allow transferring the node connection context from one PoA to another quickly.

The main design elements of IEEE 802.21 can be classified into three categories: a framework for enabling transparent service continuity while handing over between heterogeneous access technologies; a set of handover-enabling functions; and a set of *Service Access Points* (SAPs).

Transparent Service Continuity

IEEE 802.21 specifies a framework that enables transparent service continuity while a mobile node switches between heterogeneous access technologies. The consequences of a particular handover need to be communicated and considered early in the process and, clearly, before the handover execution. In soft handovers, it is crucial that service continuity, during and after the handover, is ensured without any user intervention. To this end, IEEE 802.21 specifies essential mechanisms to gather all necessary information required for an affiliation with a new access point before breaking up the currently used connection. Interactive applications, such as VoIP, are typically the most demanding in terms of handover delays, and high-quality VoIP calls can be served only by soft handovers. On the other hand, video streaming can accommodate hard handovers, as long as the vertical break-before-make handover delay does not exceed the application buffer interval delay. In the case of hard handovers, handover preparation signaling can initiate the connection context transfer from the serving PoA to the target PoA beforehand.

For instance, lack of the required level of QoS support or low available capacity in a candidate access network may lead the network selecting entity to prevent a planned handover. On the other hand, for example, increasing delay, jitter, or packet-loss rates in the currently serving network may degrade the perceived QoS throughout the network, or only for a particular application, triggering the mobility manager to start assessing the potential of candidate target access networks and subsequently initiate an IEEE 802.21-assisted handover.

IEEE 802.21 also allows the reception of dynamic information about the performance of the serving network and other networks in range. In other words, IEEE 802.21 provides methods for continuous monitoring of available access conditions. However, IEEE 802.21 does not specify any methods for collecting this dynamic information at the link layer.

Handover-Enabling Functions

IEEE 802.21 defines a set of handover-enabling functions, which are specified with respect to existing network elements in the protocol stack, and introduces a new logical entity called *Media-Independent Handover Function* (MIHF). The MIHF logically resides between the link layer and the network layer. It provides, among others, abstracted services to entities residing at the network layer and above, called *MIH Users* (MIHUs). MIHUs are anticipated to make handover and link-selection decisions based on their internal policies, context, and the information received from the MIHF. To this end, the primary role of the MIHF is to assist in handovers and handover decision making by providing all necessary information to the network selector or mobility management entities. The latter are responsible for handover decisions regardless of the entity position in the network. The MIHF is not meant to make any decisions with respect to network selection.

Service Access Points

SAPs with associated primitives between the MIHF and MIHUs (MIH_SAP) give MIHUs access to the following services that the MIHF provides:

- The *Media-Independent Event Service* (MIES) provides event reporting about, for example, dynamic changes in link conditions, link status, and link quality. Events can be both local and remote. Remote events are obtained from a peer MIHF entity.
- The *Media-Independent Command Service* (MICS) enables MIHUs to manage and control the parameters related to link behavior and handovers. MICS provides a set of commands for accomplishing that, as we will see later in this article. Commands can be both local and remote. The information obtained with MICS is dynamic.
- The *Media-Independent Information Service* (MIIS) allows MIHUs to receive static information about the characteristics and services of the serving network and other available networks in range. This information can be used to assist in making a decision about which handover target to choose and to make preliminary preparations for a handover.

Figure 2 illustrates the general reference model of IEEE 802.21. The scope of IEEE 802.21 includes only the operation of MIHF and the primitives associated with the interfaces between MIHF and other entities. A single media-independent interface between MIHF and MIHU (MIH_SAP) is sufficient.

On the other hand, there is a need for defining a separate technology-dependent interface, which is specific to the corresponding media type supported, between the MIHF and the lower layers (MIH_LINK_SAP).

The primitives associated with the MIH_LINK_SAP enable MIHF to receive timely and consistent link information and control link operation during handovers. For example, the currently supported link layers include wired and wireless media types from the IEEE family of standards (for example, 802.3, 802.11, 802.15, and 802.16), as well as those defined by the *Third-Generation Partnership Project* (3GPP) and *Third-Generation Partnership Project 2* (3GPP2). Besides these, IEEE 802.21 specifies a media-independent SAP (MIH_NET_SAP), which provides transport services for Layer 2 (L2) and Layer 3 (L3) MIH message exchange with remote MIHFs. Functions over the LLC_SAP are not specified in IEEE 802.21.

Figure 2: The IEEE 802.21-2008 Reference Model

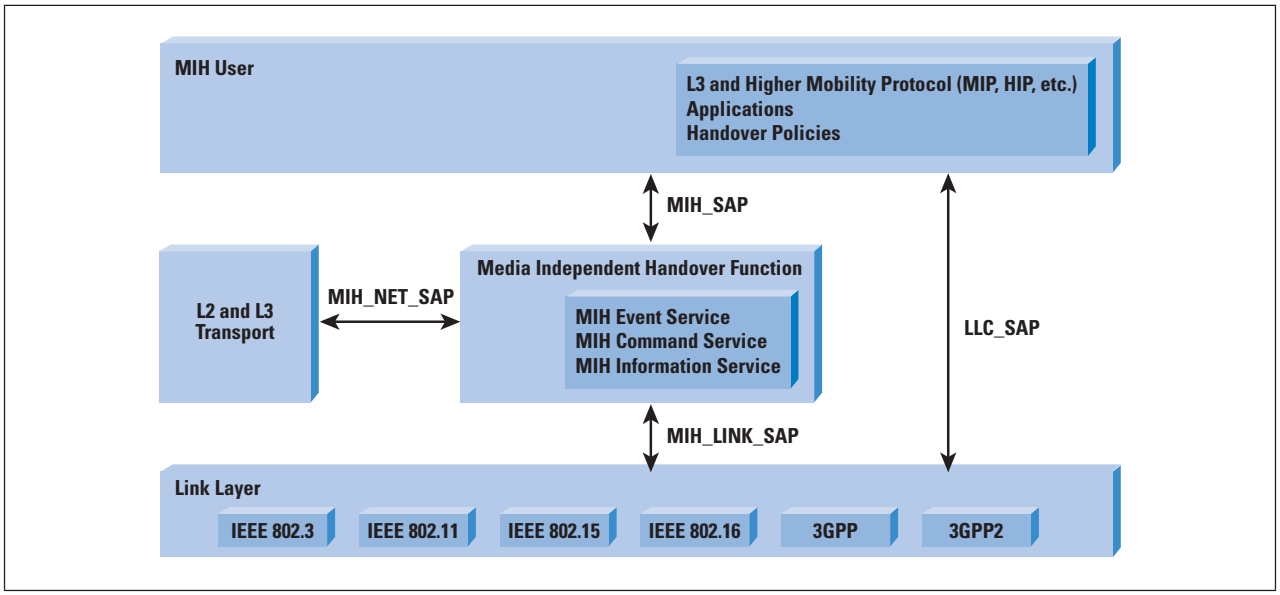


Figure 3 presents the messages directions of each MIHF service class, including both local and remote events and commands. The MIHF can subscribe to particular sets of events from a peer MIHF. Remote commands are initiated by local MIHUs and are conveyed to the peer MIHF through the local MIHF. Finally, MIIS information can be obtained through queries to the local database and to remote Information Servers.

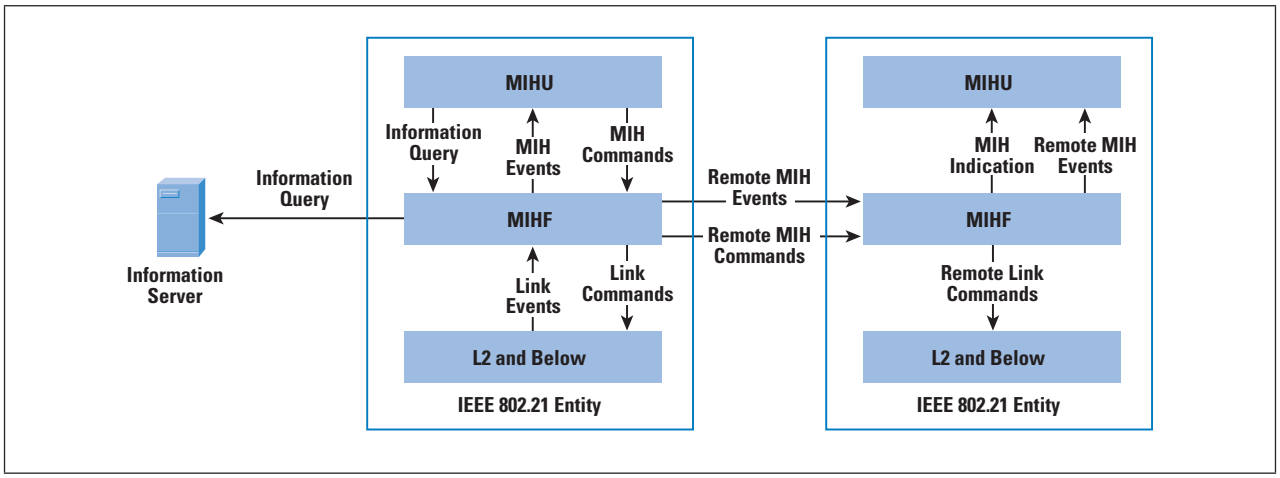
Figure 3: MIHF Services



IEEE 802.21 Illustrated

Figure 4 illustrates an example topology where different wireless networks overlap. Imagine that the multiaccess mobile device user watches a high-bitrate IPTV channel as she moves in this area. Three wireless access technologies are considered in this example: Wi-Fi (IEEE 802.11), WiMAX (IEEE 802.16), and 3G/UMTS (3GPP). In this example, we assume that all networks and the mobile device are IEEE 802.21-compatible and that the Wi-Fi area is covered by several 802.11 PoAs, as would be the case in a campus- or citywide deployment.

Figure 4: Example Topology with Heterogeneous Overlapping Wireless Access Networks

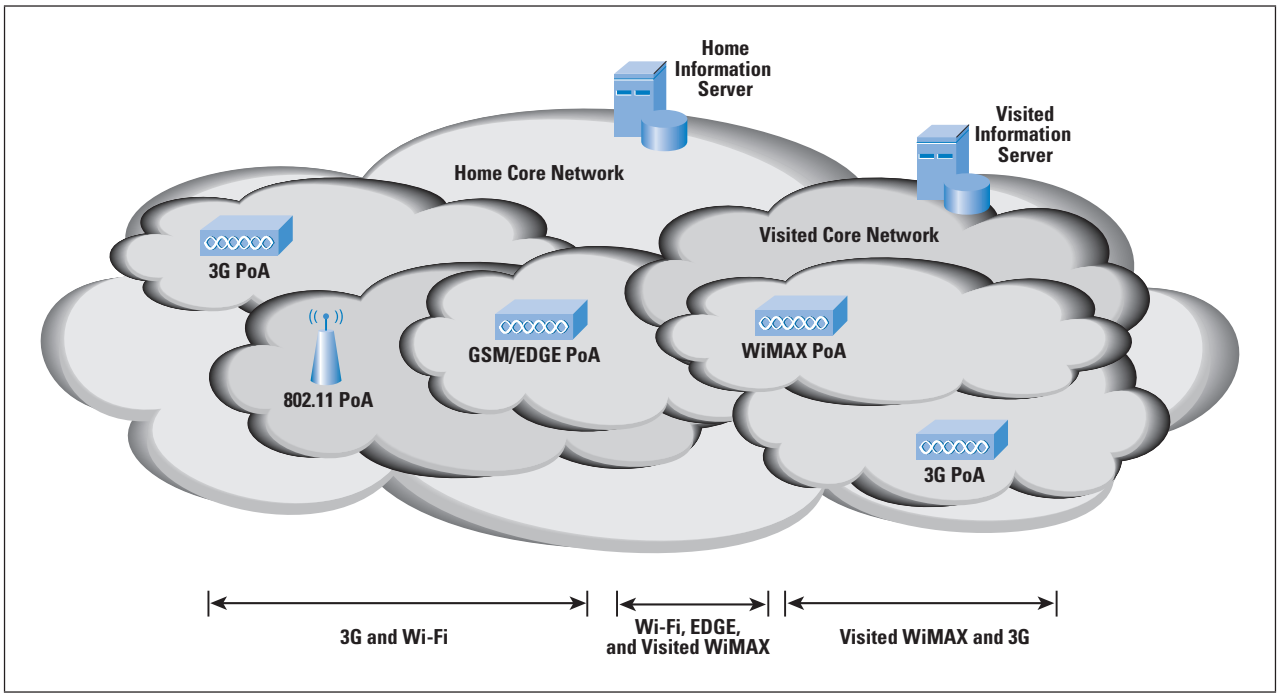


Figure 5 illustrates the network access environment as perceived by a mobile device in the area. The figure depicts three snapshots, indicating the overlapping networks in range at different locations. In order to deliver the IPTV stream transparently, for each of the available access networks we need to consider their effective available bandwidth, the associated cost per traffic unit, the terminal speed, the cell coverage area, the level of QoS support it can provide, and so on. Using information made available through the MIHF, we can determine which should be the next target access network.

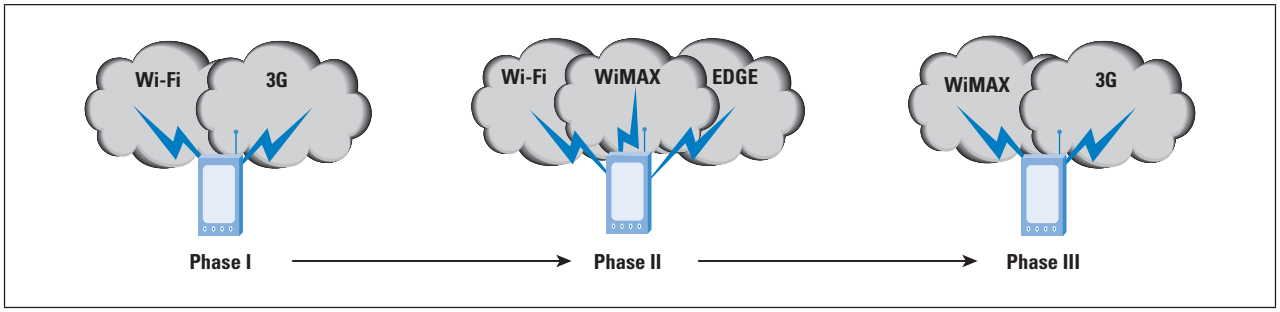
Figure 5: Example Network Environment in Different Locations



In Phase I, the mobile node has two network access options. It can use a free and open Wi-Fi network or connect to the cellular operator's 3G/UMTS network. Note that opting to use the latter may, for instance, depend on the charging scheme of the operator. If subscribers pay based on traffic volume, one would assume that the free Wi-Fi network is a better option. On the other hand, as flat-rate plans become more popular, 3G may be a better option with its extended coverage and QoS guarantees. The IEEE 802.21 MIIS can provide this type of information, allowing for automation in dynamic access selection.

In Phase II, as the user moves, the device goes through a cellular technology handover from 3G/UMTS to *Enhanced Data rates for GSM Evolution* (EDGE)[8]. At the same place, the public Wi-Fi network is still available and a new WiMAX network has just been detected. Assume that EDGE is not sufficient for delivering the IPTV stream. If in Phase I the network selection process opted for using the cellular network, then in Phase II the client application will experience significant degradation in service if it continues to use the EDGE access network. A vertical handover to the Wi-Fi or the WiMAX network should be considered. In contrast, if the mobile node first chose to stream the IPTV channel over the Wi-Fi access network, then it may need to reassess the situation based on events and link parameter reports using MIES and MICS, as we explain in the following sections. For example, an information query can reveal whether the WiMAX network is operated by a partner *Internet Service Provider* (ISP), and what the roaming cost would be.

Finally, in Phase III, the coverage area of the public Wi-Fi network ends. Through IEEE 802.21 services we find out that the only available networks are the roaming partner WiMAX and the home cellular network that is now offering 3G service.

The environment with several overlapping networks described previously and illustrated in Figures 4 and 5 is already a reality today in many places, and it is widely anticipated to be prevalent in the future. Next, we examine the three services defined by IEEE 802.21, namely MIES, MICS, and MIIS.

Media-Independent Event Service

Events indicate or predict changes in the state and transmission behavior of physical, data link, and logical link layers. In general, events are triggers for initiating candidate network discovery and handover procedures. The events defined in IEEE 802.21 are categorized as either *Link Events* or *MIH Events,* depending on their origin. Link events emanate from the link layers, whereas MIH events emanate from the MIHF and can be both remote and local. Local events propagate from lower layers to upper layers through the MIHF. Remote events occur at the protocol stack of another network entity and are transmitted from a peer MIHF to the local MIHF, as illustrated in Figure 3.

The *Media-Independent Event Service* (MIES) currently supports five types of events: MAC and PHY State Change events, Link Parameter events, Predictive events, Link Handover events, and Link Transmission events. A short introduction to the event types and corresponding events follows.

MAC and PHY State Change events correspond to state changes in MAC and *physical* (PHY) layers. The most characteristic events in this category are *Link_Up* and *Link_Down* events, which are generated when a Layer 2 connection with an access point is established or is torn down, respectively. Another event, called *Link_Detected,* indicates that a PoA has been detected but no affiliation is established yet.

Link Parameter events relate to changes in Layer 2 parameters. A *Link_Parameters_Report* can be sent when a MIHU has set thresholds for certain parameters. For example, a MIHU can set thresholds for the *Received Signal Strength Indicator* (RSSI) on IEEE 802.11 links, so that when a threshold is crossed proper action can be taken. A *Link_Parameters_Report* is also used for issuing periodical notifications about link conditions. Based on Link Parameter events, a MIHU can initiate the handover candidate discovery process, or trigger applications to adapt to changing link conditions.

Predictive events inform about the probability of dramatic (negative) changes in link characteristics in the near future. For example, if strong decay in signal strength is observed, this decay may indicate imminent loss of link connectivity. Predictive events may include temporal information about when the actual event is expected to occur and what its presumed likelihood is. A *Link_Going_Down* event, for instance, may trigger a MIHU to consider possibilities for handing over to other available networks in range.

Link Handover events indicate the occurrence of Layer 2 handovers. The *Link_Handover_Imminent* event serves as a notification for an imminent handover, whereas a *Link_Handover_Complete* event reports the successful change of PoA. These events emanate from the link layer and are based solely on local Layer 2 information.

Link Transmission events show the transmission status of individual higher-layer *Protocol Data Units* (PDUs) at the link layer. Upper layers can, for example, adapt to data loss during a handover by improving buffer management based on Link Transmission events. These events may allow future upper-layer implementations to identify lost packets and recover without waiting for the expiration of retransmission timers.

Currently, for example, in the case of an ongoing session over TCP, the occurrence of a handover may have dramatic effects in performance. With IEEE 802.21, MIHUs can be informed about individual packets that have already been delivered to the sending buffer of the MAC layer but were not successfully transmitted before the handover occurred. In other words, the MAC layer outgoing buffer may contain TCP segments that cannot be delivered through the wireless network to the peer at the other end of the TCP connection. These segments were not successfully delivered from the local *Automatic Repeat-reQuest* (ARQ) module over the first hop, but are still buffered and cannot be transmitted because there is no link connectivity. In this case, TCP could use the information from Link Transmission events that identifies which packets need to be resent through the new access network, as illustrated in Figure 6 for packet numbers 1 and 2. Note, however, that IEEE 802.21 does not define any identifier for reliable packet identification, only the size of the packet ID (2 bytes), and it is up to the implementer to determine how different messages will be locally identified.

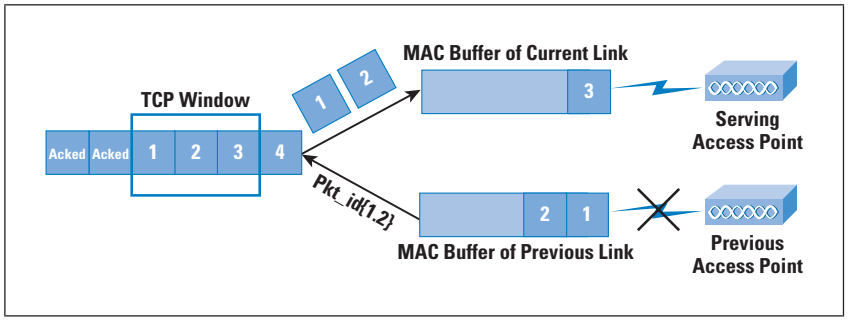


Figure 6: Link Transmission Event Indicating Undelivered Packets

Media-Independent Command Service

The *Media-Independent Command Service* (MICS) enables higher layers to control the stream of events originating from lower layers. Commands can originate from MIHUs (MIH commands) or from the MIHF (Link commands) and the destination can be the MIHF or any lower layer, respectively, as shown in Figure 3. The responses to Link commands are sent to MIHUs as indications. MIHUs can use command services to determine the status of different links in a uniform way, and control each interface accordingly, aiming for optimal connectivity. MICS defines the following set of commands that enable MIHUs to configure, control, and get information from the lower layers:

- *MIH commands* can be directed to lower layers residing at both local and remote MIHF entities. They originate from the upper layers and are directed to the MIHF. Similarly with MIH events, MIH commands can be both remote and local. MIH commands are typically used for network selection and handover management because they allow upper layers to initialize, prepare for, and execute handovers. MIH commands are also used to configure custom thresholds for link parameters. As mentioned previously, when set thresholds are crossed, MIHUs get the corresponding notifications through Link Parameter events.
- *Link commands* originate from the MIHF and are sent to lower layers in order to control their operation. Link commands can be issued only locally. Nevertheless, Link commands can be executed on behalf of local MIHUs, which could act on information received from a remote peer. Link commands are often initiated by MIHUs. For example, an MIHU can issue the *MIH_Get_Link_Parameters* MIH command, which when received by the local MIHF will lead to the generation of a remote *Link_Get_Parameters* Link command, as shown in Figure 3. This way, the MIHF can acquire the current parameter values of active link(s) for MIHU, and then deliver this information to the requesting MIHU. Note that MICS provides dynamic information about different link parameters, in contrast with MIIS, described next, which can report only static information.

Media-Independent Information Service

The *Media-Independent Information Service* (MIIS) facilitates handovers through a unified set of mechanisms that the MIHF can use to discover and obtain static (or rarely changing) information about networks in the vicinity of a multiaccess node. In other words, MIIS allows mobile nodes to check for available networks in range while using their currently active access network. MIIS information exchange occurs at the link layer (Layer 2) or network layer (Layer 3), so that all necessary information related to link layer or higher-layer services is collected before a mobile node authenticates with a new PoA.

MIIS defines a set of *Information Elements* (IEs) that are indispensable for network selection, classified into three groups: General Information and Access Network-Specific Information; PoA-Specific Information; and Other Information, which includes vendor- and network-specific details. The types of information handled by MIIS are solely related to handover decisions and conformance to the affiliation with the new PoA. Information relevant for assessing candidate networks by the handover machinery includes connection establishment details, such as PoA address and location; which security mechanisms are supported in a given access network; and what QoS guarantees can be provided.

General Information Elements and *Access Network-Specific Information Elements* give a general overview of neighboring networks. Information Elements may include, for instance, a list of available networks and their associated operators, roaming agreements and costs, and security and QoS support. For instance, user policies, defined at higher layers, may dictate that if a given access network operator charges users based on their traffic volume, then the network selector entity should not consider the corresponding access when a high-bitrate service, such as IPTV, is active.

PoA-Specific Information Elements refer to each PoA available in the access network and report PoA location and addressing information, supported data rates, PHY and MAC layer types, and channel parameters that can optimize link layer connectivity. Some additional information related to higher-layer services and individual capabilities of particular PoAs may be included as well. For instance, an advanced mobility manager on the mobile node can use the information about the geographical position of a PoA and compare it with the current or expected node location based on its mobility patterns. With careful planning and by taking advantage of this information, mobile nodes may be able to reduce the number of handovers and optimize the use of network resources.

MIIS provides mechanisms for issuing and responding to queries for Information Elements. Such information may reside in a separate server or in a local information database at the mobile node (see Figure 3). An MIHF could have access to an information server in its IEEE 802.21-enabled *Point-of-Service* (PoS) range from which it can obtain information regarding the home PoS and possibly other PoSs, such as those of roaming partners. If the home information server is not able to provide any information regarding the visited network, an MIIS query can be directed to the peer MIHF, residing in the visited PoS, which can access the visited PoS information server. Information queries can often be answered locally, based on information gathered from previous queries and by preprovisioning, for example, from the information server.

Information Elements and their relationships are captured in an Information Service schema which, in turn, defines the information structure. IEEE 802.21 specifies that information that is to be presented across different technologies should be in a standardized, common, and open format, such as XML or *Type Length Value* (TLV).

Service Management

In order to use and provide MIHF services, MIHF entities need to be configured appropriately. IEEE 802.21 defines three service management functions: MIH capability discovery, MIH registration, and MIH event subscription.

MIHF may discover other MIHF entities and their capabilities using the MIH capability discovery procedure. Depending on the information obtained from this procedure, the local MIHF can determine which peer MIHFs it should register with. The MIH capability discovery function uses the MIH protocol (introduced in the following section) at Layer 2 or Layer 3, and media-specific Layer 2 broadcast messages are allowed. For example, an MIHF can listen to media-specific broadcast messages, such as IEEE 802.11 beacons, or media-independent Layer 2 *MIH_Capability_Discover* broadcast messages, because an MIHF entity residing in the network may announce its existence and capabilities periodically. MIHF can also send *MIH_Capability_Discover* request messages using multicast or unicast to detect peer MIHFs in a solicited way. For instance, MIHF can send a request by unicast for obtaining the capabilities of a specific IEEE 802.21 network entity. In this case, only the IEEE 802.21 network entity addressed should respond to these request messages.

MIH registration is a symmetric procedure by which two peer MIHFs authenticate and can then communicate with each other in a more trusted manner. After MIH registration is completed, the two peer MIHF entities can symmetrically request services from their registered peer. Note that MIH registration is not necessary for obtaining some level of support from a peer MIHF. However, by registering and authenticating, peer MIHFs typically will get access to much more extensive information. That is, although the MIHF residing on the mobile node may be able to access information services from the network-side MIHFs without registration and authentication, the available information may be only a subset of that provided after authenticating.

Finally, MIH event subscription enables MIHUs to subscribe to a particular set of events provided by MIES from the local or peer MIHF. Event subscription from a peer MIHF requires registration and knowledge about its capabilities. The subscription contains only the list of events the MIHU is interested in. Note that event sources may not be necessarily capable of providing all events that the subscriber is interested in subscribing to. Each subscription request is matched by a confirmation message from the event source indicating the events approved for subscription.

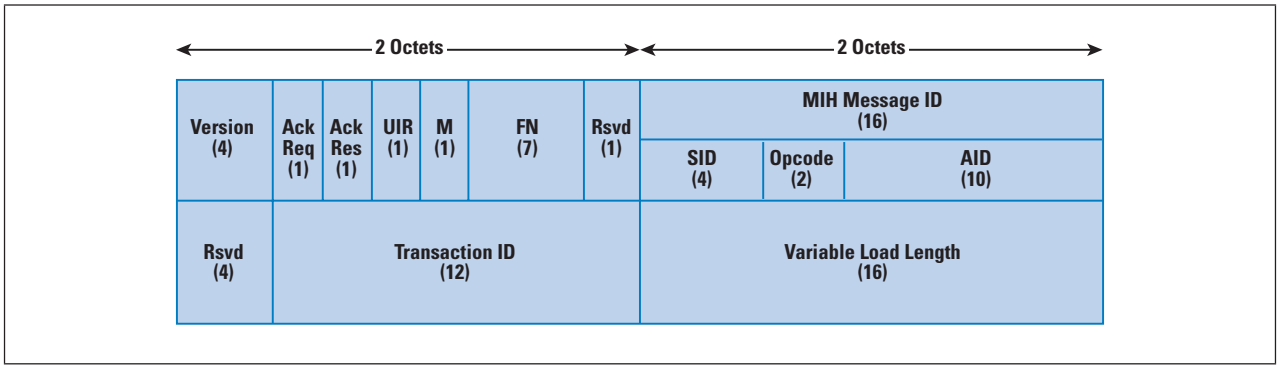
Media-Independent Handover Protocol

The *Media-Independent Handover Protocol* (MIHP) specifies the rules and services for unified communication between peer MIHFs. The protocol defines the message format, header, and encoding format and is meant to be used solely for communicating with peer MIHF entities. For internal communication no particular encoding is dictated.

MIH protocol messages can be carried over Layer 2 management frames, Layer 2 data frames, or over Layer 3/IP transport. Note that cellular technologies do not provide Layer 2 transport without changes in their protocol stack.

The MIH protocol messages, or frames, comprise a header part and a TLV-encoded payload part. The MIHF frame header consists of eight octets. Figure 7 illustrates the MIH protocol header indicating the corresponding bit length for each field in parentheses.

Figure 7: MIH Protocol Header



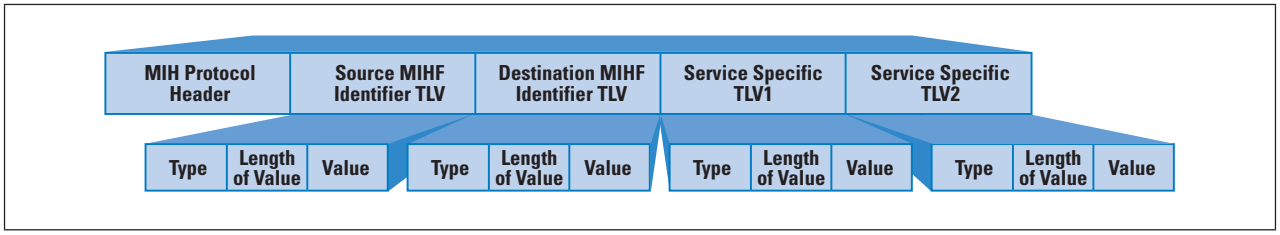
The *Version* field in the MIH frame header specifies the version of the MIH protocol used. The two *Ack* fields are for acknowledgement purposes and are discussed later in the article. The *Unauthenticated Information Request* (UIR) flag indicates that the response message may be sent with a limited length because of the nature of unauthenticated message exchange. Recall that when an MIHF issues requests without registering first with its peer, it may receive less information than if it had registered earlier. If this flag is set, then the information included in the response message may not reflect the complete information available to registered MIHFs. The *More Fragments* (M) and *Fragment Number* (FN) fields are used in message fragmentation.

The *MIH Message ID* field comprises three subfields. The *Service Identifier* (SID) field indicates the MIHF service class (MIES, MICS, MIIS, or Service Management) that this message belongs to. The *Operation code* (Opcode) specifies whether the message is a request, response, or indication. The *Action Identifier* (AID) is related with and scoped by the SID. For instance, if the SID indicates MIES, AID points to the actual event type. The *Variable Load Length* field contains the total length of the variable, TLV-encoded payload carried by this message frame.

The MIH protocol messages use the *Transaction ID* and *MIHF ID* fields as identifiers, but only the former is included in the header. The Transaction ID field is an identifier that helps to match each request, response, or indication message with its acknowledgement.

The payload part contains service-specific messages encoded in TLV format. The first two TLVs in the payload part (not shown in Figure 7) should be the *Source Identifier* and *Destination Identifier,* which are both the same data type as the MIHF ID. Every MIHF must have a unique MIHF ID, which may be assigned to it at configuration time. The MIHF ID shall be invariant and could be, for example, a *Fully Qualified Domain Name* (FQDN) or *Network Access Identifier* (NAI). The MIHF ID is used during the MIH registration phase and is appended to the payload part of every message requiring endpoint identification. In broadcast messages, the Destination Identifier TLV is defined as zero length. Figure 8 shows the message structure consisting of the MIH Protocol header, source and destination identifiers, and service-specific TLVs. In TLV encoding, the Type field (1 octet) denotes the parameter type, the Length field (variable octets) indicates the length of the Value field, and the Value field (variable octets) carries the actual value of the parameter.

Figure 8: MIH Protocol Frame Structure



Acknowledging MIH messages is not mandatory. Still, the MIH protocol does support the use of acknowledgements to ensure reliable message exchange. The sender MIHF can set the *ACK-Req* field to instruct the receiver to return an acknowledgement with *ACK-Rsp* bit set. The *MIH Message ID* and *Transaction ID* must be the same in the request message and its acknowledgement. An acknowledgement message may carry no payload. Note, however, that despite employing these two ID fields, the MIH protocol does not specify any further mechanisms for reliable authentication or shielding message exchanges from third parties.

MIH Communication Model

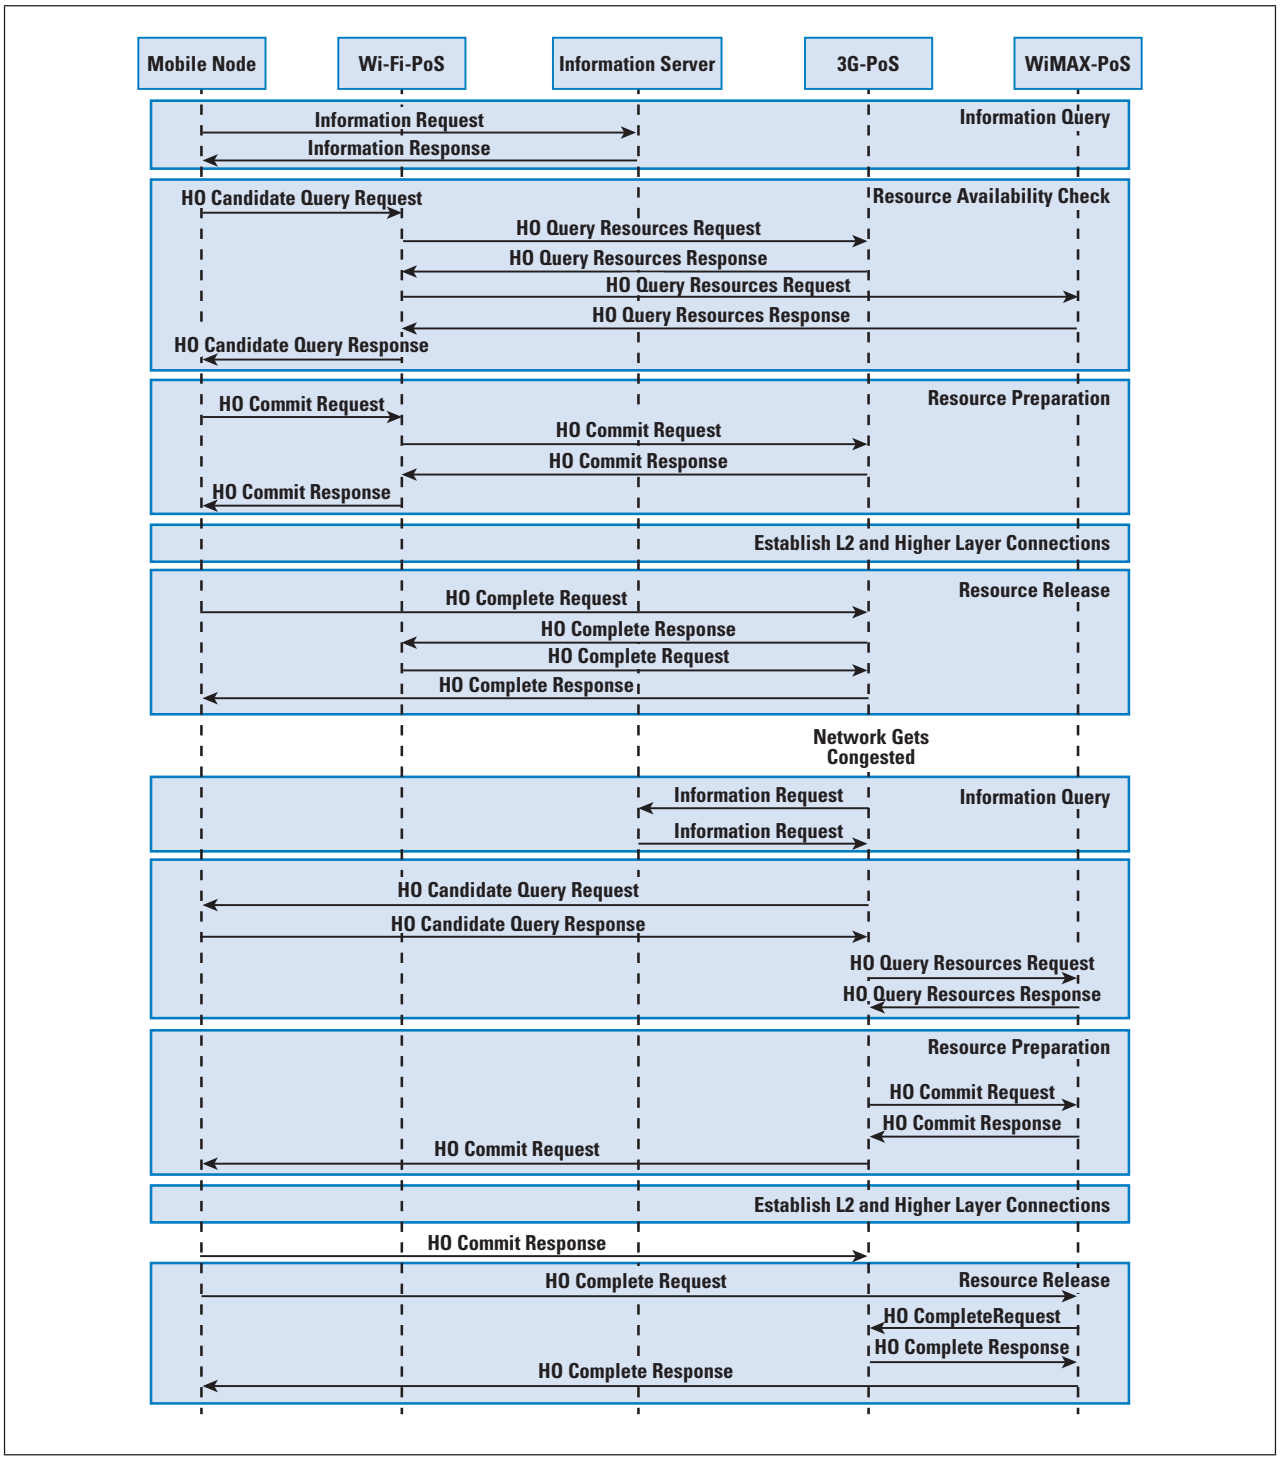
The MIHF communication model specifies different MIHF roles and their communication relationships, such as supported transport mechanisms and service classes. The assigned MIHF roles depend on their location in the network. For example, an MIHF on a mobile node can communicate directly with network-side entities called *MIH PoSs* using Layer 2 or Layer 3 communication. MIH PoSs may include the serving PoA or candidate PoAs. Network-side MIHFs can communicate with each other at Layer 3 or above using the MIH protocol, introduced in the previous section.

Let us revisit the example use case of IEEE 802.21 illustrated in Figures 4 and 5. Figure 9 presents the IEEE 802.21 message exchanges in mobile- and network-initiated handover procedures in the case where the mobile node hands over from a Wi-Fi to the 3G cellular network (between Phase II and Phase III in Figure 5) and then hands over to a WiMAX network (Phase III in Figure 5). First, during the discovery of handover candidate PoAs, the mobile node MIHF employs MIIS to gather static information about the surrounding networks. The request is issued over the currently used Wi-Fi access. This information is obtained from the information server that may reside in a different network than the one currently in use.

After receiving the response to its Information Request, the mobile node initiates the handover process by querying about the availability of resources in the networks it is interested in. These requests are sent through the serving PoS (*Wi-Fi-PoS* in Figure 9), which disseminates the requests to the MIH PoSs of the candidate networks (*3G-PoS* and *WiMAX-PoS* in Figure 9). The response indicating the capabilities of the two candidate networks is returned to the mobile node MIHF from the serving PoS. After receiving this information, an MIHU on the mobile node decides which network to hand over to, based on policies and the output of its network selection algorithms. Then a *Handover Commit Request* message is sent, and after the candidate network has made its final commitment for the handover (and the appropriate resources are reserved successfully), the mobile node establishes a Layer 2 connection with the PoA in the area of the candidate PoS, that is, the 3G-PoS in our example case. Following this successful intertechnology handover, the resources used in the previous link can optionally be released. In the case where no resources are explicitly reserved, this step is skipped.

As we progress in the timeline of our example case, the network-side MIHU initiates a handover to the WiMAX network. This handover could be, for example, the result of observing congestion in the cellular network that indicates that a new PoS should be found for the mobile node. The serving PoS (3G-PoS) collects information about networks in the range of the mobile node from the Information Server. Upon determining that a suitable WiMAX candidate network that can serve the mobile node exists, the 3G-PoS triggers a network-initiated handover. First, the serving PoS requests permission from the mobile node to proceed with the handover. If the mobile node does not object, the serving PoS proceeds with the rest of the handover procedure, which is similar to the mobile-initiated handover described previously except that it is handled by a network entity.

Figure 9: IEEE 802.21-Assisted Handover Message Sequence Diagram



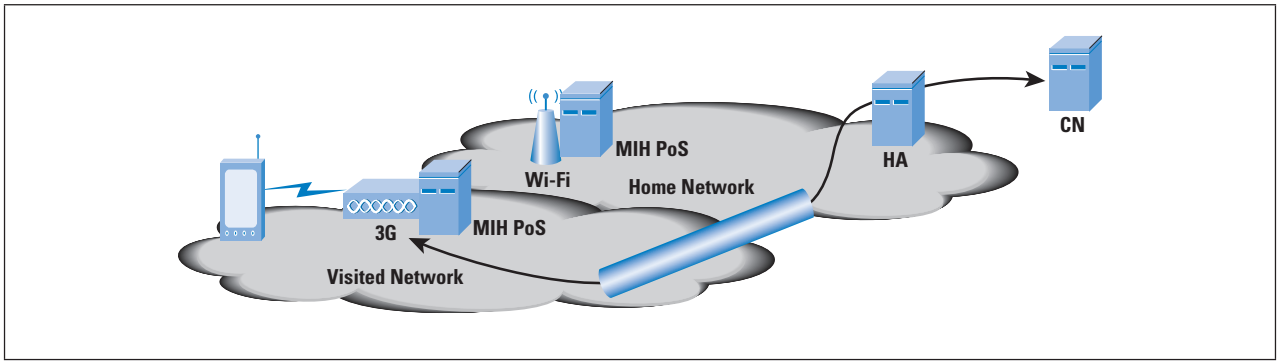
Handover Execution

As illustrated in the example, the handover decision and target assessment constitute a multiphase process where the assistance of IEEE 802.21 is essential. However, the actual handover execution is outside the scope of the standard. This section briefly describes how handovers can be carried out by MIP with the cooperation of IEEE 802.21. After choosing the target network by capitalizing on the IEEE 802.21 services, the mobile node establishes a new connection with the handover target network while still routing traffic through the currently serving network. The mobile node obtains a *Care-of Address* (CoA) for this new link from the IP address space of the target network. The CoA is an IP address assigned to the new link of the mobile node and is used while connected to the visiting network[11]. With MIPv4, the CoA is provided by a *Foreign Agent* (FA) in the visited network, which also acts as a router for the mobile node[12]. With MIPv6, the Foreign Agent is not needed[13] and the CoA is obtained directly, say, for example, from a *Dynamic Host Configuration Protocol* (DHCP) sever. The mobile node can obtain the IP address of the DHCP server in the target network through the IEEE 802.21MIIS.

In MIP, each mobile node has a *Home Agent* (HA), which routes the traffic of the mobile node. After successfully affiliating with a PoA in the target network, the mobile node notifies the Home Agent of the CoA by performing a binding update. In a bidirectional tunnel mode, the Home Agent establishes an IP-IP tunnel between the Home Agent and the Foreign Agent (MIPv4) or the Home Agent and the mobile node CoA (MIPv6). This mode does not require any binding updates on the *Correspondent Node* (CN). In other modes, either the uplink traffic of the mobile node is sent directly to the Correspondent Node using the CoA as source address, or all bidirectional communication between the Correspondent Node and the mobile node uses the CoA only. In the first case, traffic from the Correspondent Node to the mobile node travels through the Home Agent, but in the latter case there is no need for the Home Agent detour. However, these modes need address binding at the Correspondent Node and are in practice less frequently used than the bidirectional tunnel mode.

Figure 10 illustrates a situation where a link with the Wi-Fi PoA is broken down by the mobile node and the IPv6 traffic between the Correspondent Node and the mobile node, now employing IEEE 802.21-enabled 3G network, travels through the tunnel between Home Agent and the mobile node.

Figure 10: Mobile IPv6 Tunnel



Layer 3 handover executions based on RFC 3344[12] and RFC 3775[13] may often exceed the typical handover delay budgets, thus introducing gaps in connectivity that are perceptible at the application layer. Recent standardization efforts have focused on decreasing handover delays by enhancing MIP so that it can provide for transparent mobility management for both IPv4[16] and IPv6[17, 18]. The proposed enhancements either reduce the amount of signaling or allow the mobile node to configure the new Layer 3 connection before reassociating with the new network. In this context, IEEE 802.21 can provide the essential information for preestablishing the connection based on media-independent Layer 2 link detection events as well as static address information from the target network.

Summary and Outlook

We presented an overview of the IEEE 802.21 Media-Independent Handover Services standard. We anticipate that its adoption in the near future will allow for better network resource usage and permit multiaccess devices to select the network access best suited for their communication needs. After motivating the needs for a standard to cope with heterogeneous network handovers, we introduced the IEEE 802.21 Reference Model and the MIH Services. We briefly presented the MIH Protocol, although a more thorough description calls for a separate overview article. Finally, we illustrated network operation when IEEE 802.21 is adopted using example use cases featuring both network- and terminal-initiated intertechnology (or vertical) handovers.

We expect that in the future, when IEEE 802.21-2008 is widely deployed, there will be significant efforts to further amend and extend it in order to provide for even better services. In fact, because security mechanisms are outside the scope of the base IEEE 802.21 standard, the work on defining a security-related extension to IEEE 802.21 (IEEE P802.21a) has already begun. Moreover, another amendment (IEEE P802.21b) that deals with handovers with downlink-only technologies, such as *Digital Video Broadcasting* (DVB), has also been introduced (see `www.ieee802.org/21` for more information about the amendments). Nevertheless, it remains uncertain whether vendors will stand by this promising standard and incorporate it in future products and solutions.

ESA PIRI received his M.Sc. from the University of Oulu, Oulu, Finland, in 2008. During his studies, he specialized in information networks systems and wrote his Master's thesis on mobility management issues in heterogeneous networks. Currently he is working as a Research Scientist at VTT Technical Research Centre of Finland in Oulu, Finland. He can be contacted by e-mail at: **esa.piri@vtt.fi**

KOSTAS PENTIKOUSIS studied computer science at Aristotle University of Thessaloniki, Greece (B.Sc. 1996, summa cum laude) and State University of New York at Stony Brook, USA (M.Sc. 2000, Ph.D. 2004). He has published internationally in several areas, including mobile computing; transport protocols; applications; network traffic measurements and analysis; and simulation and modeling. Dr. Pentikousis is a Senior Research Scientist at VTT Technical Research Centre of Finland. Visit **http://ipv6.willab.fi/kostas** for more information and contact details.

Book Review

Geeks Bearing Gifts

Geeks Bearing Gifts v1.1: How the computer world got this way, by Ted Nelson, ISBN: 978-0-578-00438-9, Published by Mindful Press, 2009, distributed through Lulu.Com, `http://www.lulu.com`

In a short but interesting book, computer pioneer Ted Nelson takes a very broad look at the origins and evolution of many of the basic ideas that underpin today's computer industry. The emphasis is on concepts and technologies rather than the success of individuals, the companies they founded, and the shape of the computer industry. This approach differentiates the book from other accounts, such as Robert X. Cringley's *Accidental Empires* and Martin Campbell-Kelly's *From Airline Reservations to Sonic the Hedgehog*.

Although the book is suitable for a fairly broad readership, an appreciation of the current makeup of the industry is helpful in understanding the significance of some of Nelson's ideas.

Organization

Geeks Bearing Gifts is divided into 60 short chapters, arranged in chronological order from the time the ideas originated, rather than when they appeared in fully developed form (indeed many are still developing). In the initial chapters Nelson covers topics such as language, alphabets, and encryption before moving on to examine the origins of computing. He then examines the contribution of pioneers from both inside and outside the United States, giving more credibility to contributors from outside of the United States than is normal.

As would be expected, Nelson deals in some detail with the topic of information presentation, in particular the origins of hypertext and associated developments such as *Xanadu* and the World Wide Web. He discusses the differences between these technologies, spending some time reflecting on his attempts to develop Xanadu at Brown University; he suggests that many of the deficiencies of the Web come from misdirection of that phase of the project.

Nelson next examines a wide selection of topics ranging from networks (both local and the Internet), object-orientated programming, and early desktop machines, before reaching the pivot point of his book: the UNIX operating system. He chose UNIX as the fulcrum of his analysis because he believes "so much led into it and so much has resulted from it."

Nelson next considers PUI (the PARC user interface), PCs, the role of the Microsoft and Apple operating systems and their evolution, the influence of the spreadsheet, the Internet, browsers, the Internet crash, and the current major companies in computing. He explores the promise, hype, and reality of the Web 2.0 model and its likely influence. (PARC stands for the Xerox *Palo Alto Research Center*.)

The last two chapters are summaries and thought guides. The first of these suggests that it is people and ideas rather than technology that advance the computer industry and that the myth of technological necessity has stifled imagination. The final chapter illustrates what the book is about—the disagreements and decisions that have made the technical world what it is today.

Synopsis

Nelson captures most of the important developments in the computer industry, although he acknowledges that in 199 pages it is possible to tell the reader only a little of where the software ideas come from and what they are. He sets out to show how varied and conflicting the initiatives that have propelled the evolution of computer technology have been, exposing the "ideas, disagreements, manoeuvres, forgotten possibilities, and politics."

The book reads like a collection of themed essays, rather than a coherent sequence of stories. Nonetheless it is both informative and thought-provoking.

The Author

Ted Nelson is considered to be a radical thinker; he is one of the pioneers of the computer industry initiating the Xanadu project, which was started in the early 1960s with the objective of developing a computer network with a simple user interface. He is credited with inventing the term "hypertext."

He holds a first degree in philosophy, a Masters in sociology, and a Doctorate in Media and Governance. Among his honors are a visiting fellowship at the Oxford Internet Institute and a Fellowship of Wadham College, Oxford; in addition, France has knighted him as "Officier des Arts et Lettres." Visit:

RIPE Announces IPv6 Website

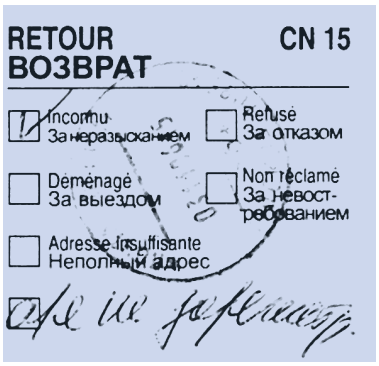
The RIPE NCC recently announced the launch of the *IPv6 Act Now!* website. Available at **www.IPv6ActNow.org**, the website explains IPv6 in terms that everyone can understand and provides a variety of useful information aimed at promoting the global adoption of IPv6. The site is designed for anyone with an interest in IPv6, including network engineers, company directors, law enforcement agencies, government representatives and civil society. The content is regularly updated and includes:

- Education, advice and opinions from the experts
- Latest IPv6-related news stories
- Videos and articles from Internet community leaders
- Current IPv4 exhaustion and IPv6 uptake statistics
- The RIPE community's statement on IPv6 deployment
- Information on community-developed IPv6 distribution policies
- Useful links to other sources of information about IPv6
- A forum for everyone to share experiences, ask questions and find answers

The site also includes contributions from other *Regional Internet Registries* (RIRs) and industry partners. If you have and comments or suggestions about the website, please contact:
ipv6actnow@ripe.net

Four-byte AS numbers from APNIC

From July 1, 2009, the *Asia Pacific Network Information Centre* (APNIC) will assign four-byte *Autonomous System* (AS) numbers by default when receiving requests. Two-byte AS numbers will only be assigned if the applicant can demonstrate that a four-byte only AS number is unsuitable. This change marks the next phase of the transition to four-byte AS numbers. The final phase begins in January 2010, when APNIC will cease to make any distinction between two-byte and four-byte AS numbers, and will operate AS number assignments from an undifferentiated four-byte AS number pool. For more information please see: **http://icons.apnic.net/asn**



Please Tell Us When You Move

We receive large quantities of undeliverable copies of *The Internet Protocol Journal*. For international mailings, the returned mail piece usually includes a standard CN 15 label, an example of which is shown here. We have an extensive collection of CN 15 labels from all over the world, but we would much rather ensure that your journal is delivered to the correct address. So, if you're moving your home or office, please use the online subscription system to update your details, or just send an e-mail message to **ipj@cisco.com** with the new information. You can also suspend paper delivery and read IPJ online if you wish.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ contains standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

From The Editor

This journal has covered numerous emerging technologies since we started publishing in June 1998. It would be an interesting excercise to look at which of these technologies have been successfully deployed, which ones have been rejected, and which ones are still emerging or slowly being deployed. In this issue we examine another emerging technology, or perhaps "a new concept" would be a better term, because a collection of new and old technologies are coming together to form what is collectively known as *Cloud Computing*. In a two-part article on cloud computing, T. Sridhar gives an overview of the concepts underlying this area of development. Part 1 of the article is subtitled "Models and Technologies." It will be followed by Part 2: "Infrastructure and Implementation Topics," which will be published in our next issue.

In the last year, I have had one of my credit cards "compromised" (unauthorized charges posted to the account) and subsequently replaced twice. This situation is always annoying and worrisome. Most likely, these breaches resulted from the card information being captured through an online purchase transaction. I am sure I will never know the full story, and luckily the credit card companies are pretty good about detecting fraudulent charges and quickly resolving the matter. When you start thinking about the number of network and server elements involved in a typical e-commerce transaction, it isn't entirely surprising that someone with criminal intentions could exploit a weakness in the overall system. Our second article, by Michael Behringer, explores the topic of "end-to-end security" in more detail.

Those of you who have been subscribers to this journal for several years have probably noticed that your subscription has been "auto-renewed" once a year without requiring any renewal action on your part. Starting with the December 2009 issue, we will no longer extend your subscription when it expires unless you renew it by visiting the IPJ "Subscriber Services" webpage. You will need to use your e-mail address and Subscription ID in order to gain access to your record, where you can renew, update your delivery address, or change delivery method. IPJ is available on paper, as well as online in both HTML and PDF formats. You can also contact us at **ipj@cisco.com** regarding your renewal. The expiration date and Subscription ID are printed on the back of the journal for subscribers in the United States, and on the envelope for our international subscribers. We believe that this new renewal policy will result in fewer undeliverable or unwanted copies being mailed out—a plus for the environment.

—Ole J. Jacobsen, Editor and Publisher

Cloud Computing—A Primer Part 1: Models and Technologies

by T. Sridhar

Cloud computing is an emerging area that affects IT infrastructure, network services, and applications. Part 1 of this article introduces various aspects of cloud computing, including the rationale, underlying models, and infrastructures. Part 2 will provide more details about some of the specific technologies and scenarios.

The term "cloud computing" has different connotations for IT professionals, depending upon their point of view and often their own products and offerings. As with all emerging areas, real-world deployments and customer success stories will generate a better understanding of the term. This discussion starts with the *National Institute of Standards and Technology* (NIST) definition:

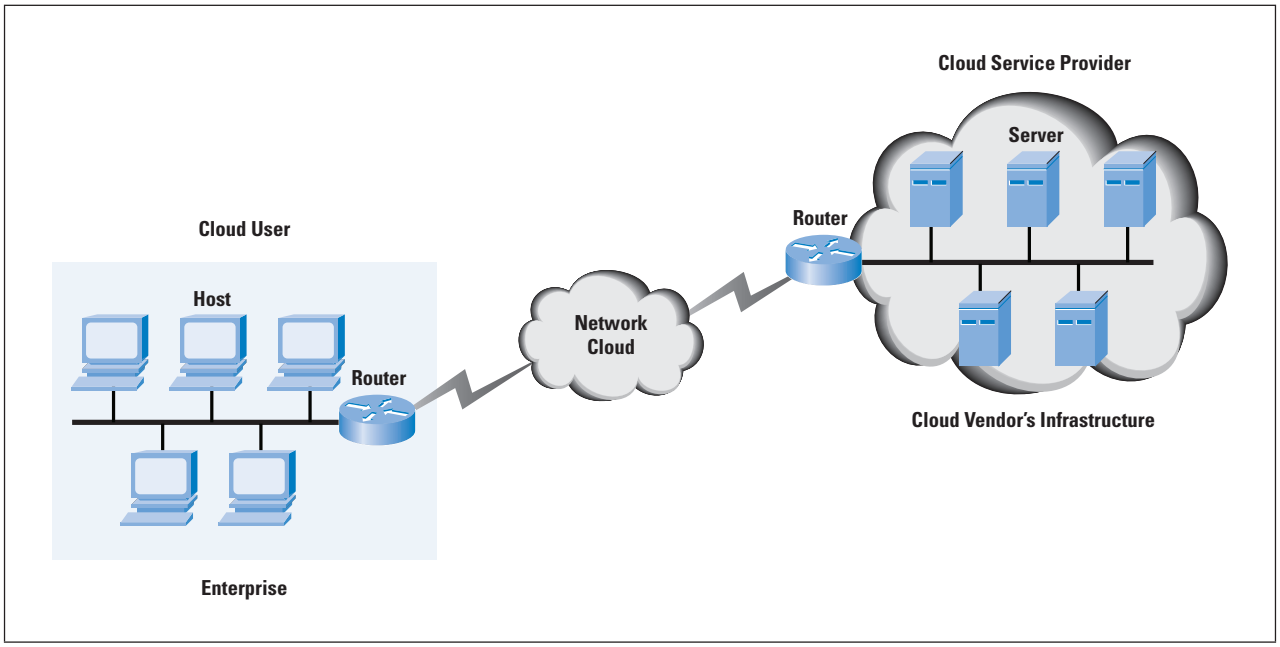
> "Cloud computing is a model for enabling convenient, on-demand network access to a shared pool of configurable computing resources (for example, networks, servers, storage, applications, and services) that can be rapidly provisioned and released with minimal management effort or service provider interaction."

The following is a list of characteristics of a cloud-computing environment. Not all characteristics may be present in a specific cloud solution.

- *Elasticity and scalability:* Cloud computing gives you the ability to expand and reduce resources according to your specific service requirement. For example, you may need a large number of server resources for the duration of a specific task. You can then release these server resources after you complete your task.
- *Pay-per-use:* You pay for cloud services only when you use them, either for the short term (for example, for CPU time) or for a longer duration (for example, for cloud-based storage or vault services).
- *On demand:* Because you invoke cloud services only when you need them, they are not permanent parts of your IT infrastructure—a significant advantage for cloud use as opposed to internal IT services. With cloud services there is no need to have dedicated resources waiting to be used, as is the case with internal services.
- *Resiliency:* The resiliency of a cloud service offering can completely isolate the failure of server and storage resources from cloud users. Work is migrated to a different physical resource in the cloud with or without user awareness and intervention.
- *Multitenancy:* Public cloud services providers often can host the cloud services for multiple users within the same infrastructure. Server and storage isolation may be physical or virtual—depending upon the specific user requirements.

- *Workload movement:* This characteristic is related to resiliency and cost considerations. Here, cloud-computing providers can migrate workloads across servers—both inside the data center and across data centers (even in a different geographic area). This migration might be necessitated by cost (less expensive to run a workload in a data center in another country based on time of day or power requirements) or efficiency considerations (for example, network bandwidth). A third reason could be regulatory considerations for certain types of workloads.

Figure 1: Cloud Computing Context



Cloud computing involves shifting the bulk of the costs from *capital expenditures* (CapEx), or buying and installing servers, storage, networking, and related infrastructure) to an *operating expense* (OpEx) model, where you pay for usage of these types of resources. Figure 1 provides a context diagram for the cloud.

How Is Cloud Computing Different from Hosted Services?

From an infrastructure perspective, cloud computing is very similar to *hosted services*—a model established several years ago. In hosted services, servers, storage, and networking infrastructure are shared across multiple tenants and over a remote connection with the ability to scale (although scaling is done manually by calling or e-mailing the hosting provider). Cloud computing is different in that it offers a pay-per-use model and rapid (and automatic) scaling up or down of resources along with workload migration. Interestingly, some analysts group all hosted services under cloud computing for their market numbers.

Virtualization and Its Effect on Cloud Computing

It can be argued to good effect that cloud computing has accelerated because of the popularity and adoption of virtualization, specifically server virtualization. So what is virtualization? Here, virtualization software is used to run multiple *Virtual Machines* (VMs) on a single physical server to provide the same functions as multiple physical machines. Known as a *hypervisor,* the virtualization software performs the abstraction of the hardware to the individual VMs.

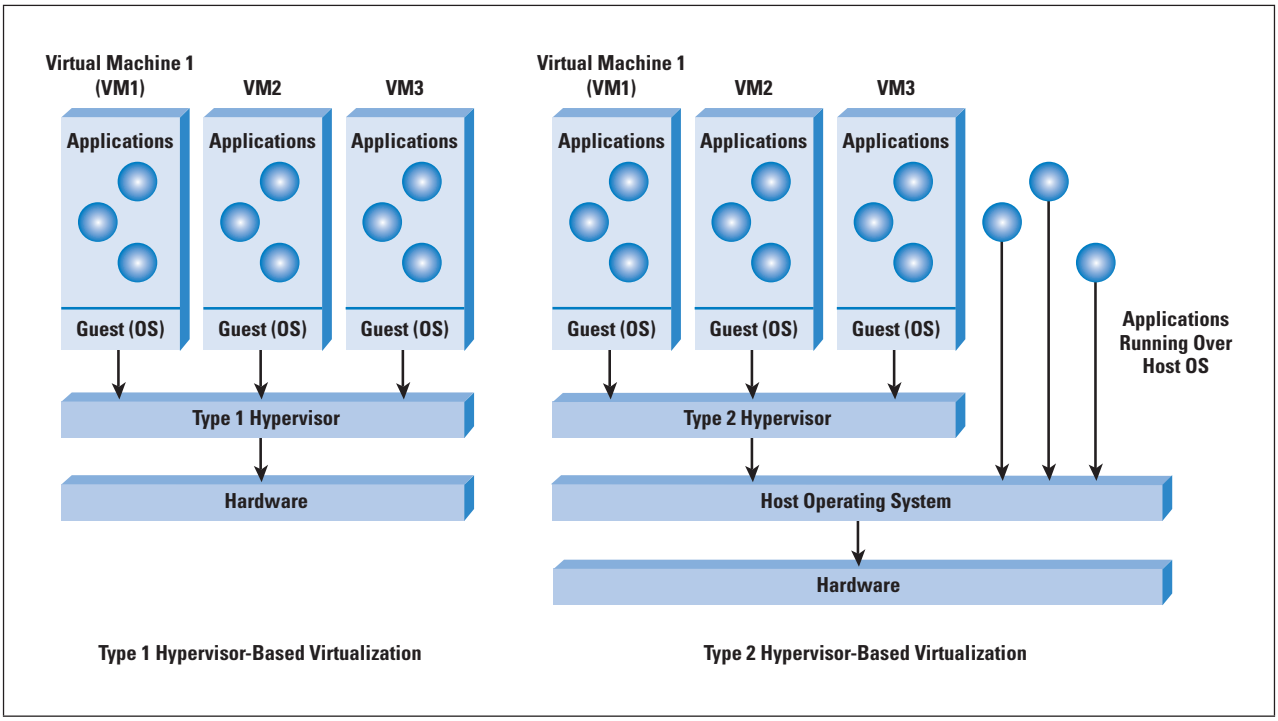
Virtualization is not new—it was first invented and popularized by IBM in the 1960s for running multiple software contexts on its mainframe computers. It regained popularity in the past decade in data centers because of server usage concerns. Data centers and web farms consisted of multiple physical servers. Measurement studies on these server farms noted that individual server usage was often as low as 15 percent for various reasons, including traffic loads and the nature of the applications (available, not always used fully), among others. The consequence of this server sprawl with low usage was large financial outlays for both CapEx and OpEx—extra machines and related power and cooling infrastructure and real estate.

Enter virtualization. A hypervisor is implemented on a server either directly running over the hardware (a *Type 1 hypervisor*) or running over an *operating system* (OS) (a *Type 2 hypervisor*). The hypervisor supports the running of multiple VMs and schedules the VMs along with providing them a unified and consistent access to the CPU, memory, and I/O resources on the physical machine. A VM typically runs an operating system and applications. The applications are not aware that they are running in a virtualized environment, so they do not need to be changed to run in such an environment. Figure 2 depicts these scenarios. The OS inside the VM may be virtualization-aware and require modifications to run over a hypervisor—a scheme known as paravirtualization (as opposed to *full virtualization*).

VM Migration: An Advantage of Virtualization

Some vendors have implemented VM migration in their virtualization solution—a big advantage for application uptime in a data center. What is VM migration? Consider the case of a server with a hypervisor and several VMs, each running an OS and applications. If you need to bring down the server for maintenance (say, adding more memory to the server), you have to shut down the software components and restart them after the maintenance window—significantly affecting application availability. VM migration allows you to move an entire VM (with its contained operating system and applications) from one machine to another and continue operation of the VM on the second machine. This advantage is unique to virtualized environments because you can take down physical servers for maintenance with minimal effect on running applications.

Figure 2: Hypervisors in Virtualization



You can perform this migration after suspending the VM on the source machine, moving its attendant information to the target machine and starting it on the target machine. To lower the downtime, you can perform this migration while the VM is running (hence the name "live migration") and resuming its operation on the target machine after all the state is migrated.

The following are some of the benefits of virtualization in a cloud-computing environment:

- *Elasticity and scalability:* Firing up and shutting down VMs involves less effort as opposed to bringing servers up or down.
- *Workload migration:* Through facilities such as live VM migration, you can carry out workload migration with much less effort as compared to workload migration across physical servers at different locations.
- *Resiliency:* You can isolate physical-server failure from user services through migration of VMs.

It must be clarified that virtualization is not a prerequisite for cloud computing. In fact, there are examples of large cloud service providers using only commodity hardware servers (with no virtualization) to realize their infrastructure. However, virtualization provides a valuable toolkit and enables significant flexibility in cloud-computing deployments.

Major Models in Cloud Computing

This section discusses some popular models of cloud computing that are offered today as services. Although there is broad agreement on these models, there are variations based on specific vendor offerings—not surprising during these early days of cloud computing.

Software as a Service

Consider the case of an enterprise with its set of software licenses for the various applications it uses. These applications could be in human resources, finance, or customer relationship management, to name a few. Instead of obtaining desktop and server licenses for software products it uses, an enterprise can obtain the same functions through a hosted service from a provider through a network connection. The interface to the software is usually through a web browser. This common cloud-computing model is known as *Software as a Service* (SaaS) or a hosted software model; the provider is known as the *SaaS Provider.*

SaaS saves the complexity of software installation, maintenance, upgrades, and patches (for example, for security fixes) for the IT team within the enterprise, because the software is now managed centrally at the SaaS provider's facilities. Also, the SaaS provider can provide this service to multiple customers and enterprises, resulting in a multitenant model. The pricing of such a SaaS service is typically on a per-user basis for a fixed bandwidth and storage. Monitoring application-delivery performance is the responsibility of the SaaS provider. `Salesforce.com` is an example of a SaaS provider. The company was founded to provide hosted software services, unlike some of the software vendors that have hosted versions of their conventional offerings.

Platform as a Service

Unlike the fixed functions offered by SaaS, *Platform as a Service* (PaaS) provides a software platform on which users can build their own applications and host them on the PaaS provider's infrastructure. The software platform is used as a development framework to build, debug, and deploy applications. It often provides middleware-style services such as database and component services for use by applications. PaaS is a true cloud model in that applications do not need to worry about the scalability of the underlying platform (hardware and software). When enterprises write their application to run over the PaaS provider's software platform, the elasticity and scalability is guaranteed transparently by the PaaS platform.

The platforms offered by PaaS vendors like Google (with its *AppEngine*) or `Force.com` (the PaaS offering from `Salesforce.com`) require the applications to follow their own *Application Programming Interface* (API) and be written in a specific language. This situation is likely to change but is a cause for concerns about lock-in. Also, it is not easy to migrate existing applications to a PaaS environment. Consequently, PaaS sees the most success with new applications being developed specifically for the cloud. Monitoring application-delivery performance is the responsibility of the PaaS provider. Pricing for PaaS can be on a per-application developer license and on a hosted-seats basis. Note that PaaS has a greater degree of user control than SaaS.

Infrastructure as a Service

Amazon is arguably the first major proponent of *Infrastructure as a Service* (IaaS) through its *Elastic Computing Cloud* (EC2) service. An IaaS provider offers you "raw" computing, storage, and network infrastructure so that you can load your own software, including operating systems and applications, on to this infrastructure. This scenario is equivalent to a hosting provider provisioning physical servers and storage and letting you install your own OS, web services, and database applications over the provisioned machines. Amazon lets you rent servers with a certain CPU speed, memory, and disk capacity along with the OS and applications that you need to have installed on them (Amazon provides some "canned" software for the OS and applications known as *Amazon Machine Images* [AMIs], so that is one starting point). However, you can also install your own OSs (or no OS) and applications over this server infrastructure.

IaaS offers you the greatest degree of control of the three models. You need to know the resource requirements for your specific application to exploit IaaS well. Scaling and elasticity are your—not the provider's—responsibility. In fact, it is a mini do-it-yourself data center that you have to configure to get the job done. Interestingly, Amazon uses virtualization as a critical underpinning of its EC2 service, so you actually get a VM when you ask for a specific machine configuration, though VMs are not a prerequisite for IaaS. Pricing for the IaaS can be on a usage or subscription basis. CPU time, storage space, and network bandwidth (related to data movement) are some of the resources that can be billed on a usage basis.

In summary, these are three of the more common models for cloud computing. They have variations and add-ons, including *Data Storage as a Service* (providing disk access on the cloud), communications as a service (for example, a universal phone number through the cloud), and so on.

Public, Private, and Internal Clouds

We have focused on cloud service providers whose data centers are external to the users of the service (businesses or individuals). These clouds are known as *public clouds*—both the infrastructure and control of these clouds is with the service provider. A variation on this scenario is the *private cloud*. Here, the cloud provider is responsible only for the infrastructure and not for the control. This setup is equivalent to a section of a shared data center being partitioned for use by a specific customer. Note that the private cloud can offer SaaS, PaaS, or IaaS services, though IaaS might appear to be a more natural fit.

An *internal cloud* is a relatively new term applied to cloud services provided by the IT department of an enterprise from the company's own data centers. This setup might seem counterintuitive at first—why would a company run cloud services for its internal users when public clouds are available? Doesn't this setup negate the advantages of elasticity and scalability by moving this service to inside the enterprise?

It turns out that the internal cloud model is very useful for enterprises. The biggest concerns for enterprises to move to an external cloud provider are security and control. CIOs are naturally cautious about moving their entire application infrastructure and data to an external cloud provider, especially when they have several person-years of investment in their applications and infrastructure as well as elaborate security safeguards around their data. However, the advantages of the cloud—resiliency, scalability, and workload migration—are useful to have in the company's own data centers. IT can use per-usage billing to monitor individual business unit or department usage of the IT resources and charge them back. Controlling server sprawl through virtualization and moving workloads to geographies and locations in the world with lower power and infrastructure costs are of value in a cloud-computing environment. Internal clouds can provide all these benefits.

This classification of clouds as public, private, and internal is not universally accepted. Some researchers see the distinction between private and internal clouds to be a matter of semantics. In fact, the NIST draft definition considers a private cloud to be the same as an internal cloud. However, the concepts are still valid and being realized in service provider and enterprise IT environments today.

When Does Cloud Computing Make Sense?

Outsourcing your entire IT infrastructure to a cloud provider makes sense if your deployment is a "green field" one, especially in the case of a startup. Here, you can focus on your core business without having to set up and provision your IT infrastructure, especially if it primarily involves basic elements such as e-mail, word processing, collaboration tools, and so on. As your company grows, the cloud-provided IT environment can scale along with it.

Another scenario for cloud usage is when an IT department needs to "burst" to access additional IT resources to fulfill a short-term requirement. Examples include testing of an internally developed application to determine scalability, prototyping of "nonstandard" software to evaluate suitability, execution of a one-time task with an exponential demand on IT resources, and so on. The term *cloud bursting* is sometimes used to describe this scenario. The cloud resources may be loosely or tightly coupled with the internal IT resources for the duration of the cloud bursting. In an extremely loosely coupled scenario, only the results of the cloud bursting are provided to the internal IT department. In the tightly coupled scenario, the cloud resources and internal IT resources are working on the same problem and require frequent communication and data sharing.

In some situations cloud computing does not make sense for an enterprise. Regulation and legal considerations may dictate that the enterprise house, secure, and control data in a specific location or geographical area. Access to the data might need to be restricted to a limited set of applications, all of which need to be internal. Another situation where cloud computing is not always the best choice is when application response time is critical. Internal IT departments can plan their server infrastructure and the network infrastructure to accommodate the response-time requirements. Although some cloud providers provide high-bandwidth links and can specify *Service-Level Agreements* (SLAs) (especially in the case of SaaS) for their offerings, companies might be better off keeping such demanding applications in house.

An interesting variation of these scenarios is when companies outsource their web front ends to a cloud provider and keep their application and database servers internal to the enterprise. This setup is useful when the company is ramping up its offerings on the web but is not completely certain about the demand. It can start with a small number of web servers and scale up or down according to the demand. Also, acceleration devices such as *Application Delivery Controllers* (ADCs) can be placed in front of the web servers to ensure performance. These devices provide server load balancing, *Secure Sockets Layer* (SSL) front ends, caching, and compression. The deployment of these devices and the associated front-end infrastructure can be completely transparent to the company; it only needs to focus on the availability and response time of its application behind the web servers.

Cloud Computing Infrastructure

The most significant infrastructure discussion is related to the data center, the interconnection of data centers, and their connectivity to the users (enterprises and consumers) of the cloud service.

A simple view of the cloud data center is that it is similar to a corporate data center but at a different scale because it has to support multiple tenants and provide scalability and elasticity. In addition, the applications hosted in the cloud as well as virtualization (when it is used) also play a part.

A case in point is the *MapReduce* computing paradigm that Google implements to provide some of its services (other companies have their own implementations of MapReduce). Put simply, the MapReduce scheme takes a set of input key-value pairs, processes it, and produces a set of output key-value pairs. To realize the implementation, Google has an infrastructure of commodity servers running Linux interconnected by Ethernet switches. Storage is local through inexpensive *Integrated Drive Electronics* (IDE) disks attached to each server.

Jobs, which consist of a set of tasks, are scheduled and mapped to the available machine set. The scheme is implemented through a *Master* machine and *Worker* machines. The latter are scheduled by the Master to implement Map and Reduce tasks, which themselves operate on chunks of the input data set stored locally. The topology and task distribution among the servers is optimized for the application (MapReduce in this case). Although Google has not made public the details of how the back-end infrastructure is implemented for Google Apps and Gmail, we can assume that the physical and logical organization is optimized for the tasks that need to be carried out, in a manner similar to what is done for MapReduce.

SaaS vendors can partition their cloud data center according to load, tenant, and type of application that they will offer as a service. In some cases they might have to redirect the traffic to a different data center, based on the load in the default data center. IaaS provides the greatest degree of control for the user, as discussed earlier. Even here, the topology and load assignment can be based on the number and type of servers that are allocated.

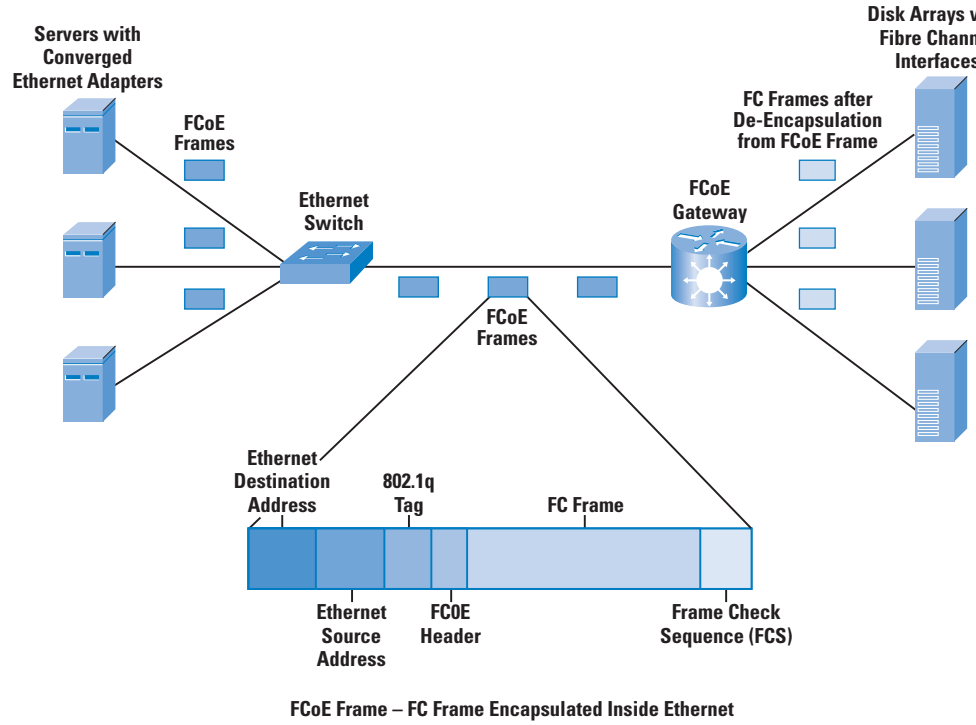
Storage Infrastructure

Storage plays a major part in the data center and for cloud services, especially in environments with virtualization. Storage can be locally attached or accessible through a network—the most popular storage network technologies being *Fibre Channel* and Ethernet. For such network access of storage, servers are equipped with Fibre Channel or Ethernet adapters through which they connect to a Fibre Channel or Ethernet switch. The switch provides the connectivity to storage arrays. Fibre Channel is more popular, though *Network Attached Storage* (NAS) devices with Ethernet interfaces also have a strong presence in the data center. Another Ethernet-based storage option is the *Internet Small Computer System Interface* (iSCSI), which is quite popular among smaller data centers and enterprises because of the cost benefits. This technology involves running the SCSI protocol on a TCP/IP-over-Ethernet connection.

Fibre Channel connections to the storage network necessitate two types of network technologies in the data center: Ethernet for server-to-server and server-to-client connectivity and Fibre Channel for server-to-storage connectivity. A recent initiative in data-center technology is a converged network, which involves the transport of *Fibre Channel over Ethernet* (FCoE). FCoE removes the need for each server to have an Fibre Channel adapter to connect to storage. Instead, Fibre Channel traffic is encapsulated inside an Ethernet frame and sent across to a FCoE gateway that provides Ethernet-to-FCoE termination to connect to Fibre Channel storage arrays (refer to Figure 3). Some storage products provide FCoE functions, so the Ethernet frame can be carried all the way to the storage array. An adapter on the server that provides both "classical" Ethernet and FCoE functions is known as a *Converged Network Adapter* (CNA). Cloud-computing environments can reduce the data-center network complexity and cost through this converged network environment.

Another area in which storage is important is in virtualization and live migration. When a VM migrates to a different physical machine, it is important that the data used by the VM is accessible to both the source and the target machines. Alternatively, if the VM is migrated to a remote data center, the stored data needs to be migrated to the remote data center too. Also, in a virtualized environment, the Fibre Channel, Ethernet, or converged adapter driver should support multiple VMs and interleave its storage traffic to the storage devices. This interleaving is done in consonance with the hypervisor and a designated VM (paravirtualized environments often use this tool), as appropriate.

Figure 3: FCoE in a Cloud Data-Center Environment



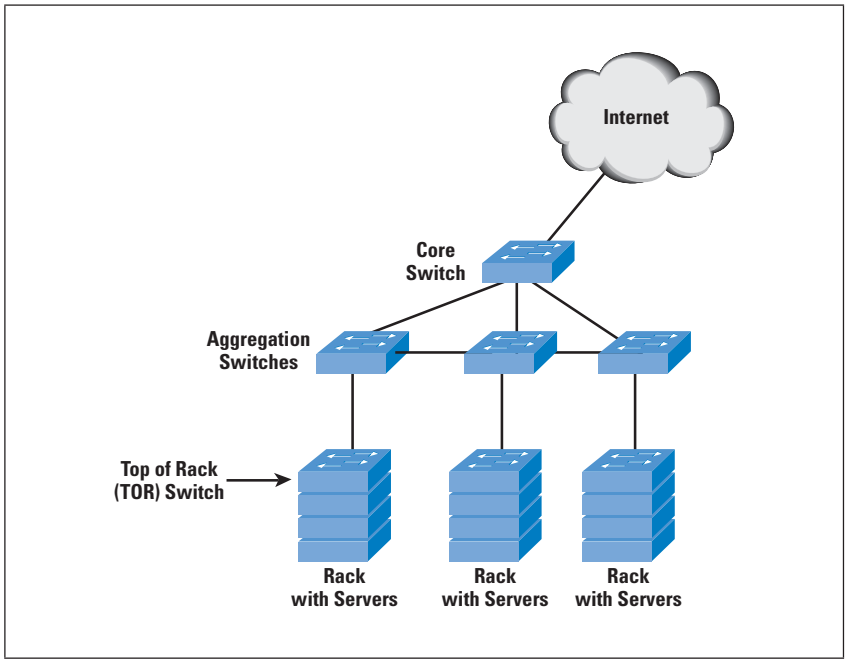
Cloud Computing: Effect on the Network

The previous discussion indicated that the network is a big part of cloud computing. A cloud user connects to the network to access the cloud resources, as indicated earlier in Figure 1. The cloud is accessible through a public network (the Internet) or through a private network (dedicated lines or *Multiprotocol Label Switching* [MPLS] infrastructure, for example). Response-time guarantees depend upon this connectivity. Some cloud vendors offer dedicated links to their data centers and provide appropriate SLAs for uptime or response time and charge for such SLAs. Others might implement a best-effort scheme but provide tools for monitoring and characterizing application performance and response time, so that users can plan their bandwidth needs.

The most significant effect on the network is in the data center, as indicated previously. Let us start with the network architecture or topology. The most common network architecture for enterprises is the three-layer architecture with access, aggregation or distribution, and core switches. The data center requires a slightly different variation to this layering, as proposed by some vendors. The data center consists mainly of servers in racks interconnected through a *Top-of-Rack* (TOR) Ethernet switch which, in turn, connects to an aggregation switch, sometimes known as an *End-of-Rack* (EOR) switch (Figure 4).

The aggregation switch connects to other aggregation switches and through these switches to other servers in the data center. A core switch connects to the various aggregation switches and provides connectivity to the outside world, typically through Layer 3 (IP). It can be argued that most of intra-data center traffic traverses only the TOR and the aggregation switches. Hence the links between these switches and the bandwidth of those links need to account for the traffic patterns. Some vendors have proposed a fat-tree or a leaf-spine topology to address this anomaly, though this is not the only way to design the data-center network. Incidentally, the fat-tree topology is not new—it has been used in *Infiniband* networks in the data center.

Figure 4: Example Data-Center Switch Network Architecture



The presence of virtualized servers adds an extra dimension. Network connections to physical servers will need to involve "fatter pipes" because traffic for multiple VMs will be multiplexed onto the same physical Ethernet connection. This result is to be expected because you have effectively collapsed multiple physical servers into a single physical server with VMs. It is quite common to have servers with 10-Gbps Ethernet cards in this scenario.

New Protocols for Data-Center Networking

Numerous initiatives and standards bodies are addressing the standards related to cloud computing. From the networking side, the IEEE is working on new protocols and the enhancement of existing protocols for data centers. These enhancements are particularly useful in data centers with converged networks—the area is often known as *Convergence Enhanced Ethernet* (CEE).

A previous section indicated the importance of FCoE for converged storage network environments. The IEEE is working to enable FCoE guarantees (because Fibre Channel is a reliable protocol as compared to best-effort Ethernet) through an Ethernet link in what is known as "Lossless Ethernet." FCoE is enabled through a *Priority Flow Control* (PFC) mechanism in the 802.1Qbb activities in the IEEE. In addition, draft IEEE 802.1Qau provides end-to-end congestion notification through a signaling mechanism propagating up to the ingress port, that is, the port connected to the server *Network Interface Card* (NIC). This feature is useful in a data-center topology.

A third draft IEEE 802.1aq defines shortest-path bridging. This work is similar to the work being done in the IETF TRILL *(Transparent Interconnect of Lots of Links)* working group. The key motivation behind this work is the relatively flat nature of the data-center topology and the requirement to forward packets across the shortest path between the endpoints (servers) to reduce latency, rather than a root bridge or priority mechanism normally used in the *Spanning Tree Protocol* (STP). The shortest-path bridging initiative in IEEE 802.1aq is an incremental advance to the *Multiple Spanning Tree Protocol* (MSTP), which uses the *Intermediate System-to-Intermediate System* (IS-IS) link-state protocol to share learned topologies between switches and to determine the shortest path between endpoints.

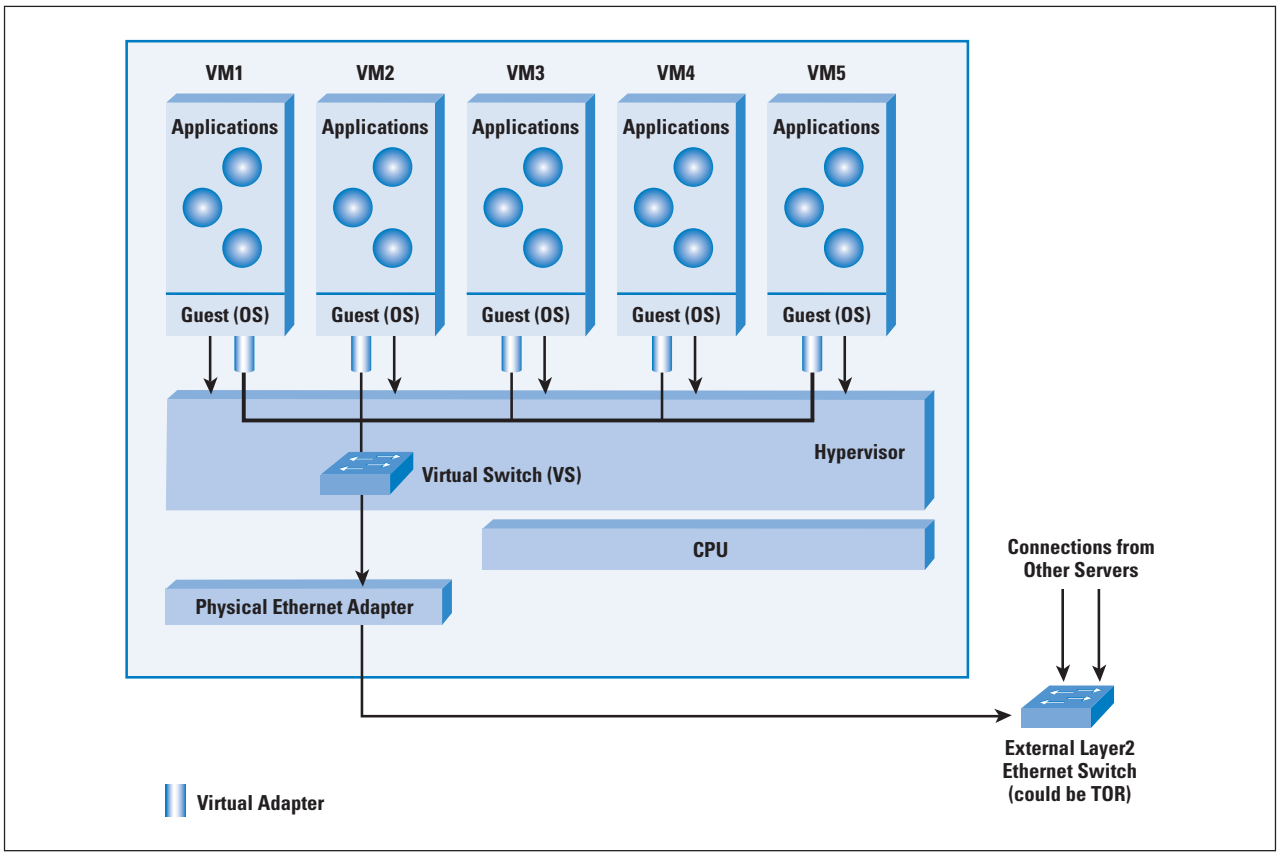
The fourth draft 802.1Qaz is also known as *Enhanced Transmission Selection* (ETS). It allows lower-priority traffic to burst and use the unused bandwidth from the higher-priority traffic queues, thus providing greater flexibility.

Virtualized Network Equipment Functions

Though cloud computing does not depend upon virtualization, several cloud infrastructures are built with virtualized servers. In an environment with physical servers, switches are used to connect servers to other servers. Firewalls and application-delivery controllers are other types of equipment that you can use in a data center on the connection to external clients. With a virtualized environment, you can move some or all of these functions to reside inside a server.

Consider the case of the software-based *Virtual Switch* as shown in Figure 5. You can use the Virtual Switch to switch between VMs inside the same physical server and aggregate the traffic for connection to the external switch. The Virtual Switch is often implemented as a plug-in to the hypervisor. The VMs have virtual Ethernet adapters that connect to the Virtual Switch, which in turn connects to the physical Ethernet adapter on the server and to the external Ethernet switch. To the network manager, the virtual switch can appear as a part of the network. Unlike physical switches, the Virtual Switch does not necessarily have to run network protocols for its operation, nor does it need to treat all its ports the same because it knows that some of them are connected to virtual Ethernet ports (for example, it can avoid destination address learning on the ports connected to the VMs). It can function through appropriate configuration from an external management entity.

Figure 5: Virtual Ethernet Switch in a Virtualized Server Environment



It is possible to implement a virtualized firewall as a VM instead of as a plug-in to the hypervisor. These VMs are self-contained, with an operating system along with the firewall software. The complete package is known as a *firewall virtual appliance*. These VMs can be loaded and configured so that network packets destined for any of the VMs pass through the firewall VM, where they are validated before being passed to the other VMs. Another use of the firewall VM is as a front end to the physical servers in the data center. The disadvantage of a virtual appliance is the performance hit due to its implementation as a software function in a virtualized environment.

Management

Management has several facets in a cloud-computing environment: billing, application-response monitoring, configuring network resources (virtual and physical), and workload migration. In a private cloud or tightly coupled environment, management of the applications may have to be shared between the internal cloud and the private cloud.

You can manage cloud-computing environments in several ways, depending upon the specific area. You can manage the network equipment (physical and virtual) through the *Simple Network Management Protocol* (SNMP) and a network management console. In a virtualized environment, the virtualization vendor often offers a framework to manage and monitor VMs, so this is another part of the equation. Several vendors offer products to act as management front ends for public clouds; for example, Amazon, whose products act as brokers and management consoles for your application deployed over the Amazon cloud offering.

It is clear that this area of management for cloud computing is still evolving and needs to be tied together for a unified management view.

Cloud Computing: Common Myths

Thus far, we have considered the important technologies, terminology, and developments in cloud computing. This section outlines some common myths about cloud computing.

- *Myth: Cloud computing should satisfy all the requirements specified: scalability, on demand, pay per use, resilience, multitenancy, and workload migration.*

  In fact, cloud-computing deployments seldom satisfy all the requirements. Depending upon the type of service offered (SaaS, IaaS, or PaaS), the service can satisfy specific subsets of these requirements. There is, however, value in trying to satisfy most of these requirements when you are building a cloud service.

- *Myth: Cloud computing is useful only if you are outsourcing your IT functions to an external service provider.*

  Not true. You can use cloud computing in your own IT department for on-demand, scalable, and pay-per-use deployments. Several vendors offer software tools that you can use to build clouds within your enterprise's own data center.

- *Myth: Cloud computing requires virtualization.*

  Although virtualization brings some benefits to cloud computing, including aspects such as efficient use of servers and workload migration, it is not a requirement for cloud computing. However, virtualization is likely to see increased usage in cloud deployments.

- *Myth: Cloud computing requires you to expose your data to the outside world.*

  With internal clouds you will never need to expose your data to the outside world. If data security and privacy are concerns, you can develop a cloud model where web front ends are in the cloud and back-end data always resides in your company's premises.

- *Myth: Converged networks are essential to cloud computing.*

  Although converged networks (with FCoE, for example) have benefits and will see increased adoption in data centers in the future, cloud computing is possible without converged networks. In fact, some cloud vendors use only Fibre Channel for all their storage needs today. Use of converged networks in the future will result in cost efficiencies, but it is not a requirement today.

Cloud Computing: Gaps and Concerns

Cloud-computing technology is still evolving. Various companies, standards bodies, and alliances are addressing several remaining gaps and concerns. Some of these concerns follow:

- *Security:* Security is a significant concern for enterprise IT managers when they consider using a cloud service provider. Physical security through isolation is a critical requirement for private clouds, but not all cloud users need this level of investment. For those users, the cloud provider must guarantee data isolation and application security (and availability) through isolation across multiple tenants. In addition, authentication and authorization of cloud users and encryption of the "network pipe" from the cloud user to the service provider application are other factors to be considered.
- *Network concerns:* When cloud bursting is involved, should the servers in the cloud be on the same Layer 2 network as the servers in the enterprise? Or, should a Layer 3 topology be involved because the cloud servers are on a network outside the enterprise? In addition, how would this work across multiple cloud data centers?
- *Cloud-to-cloud and Federation concerns:* Consider a case where an enterprise uses two separate cloud service providers. Compute and storage resource sharing along with common authentication (or migration of authentication information) are some of the problems with having the clouds "interoperate." For virtualized cloud services, VM migration is another factor to be considered in federation.
- *Legal and regulatory concerns:* These factors become important especially in those cases involving storing data in the cloud. It could be that the laws governing the data are not the laws of the jurisdiction where the company is located.

Conclusion

This article introduced the still-evolving area of cloud computing, including the technologies and some deployment concerns. Definitions and standardization in this area are a work in progress, but there is clear value in cloud computing as a solution for several IT requirements. In Part 2 we will provide a more detailed look at some of the technologies and scenarios for cloud computing.

Why End-to-End Security Is Necessary But Not Sufficient

by Michael H. Behringer, Cisco Systems

End-to-end security relies on protocols and mechanisms that are implemented exclusively on the endpoints of a connection. The most typical example is an HTTPS connection (based, for example, on *Transport Layer Security* (TLS)[1]) to a web server; *IP Security* (IPsec)[2] can also be used for end-to-end security, as was initially proposed as a default connection mechanism for IPv6.

There is a perception that end-to-end security is sufficient as a security solution, and that network-based security is obsolete in the presence of end-to-end security. This article outlines why in practice end-to-end security alone is not sufficient, and why network-based security is also required.

Defining "End"

The traditional definition of an endpoint is a client or server. In this definition end-to-end security starts on the client and ends on the server. Given the multitude of applications running in parallel on an operating system, and given increasing virtualization, this definition is usually no longer precise enough. The operating system can establish a security association on either the session or application level. It can also be terminated on a front end, on behalf of numerous servers, as is the case in many TLS[1] deployments.

Because the main goal of this article is to understand why the network has a role to play in security, the precise definition of an endpoint is not relevant here. Abstractly seen, an endpoint is an entity that communicates over a network with another entity. This definition, albeit vague, is sufficient for the discussion at hand.

End-to-End Security Is Fundamental

Security on the endpoints (client-server, or client-client for peer-to-peer) is an absolute requirement for secure communications. Such a solution contains the following components:

- *Identity:* This component encompasses known and verifiable entity identities on both ends; note that an identity can be temporary for a connection. For example, a user often is identified by username and password, whereas a server may be identified through a server certificate.
- *Protocols* (for example, TLS [1] and IPsec [2]): Protocols are used to dynamically negotiate session keys, and to provide the required security functions (for example, encryption and integrity verification) for a connection. Protocols use algorithms to implement these functions.

- *Algorithms* (for example, *Advanced Encryption Standard* [AES][3], *Triple Digital Encryption Standard* [3DES][4], and *Secure Hash Algorithm* [SHA-1][5]): These algorithms use the previously mentioned session keys to protect data in transit, for example through encryption or integrity checks.
- *Secure implementation:* The endpoint (client or server) that runs one of these protocols mentioned previously must be free of bugs that could compromise security. Web browser security is relevant here. Also malware can compromise security, for example by logging key strokes on a PC.
- *Secure operation:* Users and operators have to understand the security mechanisms, and how to deal with exceptions. For example, web browsers warn about invalid server certificates, but users can override the warning and still make the connection. This concern is a nontechnical one, but is of critical concern today.

For full end-to-end security, all of these components must be secure. In networks with end-to-end security, both ends can typically (depending on the protocols and algorithms used) rely on the fact that their communication is not visible to anyone else, and that no one else can modify the data in transit. End-to-end security is used successfully today, for example, in online banking applications. Correct and complete end-to-end security is required; without it, many applications such as online banking would not be possible.

However, a single security problem in any of the components can compromise the overall security for a connection. Today, most critical are implementation problems on endpoints, as well as human errors, specifically in handling exception cases.

Practical Shortcomings of End-to-End Security

Solutions that rely exclusively on end-to-end security have many potential problems, which fall into two broad categories: those that affect the end user and those that affect the network operator (the service provider, or the enterprise network operator, for example).

The End-User View

As reports on online crime and fraud demonstrate very clearly, even in the perceived presence of end-to-end security it is difficult to ensure that none of the components mentioned previously is "broken." Although protocols and algorithms in use tend to be secure and reliable, the main problems lie in the two main areas of endpoint security (secure implementation component) and lack of user education (secure operation component).

Endpoint security concerns include the presence of malware, as well as bugs in software. Even security professionals have difficulty determining whether a PC contains malware. Such malware can control the connection before it is secured, thereby achieving the ability to see the data, as well as potentially change it in real time. Although endpoint security software such as antivirus solutions as well as zero-day prevention solutions provides good security, they are not always installed, and antivirus software is often not up-to-date. Users also can temporarily disable the solutions. Therefore, the presence of malware remains a security concern. Bugs in software are also relevant, for example in the web browser or the operating system.

The lack of user education is the other important concern on the endpoint: Users must know how to identify a secured connection, for example by the little padlock in a web browser (although not even this security mechanism is completely secure). They must also know how to deal with exceptions such as expired or invalid certificates. Most average users do not entirely understand all these details, leading to breaches of security.

The Network Operator View

In the early days of IPv6 it was postulated that the protocol would come with IPsec end-to-end security built in and always "on," thereby eliminating all security problems. This assumption turned out to be wrong, because many problems remain on the network side—for example, general problems with end-to-end security—and they apply to all variants, such as IPsec, TLS, or *Secure Sockets Layer* (SSL).

Today, most enterprise network operators as well as service providers are skeptical about the ubiquitous use of end-to-end security solutions. The fundamental concern is that the endpoints generally cannot be trusted. The network operator, whether enterprise, university, or service provider, has an obligation to enforce certain policies on the endpoint, for example, to ensure that it does not spread worms, send spam mail, or attack servers. If, however, network operators cannot "see" the traffic of an endpoint because it is end-to-end secured, then they cannot comply with their obligations to control the endpoints.

From a network operator's perspective it is therefore not generally desirable to use end-to-end security for all communications, but only for those that really need it.

Why Network-Based Security Is Essential

There are many examples where network-based security is essential, and where end-to-end security solutions not only do not help, but may actually present an additional problem. In all those cases it is essential to have strong network-based security solutions in place. Some examples explain this in more detail.

The Service Provider with DSL Customers

A service provider with DSL customers needs to control its users' traffic in various ways. However, the provider has no control over the endpoints, because those are the customers' property. Because they also cannot force their customers to use appropriate security software, there is always a certain percentage of infected PCs on any given service provider's network. Critical service provider concerns follow:

- *Control of PCs infected with malware:* Such PCs (also referred to as "bots" or "zombies") can infect other PCs and participate in illegal activities, such as spam mail, click fraud[12], *Denial-of-Service* (DoS) attacks, etc. There is a strong, often legal requirement for providers to identify such infected PCs, to isolate them, and to alert their owners and help them to "disinfect" the PC. Network-based security mechanisms are required, essentially because security on the endpoint has failed.
- *Attacks from the users:* Even in the absence of malware, a service provider's user can participate in illegal activities, such as DoS attacks, or intrusions on web servers or routers. Network-based methods are required to detect such attempts, beginning with simple forms such as IP spoofing [6], and to prevent or block them. One example is network-based solutions against DoS attacks[7,8].
- *Control of bandwidth:* Many service providers need to enforce bandwidth limits on some applications or users because they violate service agreements. Also here, applications are necessary to control the PCs, and to limit their usage of the service to remain within contracted boundaries. Service providers today employ a large number of network-based security mechanisms, ranging from visibility solutions to enforcement of certain policies. Endpoint security does not solve these problems, because the PC is not under control of the service provider, and is typically untrusted.
- *Services:* Service providers also try to differentiate themselves from their competition by offering managed services, for example managed security services[9]. Those services are also network-based, and they complement endpoint security solutions that their customers use.

The Service Provider with Customers Under Attack

Service providers may also be required to help their customers when they are under attack. DoS attacks illustrate why endpoint security may not be sufficient, and network-based security is required. Under a DoS attack, a web server, for example, may receive more traffic than it can handle. Such attacks can also overload network resources, such as subscriber lines or routers; therefore, endpoint security is not able to solve such attacks. Massive overprovisioning would be the only way to handle DoS attacks, but this approach is commercially not generally feasible. Network-based solutions based on flow analysis and selective discard of flows are required to help in such situations.

The Enterprise Network

At first glance it seems that enterprises should have full control over the PCs in the enterprise. In such a case, it would be possible to rely completely on end-to-end security. However, this assumption is unrealistic. Numerous current shortcomings make this approach impractical today:

- Enterprise PCs can also get infected with malware, leading to the same problem as for service providers described previously: the need to monitor and control the behavior of a PC in the network. Solutions to control endpoints are themselves network-based; for example, network endpoint assessment[10] and user authentication (802.1x)[11].
- Attacks from users, or against services within the enterprise, also exist in an enterprise environment, as explained previously for service providers. Solutions are network-based.
- The enforcement of *Quality of Service* (QoS) is also a security concern: Users could wrongly classify all their traffic as "high-priority." In the absence of full application control on the PC (which is impractical today), the network needs to control flows from the PC, and potentially enforce a QoS policy. If all flows were encrypted end-to-end, this control would be "blind," probably leading to undesired results. Network security mechanisms are required to control the QoS policy.
- Scale: In an enterprise with several offices that are connected over an untrusted network (for example, the Internet), it may be impractical today to roll out full end-to-end security across the entire enterprise. The currently used approach in most enterprises is to connect the offices with IPsec gateways, and leave traffic within an office in the clear. This scenario increases manageability and scalability of the network. Again, this solution is network-based security solution.
- Although PCs can theoretically be equipped with IPsec (for example) for all communications, many end devices in an enterprise do not support the security mechanisms required. Printers, faxes, and scanners are examples. Full end-to-end security, however, would require all endpoints to support a common mechanism, such as IPsec or TLS. Until all such devices have this support, network-based mechanisms are required to secure communications with them.

Summary

End-to-end security protocols and solutions are an essential cornerstone in network security. We cannot live without them. However, it is unrealistic in today's networks to assume that end-to-end security solutions alone will suffice. The fundamental underlying problem is that typically the network operator, where a PC is attached, has a need and often an obligation to monitor the behavior of the endpoint, and to control malicious activities emerging from that PC. All solutions to control endpoints, however, are by definition network-based. Therefore, network-based security mechanisms are also an essential component of overall network security: Overall security requires both endpoint security and network-based security.

[12] According to Wikipedia: "Click fraud is a type of Internet crime that occurs in pay per click online advertising when a person, automated script or computer program imitates a legitimate user of a web browser clicking on an ad, for the purpose of generating a charge per click without having actual interest in the target of the ad's link. Click fraud is the subject of some controversy and increasing litigation due to the advertising networks being a key beneficiary of the fraud.

Use of a computer to commit this type of Internet fraud is a felony in many jurisdictions, for example, as covered by *Penal Code 502* in California, USA, and the *Computer Misuse Act 1990* in the United Kingdom. There have been arrests relating to click fraud with regard to malicious clicking in order to deplete a competitor's advertising budget."

Letter to the Editor

End of Eternity

Dear Ole,

In their "The End of Eternity" articles, (IPJ Volume 11, No. 4 and Volume 12, No. 1) Niall Murphy and David Wilson provide a detailed and compelling description of the lasting harm that could result from the exhaustion of unallocated IPv4 addresses—harm to Internet users and aspiring new entrants, to technical-coordination and fault-management mechanisms, and to the likely irreplaceable cooperative decision-making and consensus-development mechanisms that distinguish the Internet from every other important transnational sphere of activity in human history. Thankfully, the authors foresee a potential happy ending—or at least yet another chapter in the story—in "an IPv6 Internet, or at least enough of one to keep off address scarcity for a workable subset of the industry."

However, having foreshadowed how they expect the IP addressing cliffhanger to be resolved, the authors go on to detail a variety of interesting but considerably less persuasive assumptions and predictions, all based on the *stipulation* that establishing IPv4 address markets would represent the best means to "shorten the gap" between the end of IPv4 and the return to a "normal" state of Internet growth and development, that is, one that is unconstrained by IP address-related scarcity (or at least no more constrained than it has been over the last decade-plus of CIDR and hierarchical interdomain routing).

I believe that it is worth highlighting here the logic that binds these two engaging and well-written articles together into something that is, unfortunately, substantially less than the sum of its parts. If the authors are to be taken at their word that "an IPv6 Internet" represents the only currently feasible and also *satisfactory* conclusion to "the IPv4 end game," then that conclusion does not by itself entail that IPv4 markets are the only, or most obvious or effective—or even *workable*—candidate mechanisms for coordinating the distribution of IP addressing in the run-up to more widespread IPv6 adoption. And yet, that postulate is offered, without explanation or defense, as the grounding justification for an investigation of various optional features and collateral effects that the foretold IPv4 address market might have.

Many observers have committed untold pages and pixels to the exploration of hypothetical IPv4 address markets, both in IPJ and elsewhere, going back as far as RFC 1744 (1994). The two articles by Murphy and Wilson represent valuable additions to that growing corpus. However, to my knowledge, no other writings in this area have built on the proposition that IPv6 is indispensable; therefore, IPv4 addresses should be privately traded. To put it in the most generous possible terms, this claim is highly contestable. As separate and independent analyses, IPJ readers may derive many useful insights from these two articles, but attributing any special relevance to those insights based on any presumptive connection between IPv4 markets and the future necessity or viability of IPv6 would be a mistake.

CSNET Receives 2009 Postel Service Award

The *Internet Society* (ISOC) has awarded the *Jonathan B. Postel Service Award* for 2009 to CSNET, the *Computer Science Network*, a research networking effort that during the early 1980s provided the critical bridge from the original research undertaken through the ARPANET to the modern Internet.

The award recognizes the pioneering work of the four principal investigators that conceived and later led the building of CSNET—Peter J. Denning, David Farber, Anthony C. Hearn and Lawrence Landweber—and the U.S. National Science Foundation program officer and visionary responsible for encouraging and funding CSNET—Kent Curtis.

Stephen Wolff, a past recipient of the Postel Award, said, "CSNET was a critical link in the transition from the research-oriented ARPANET to today's global Internet. CSNET also helped lead the way by sharing technologies, fostering connections, and nurturing the worldwide community that provided a foundation for the global expansion of the Internet."

ISOC presented the award, including a US$20,000 honorarium and a crystal engraved globe, during the 75th meeting of the *Internet Engineering Task Force* (IETF) in Stockholm, Sweden. The awardees have requested that the ISOC present the honorarium to non-profit organizations they believe support the spirit of the award.

Lynn St. Amour, President and CEO of the ISOC, said "In many ways, CSNET helped set the stage for the Internet that today reaches more than 1 billion people. CSNET's community-driven, self-sustaining governance structure was an early example of the model that helps ensure that even as today's Internet grows and evolves, it remains an open platform for innovation around the world."

CSNET began in 1981 with a five-year grant from the U.S. *National Science Foundation* (NSF). Five years later, CSNET connected more than 165 academic, government and industrial computer research groups comprised of more than 50,000 researchers, educators and students across the United States and around the world. It had concluded a seminal resource sharing agreement with the ARPANET and was self-governing and self-supporting. Open to all computer researchers, it demonstrated that researchers valued the kind of informal collaboration it made possible. CSNET's success was critical to the decision by NSF in 1986 to adopt the Internet technology for NSFNET, the network backbone to connect its supercomputing centers and their research communities. CSNET provided software, policies, and experienced alumni to the NSFNET teams. NSFNET became the first backbone of the modern Internet.

The CSNET architecture supported the Internet standards, SMTP and TCP/IP, and a variety of connection protocols including telephone dialup, X.25, and ARPANET. This architecture, along with strong technical support, enabled participants of differing means and skill levels to all join the community. CSNET pioneered the model of university, industry, government partnerships that were key to the pre-commercial Internet.

The CSNET proposal was assembled by a lengthy community consensus process that began in 1979. The four principal investigators, who led this effort and served as the project's management committee, were:

Peter Denning was head of the computer science department at Purdue University. His team included professor Douglas Comer, who was responsible for the software that ran TCP/IP over the GTE Telenet X.25 commercial packet network.

David Farber was a professor of electrical engineering at University of Delaware. His team included then graduate student David Crocker, who was responsible for Phonenet, dial-in telephone connections to relay servers for e-mail exchange.

Anthony Hearn was head of the information sciences department at RAND. His team included Michael O'Brien, who was responsible for the relays connecting CSNET and ARPANET.

Lawrence Landweber was a professor of computer science at the University of Wisconsin. His team included professor Marvin Solomon and Michael Litzkow who were responsible for the name server, a precursor of modern Directory Services.

At the NSF, the late *Kent Curtis* helped conceive the entire effort and, with assistance from Bill Kearn, saw it through its formative years. He was recognized for his pivotal role by the Computing Research Association's first distinguished service award in 1988.

The *Jonathan B. Postel Service Award* was established by the Internet Society to honor individuals or organizations that, like Jon Postel, have made outstanding contributions in service to the data communications community. The award is focused on sustained and substantial technical contributions, service to the community, and leadership. With respect to leadership, the nominating committee places particular emphasis on candidates who have supported and enabled others in addition to their own specific actions. Previous recipients of the Postel Award include Jon himself (posthumously and accepted by his mother), Scott Bradner, Daniel Karrenberg, Stephen Wolff, Peter Kirstein, Phill Gross, Jun Murai, Bob Braden and Joyce K. Reynolds (jointly), Nii Quaynor, and La Fundación Escuela Latinoamericana de Redes (EsLaRed). The award consists of an engraved crystal globe and a US$20,000 honorarium. For more information about the award, visit: **`http://www.isoc.org/postel`**

ISOC is a non-profit organization founded in 1992 to provide leadership in Internet related standards, education, and policy. ISOC is dedicated to ensuring the open development, evolution, and use of the Internet for the benefit of people throughout the world. More information is available at: `http://www.isoc.org`

NRO Declaration on RPKI

The *Number Resource Organization* (NRO) recently declared: "Over several years, a set of mechanisms has been under development for digital certification of Internet number resources, through a so-called *Resource Public Key Infrastructure,* or "RPKI." Like other PKIs, the RPKI requires one or more root authorities, to act as so-called *trust anchors* for one or more certification hierarchies.[1]

The RPKI architecture has been designed to allow a number of trust anchor configurations involving: either a single trust anchor located at the root of a single certification hierarchy; a set of independent trust anchors to be located at the roots of several independent hierarchies; or a hybrid of these. The alternative models may have advantages and disadvantages in various dimensions including: operational efficiency; alignment with resource allocation hierarchies; centralisation vs distribution of functions; recognised global or regional authority; and, operational capacity of the respective host organisations.

The *Regional Internet Registries* (RIRs) believe that the optimal eventual RPKI configuration involves a single authoritative trust anchor. That configuration may not be achievable in the short-term and the details and timelines for its implementation will depend among other things on discussions within the RIRs' communities and dialogues with others including the *Internet Architecture Board* (IAB) and the *Internet Engineering Task Force* (IETF).

In the meantime, the RIRs have agreed to undertake pragmatic implementations of RPKI services based on interim trust anchor models, such as, self-signed trust anchors. All such implementations will comply with the overall RPKI architecture. The implementations will also have the ability to evolve into a single trust anchor model and to provide robust and fully operational (and inter-operational) services for those who wish to use them. The objective is for all RIRs to be ready to start issuing certificates by no later than January 1, 2011.

The RIRs will continue working with and receiving feedback from their respective communities and industry partners to ensure effective ongoing evolution of the RPKI system."

For more information about the NRO, see `http://www.nro.net/`

ARIN Hosts 4-byte ASN Wiki

The *American Registry for Internet Numbers* (ARIN) has created a wiki to focus on issues related to 4-byte *Autonomous System Numbers* (ASNs)[2]. This wiki provides a central repository for ongoing discussion and information exchange associated with 4-byte ASN topics and issues. The wiki can be found at: **www.get4byteasn.info**

Ongoing Internet growth is rapidly depleting the existing pool of 2-byte ASNs (65,536 numbers in total). As a result, the IETF has approved the expansion of AS Numbers from 2-bytes to 4-bytes, to include over 4 billion ASNs. Following a globally coordinated policy, ARIN and the other RIRs began assigning 4-byte ASNs by request in January 2007 and by default in January 2009. However, some routers do not support the use of these 4-byte ASNs.

ARIN has set up this wiki to help educate the community about 4-byte ASN operational issues, to help vendors understand how to provide 4-byte ASN support in their products and to help network operators find those products. A wide range of community stakeholders will be able to share and benefit from information contributed to the wiki. ARIN looks forward to participation from everyone, including users, ISPs, and vendors, with interest in this topic.

Upcoming Events

The *North American Network Operators' Group* (NANOG) will meet in Dearborn, Michigan, October 18–21. Following the NANOG meeting, the *American Registry for Internet Numbers* (ARIN) will meet in the same venue October 21–23. For more information see: **http://nanog.org** and **http://arin.net**

The *Internet Engineering Task Force* (IETF) will meet in Hiroshima, Japan, November 8–13, 2009 and in Anaheim, California, March 21–26, 2010. For more information see:
http://www.ietf.org/meeting/

The *Internet Corporation for Assigned Names and Numbers* (ICANN) will meet in Seoul, Korea, October 25–30, 2009 and Nairobi, Kenya, March 7–12, 2010, and in Brussels, Belgium, June 21–25, 2010. For more information, see: **http://icann.org/**

The *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT) will meet in Kuala Lumpur, Malaysia, February 23–March 5, 2010. For more information see:
http://www.apricot2010.net/

From The Editor

In our last issue we brought you Part 1 of a two-part article on *Cloud Computing*. T. Sridhar introduced various aspects of cloud computing, including the rationale, underlying models, and infrastructures. Part 2, subtitled "Infrastructure and Implementation Topics," is included in the current issue. Cloud computing has received a great deal of press in recent months and continues to be an area of rapid development. I'm confident that we will have more articles about this topic in future editions of IPJ.

With this issue we start a new series of articles under the general heading "Protocol Basics." The idea is to present a series of in-depth tutorials on numerous protocols that are used every day on the Internet and in enterprise networks. The articles will cover protocol details as well as implementation, deployment, and usage scenarios. In some cases the articles will also summarize the "lessons learned" and present "best-practice" guidelines. To start the series, we asked Bill Stallings to give us an overview of the *Secure Shell* (SSH) Protocol. We invite you to send us suggestions for other protocols that you'd like to see covered in this series.

Today's Internet is a result of many years of technological development and innovative uses of the resulting infrastructure. Of equal importance has been many *policy* choices made over the years, ranging from what protocols to use to how to allocate finite resources such as the IPv4 address space. A new book, *Protocol Politics: The Globalization of Internet Governance,* explores some of this history. The book is examined in an extended review by Tom Vest.

Let me remind you that we will no longer be automatically extending your subscription when it expires. Please take a moment to check your expiration date (printed on the back of the journal for subscribers in the United States, and on the envelope for our international subscribers). Visit the "Subscriber Services" section of our webpage at **www.cisco.com/ipj** to update or renew your subscription. You can also contact us by e-mail to **ipj@cisco.com** regarding any aspect of your subscription.

Cloud Computing—A Primer
Part 2: Infrastructure and Implementation Topics

by T. Sridhar

Cloud computing is an emerging area that affects IT infrastructure, network services, and applications. In Part 1[0] of this two-part article, we introduced various aspects of cloud computing, including the rationale, underlying models, and infrastructures. In Part 2 we discuss specific infrastructure aspects of cloud computing in detail, specifically:

- Network Infrastructure
- Cloud-to-Cloud and Federation Considerations
- Security

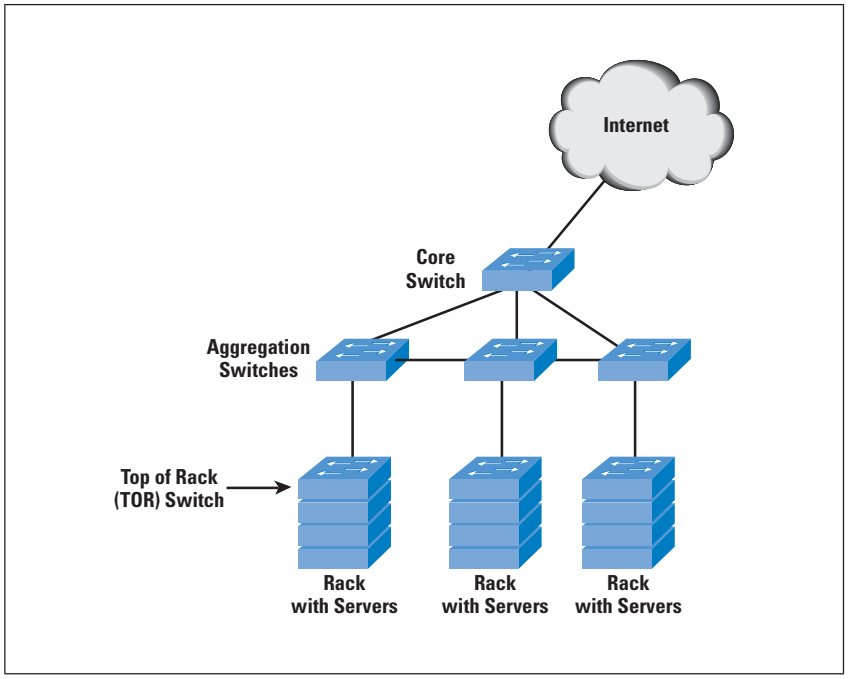
In addition, we will provide some perspective on select topics in cloud computing that have garnered interest. Remember that cloud computing is an emerging area where approaches to some of these topics are still evolving. In addition, although cloud computing is not intrinsically dependent upon virtualization, there is common agreement that virtualization (specifically, server virtualization) will be an integral part of cloud-computing solutions of the future. Consider the discussion in the following sections in this context.

Network Infrastructure

In a limited sense, the cloud can be treated as a large data center run by an external entity providing the capability for elasticity, on-demand resources, and per-usage billing. Data-center architecture often follows the common three-layer network topology of access, aggregation, and core networks with enabling networking elements (switches and routers). Consider the topology shown in Figure 4 of Part 1, reproduced here as Figure 0. The servers can be connected through a 1-Gbps link to a *Top of Rack* (TOR) switch, which in turn is connected through one or more 10-Gbps links to an aggregation *End of Row* (EOR) switch. The EOR switch is used for interserver connectivity across racks. The aggregation switches themselves are connected to core switches for connectivity outside the data center.

From a functional perspective, data-center server organization has often adopted a three-tier architecture (a specific case of an N-tier architecture). The three-tier functional architecture has a web or *Presentation Tier* on the front end, an *Application Tier* to perform the application and business-processing logic, and finally a *Database Tier* (to run the database management system), which is accessed by the Application Tier for its tasks (refer to Figure 1 on page 4).

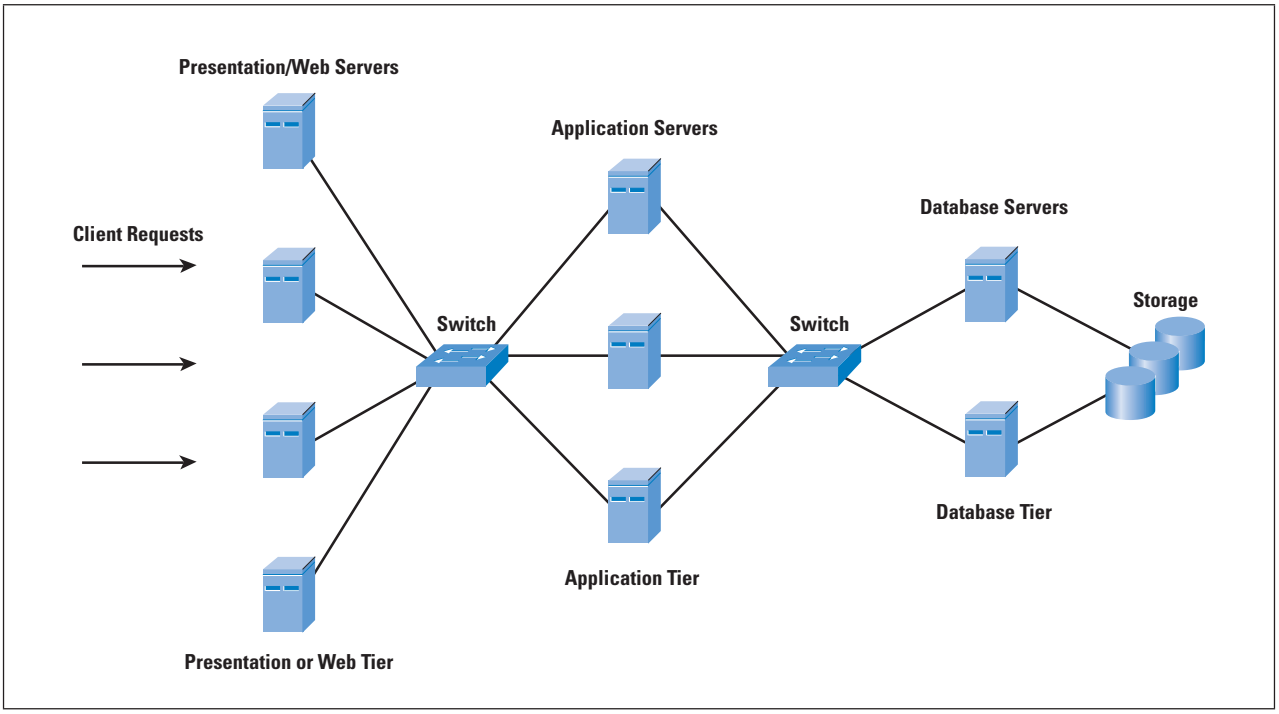
Figure 0: Example Data-Center Switch Network Architecture (from Part 1)



Although it is not necessary for each tier to be represented by its own physical servers (for example, you could have the Application and Database functions mapped into a single physical server), it is a common representation. The reason for this multitiered design is to control the connections and interactions, as well as for scaling and security. It is not uncommon for the Presentation Tier to be in a *Demilitarized Zone* (DMZ) while the other tiers are located deep inside the data center. Although all tiers could connect to storage for performing their functions, the Database Tier is the one with the maximum storage bandwidth requirements.

It follows that the server connectivity and the network topology for the cloud data centers might follow a similar organization. If you are an enterprise, you can perform the same business functions as before, but by using the external cloud. The choice of servers, software loads, and their interconnection will depend upon what you need to accomplish. In the following sections, we discuss how this design is handled in *Infrastructure as a Service* (IaaS), *Platform as a Service* (PaaS), and *Software as a Service* (SaaS).

Figure 1: Three-Tier Functional Server Architecture



Data-Center Infrastructure Extension – IaaS

If the cloud is thus seen as an extension of the existing data center, IaaS as outlined in Part 1 is a natural fit. Here, you would specify the number of servers in each tier, load the appropriate server image (web, business logic, or database manager), and "connect" them (through a menu or *Application Programming Interface* [API] provided by the IaaS provider) by specifying the links between them. You can also specify the network connectivity at this time (more on this later). For an enterprise IT administrator, this model provides the greatest degree of control and, to an extent, a familiar operating topology. The cloud provider handles the elasticity by ensuring that the number of servers and switches is adequate for you to configure and connect in the specified topology. Per-use billing and on-demand resource addition and removal are also provided by the cloud provider. Note that if you have complete control, you also are responsible for security, application usage, and resource management.

PaaS and SaaS Infrastructure

In the case of PaaS, you transfer more control to your cloud service provider. The platform used to build the service you require can scale transparently without any of your involvement other than at the time of configuration. You do not need to understand the tier connectivity, bandwidth requirements, or how it all functions under the hood.

Cloud service providers can realize this function—often with a three-tier topology similar to that for traditional data centers. However, some of them have innovated to perform parts of the function differently. For example, the database functions may rely upon a model of *scaling out* (splitting the database across multiple servers) instead of *scaling up* (increasing the capability of the machine running the database servers). Their claim is that with clouds involving large amounts of data that you can partition and work on, it is easier to scale out than scale up. According to some cloud service providers, traditional relational databases are not suitable candidates for scale-out. Hence, some cloud vendors have provided their own database models and implementations—a common one being the type known as the *Key-Value database*.

SaaS vendors have the highest degree of control among the three models. The realization of the network topology can be similar to existing data centers and scale up or down according to the number of users that are added. However, because they offer a specific set of applications to the cloud users, their server and network topology is quite straightforward.

For the following discussions, we will use IaaS as the representative cloud service model, with a primary consideration being "cloud bursting"—how an existing IT infrastructure can take advantage of the power of the cloud when it needs additional resources. Note that some of the discussion might also be relevant for internal clouds. In addition, we will assume a virtualized server infrastructure for the IaaS cloud because this infrastructure provides a greater degree of flexibility for cloud service providers (Amazon being a key example).

Virtualization and Its Demands on Switching

In Part 1, we provided the context for a virtual switch within a physical server containing multiple virtual machines. There are some addressing and control factors to consider in this model. Consider a data center with 100 servers, each with 16 virtual machines but with one physical 10-Gbps Ethernet connection to the external switch from each physical machine. If we were to carry forward the model where each physical server is replaced with its virtual equivalent but still needs to be addressable (through a *Media Access Control* [MAC] layer address and an IP address), you would need 16 MAC and IP addresses for the virtual servers that now reside "on top" of the single physical link, for a total of 1600 addresses across all servers. This problem is exacerbated when you increase the number of VMs per server. Switching between MAC addresses belonging to the virtual machines is done by the virtual switch inside the server.

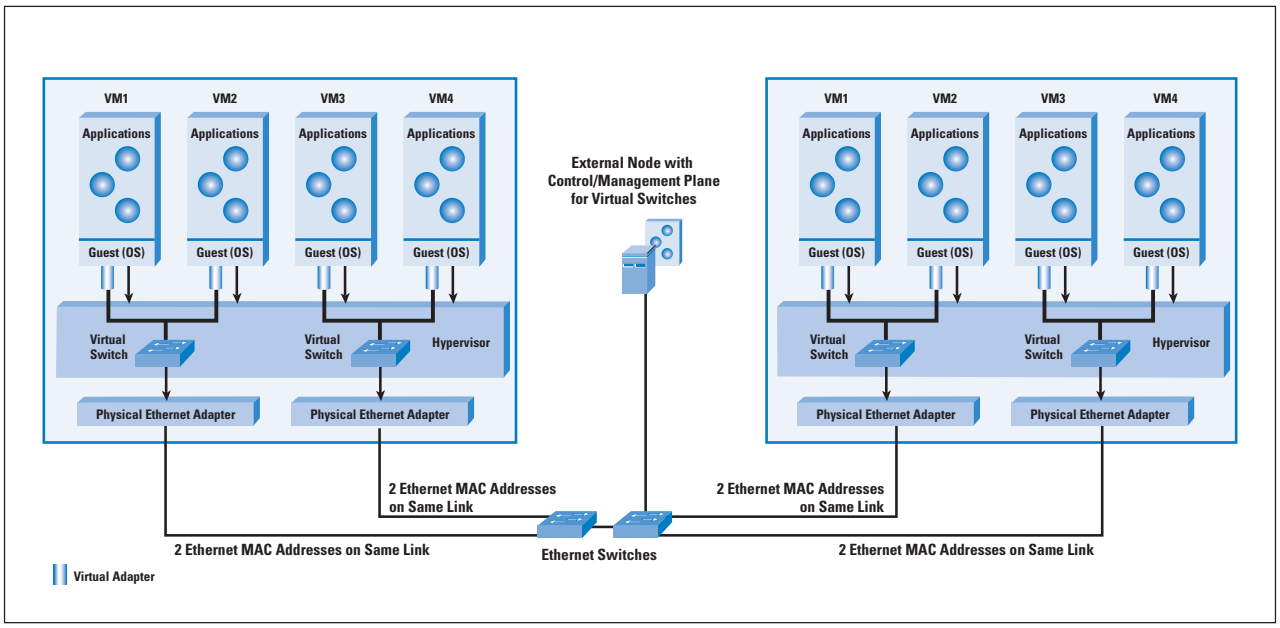
Consider the topology in Figure 2. The virtual switch treats the physical link as an uplink to the external physical switch. This intramachine *Virtual Machine* (VM) switch with an uplink to the external switch is completely in line with access and aggregation switch topologies where the access layer is subsumed inside the server. Note that each physical host can have more than one virtual switch to support greater logical segmentation. In such cases, it is common for each of the virtual switches to have its own physical uplink to the external Ethernet switch.

The virtual switch does not need to learn MAC addresses like a traditional switch—it assumes that all destination-unknown frames should be forwarded over the physical link (or uplink to the physical switch). In addition, it switches traffic between the intramachine VMs according to policy. For example, you could prohibit two VMs on the same machine from communicating with each other by configuring an access control list on the virtual switch. The VMs may all be on the same or on different VLANs. Broadcasts and intra-VLAN traffic are forwarded according to the rules for each VLAN. In effect, the virtual switch is a simple function that is used for aggregation and access control within a physical server containing VMs.

Management of these virtual switches can follow an aggregation model—where multiple virtual switches are managed through an external node (physical machine or VM), as shown in Figure 2. This external node provides the management view on behalf of the switches. Often, the external node can run control-plane protocols for Layer 2/3 functions, in effect appearing like a control or management plane with multiple data-plane instances (the virtual switches). When VMs need to be migrated to other physical servers, this separation of control- or management-plane functions permits easier migration of policy and access lists.

Virtual switches do have some disadvantages. Inter-VM traffic within the same machine is not visible to the network and cannot be subject to appropriate monitoring by network administrators. The IEEE is discussing approaches to providing external network switches the visibility into the intra-VM traffic. The options include “hair pinning,” where inter-VM traffic would still be carried over to an external switch and brought back to the same physical server.

Figure 2: Virtual Switch Aggregation and Management by External Node



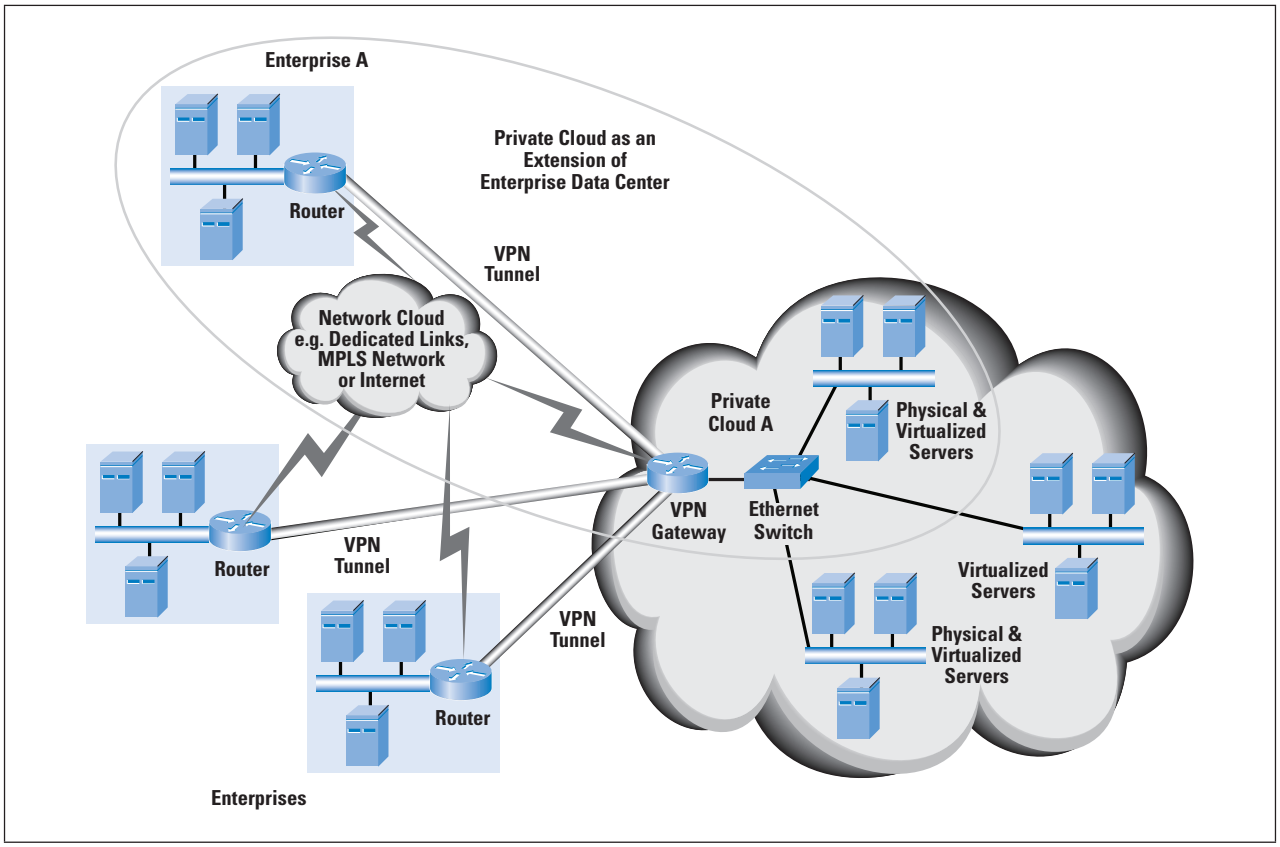
IaaS Private Clouds

Consider an IaaS cloud to which an enterprise connects to augment its server capacity for a limited period of time. Assume that the enterprise uses a `10.x.x.x` private addressing scheme for all its servers because they are internal to the enterprise. It would be ideal if the additional servers provided by the IaaS cloud were part of the same addressing scheme (the `10.x.x.x` scheme). As shown in Figure 3, the IaaS cloud service provider has partitioned a portion of its public cloud to realize a private cloud for enterprise A. The private cloud is reachable as a LAN extension to the servers in enterprise A's data center.

How is this reachability realized? A secure *Virtual Private Network* (VPN) tunnel is first established between the enterprise data center and the public cloud. This tunnel uses public IP addresses to establish the site-to-site VPN connection. The VPN gateway on the cloud service provider side uses multiple contexts—each context corresponding to a specific private cloud. Traffic from enterprise A is decrypted and forwarded over to an Ethernet switch to the private cloud for enterprise A. A server on enterprise A's internal data center sees a server on private cloud A to be on the same network.

In practice, data-center servers might be segmented into their own VLANs or IP networks according to policy and applications. The configuration and forwarding policies on the private cloud end would reflect this segmentation as well.

Figure 3: Example of Private Clouds



The following are some possible evolution scenarios for this scheme:

- *Automation of the VPN connection between the enterprise and cloud service provider:* This automation can be done through a management system responsible for the cloud bursting and server augmentation. The system sets up the VPN tunnels and configures the servers on the cloud service provider end. The management system is set up and operated by the cloud service provider.
- *Integration of the VPN functions with the site-to-site VPN network functions from service providers:* For example, service providers offer MPLS Layer 3 VPNs and Layer 2 VPNs (also known as *Virtual Private LAN Service*, or VPLS) as part of their offerings. Enterprise and cloud service providers could be set up to use these network services.
- *Cloud service providers using multiple data centers:* In such a situation, a VPLS-like service can be used to bridge the individual data centers, providing complete transparency from the enterprise side about the location of the cloud servers.

CloudNet is an example of a framework being developed by AT&T Labs and the University of Massachusetts at Amherst to address the latter two scenarios.

Layer 2 versus Layer 3 Connectivity for Cloud Networks

Enterprises and vendors follow some guidelines regarding where to use Layer 2 (switching) and Layer 3 (routing) in the network. Layer 2 is the simpler mode, where the Ethernet MAC address and *Virtual LAN* (VLAN) information are used for forwarding. The disadvantage of Layer 2 networks is scalability. When we use Layer 2 addressing and connectivity in the manner specified previously for IaaS clouds, we end up with a flat topology, which is not ideal when there are a large number of nodes. The option is to use routing and subnets—to provide segmentation for the appropriate functions at the cost of forwarding performance and network complexity.

VM migration introduces its own set of problems. The most common scenario is when a VM is migrated to a different host on the same Layer 2 topology (with the appropriate VLAN configuration). Consider the case where a VM with open *Transmission Control Protocol* (TCP) connections is migrated. If live migration is used, TCP connections will not see any downtime except for a short "hiccup." However, after the migration, IP and TCP packets destined for the VM will need to be resolved to a different MAC address or the same MAC address but now connected to a different physical switch in the network so that the connections can be continued without disruption. Proposed solutions include an unsolicited *Address Resolution Protocol* (ARP) request from the migrated VM so that the switch tables can be updated, a pseudo-MAC address for the VM that is externally managed (defined in research work being done at the University of California at San Diego), and so on.

With VPLS and similar Layer 2 approaches, VM migration can proceed as before—across the same Layer 2 network. Alternatively, it may be less complex to "freeze" the VM and move it across either a Layer 2 or Layer 3 network with the TCP connections having to be torn down by the counterpart(s) communicating with the VM. This scenario is not a desired one from an application availability consideration, but it can lower complexity.

Cloud Federation

Thus far we have considered the situation of data centers that are owned or run by the same cloud services provider. Connectivity between the data centers to provide the vision of "one cloud" is completely within the control of the cloud service provider.

There may be situations where an organization or enterprise needs to be able to work with multiple cloud providers because of migration from one cloud service to another, merger of companies working with different cloud providers, cloud providers who provide best-of-class services, and so on. Cloud interoperability and the ability to share various types of information between clouds become important in such scenarios. Although cloud service providers might see less urgency for any interoperability, enterprise customers will see a need to push them in that direction.

This broad area of cloud interoperability is sometimes known as *cloud federation*. One definition of cloud federation as proposed by Reuven Cohen of Enomaly follows:

> "Cloud federation manages consistency and access controls when two or more independent geographically distributed clouds share either authentication, files, computing resources, command and control, or access to storage resources."

The following are some of the considerations in cloud federation:

- An enterprise user wishing to access multiple cloud services would be better served if there were just a single sign-on scheme. This scheme may be implemented through an authentication server maintained by an enterprise that provides the appropriate credentials to the cloud service providers. Alternatively, a central trusted authentication server to which all the cloud services interface could be used.
- Computing and storage resources may be orchestrated through the individual enterprise or through an interoperability scheme established between the cloud providers (through a federation agreement, for example). Files may need to be transferred, services invoked, and computing resources added or removed in a useful and transparent manner. A related area is VM migration and how it can be done transparently and reliably. The *Desktop Management Task Force* (DMTF) has released a specification called the *Open Virtualization Format* (OVF) for describing a VM. It can be reasonably assumed that the payload for VM migration will be in the OVF format so that it can be interpreted across multiple vendor offerings. In effect, cloud federation has to provide transparent workload orchestration between the clouds on behalf of the enterprise user.
- Connectivity between clouds includes Layer 2 versus Layer 3 considerations and secure tunnel technologies that need to be agreed upon. Consistency and a common understanding are required irrespective of the model or technologies.
- An often-ignored concern for cloud confederation is charging or billing and reconciliation. Management and billing systems need to work together for cloud federation to be a viable option. This reality is underlined by the fact that clouds rely on per-use billing. Cloud service providers might need to look closely at telecom service provider business models for peering arrangements as a possible starting point.

Cloud federation is a relatively new area in cloud computing. It is likely that standards bodies will first need to agree upon a set of requirements before the service interfaces can be defined and subsequently realized. Provider and vendor innovation will also significantly affect this area—in fact, cloud service operators are likely to establish peering relationships and start addressing this area even before the standards bodies.

Security

As indicated in Part 1, the biggest deterrent for IT managers from venturing into cloud computing is the problem of security and loss of control. Before considering a move to a cloud service provider, enterprises need to consider some of the following security topics:

- The cloud service provider's security processes will need to be as good as or better than the processes that the enterprise uses. An audit of the vendor's processes will need to be done periodically, possibly including patches and security updates for the individual components that are used. For example, in an IaaS scenario with some preconfigured images of operating systems and applications, the cloud service provider should have the latest patches applied on the individual components.
- Infrastructure and data isolation must be assured between multiple tenants of the cloud service provider. This requirement is complicated because it is closely intertwined with the business model used by the cloud provider. For example, an IaaS provider might provide multiple tenants with VMs running on the same physical machine. Depending upon the type of work that is to be executed on the cloud, this setup may or may not be acceptable to a cloud user. In such cases, the cloud service provider should have the ability to provide separate physical servers for specific customers (and bill appropriately).
- In cases where a hypervisor and VMs are used, the hypervisor should be treated as an operating system and have the latest security patches applied to it. Security patches and updates are also essential for paravirtualized operating systems used in the VMs.
- Security functions can run as virtual appliances over hypervisors in a cloud environment. Thus it is possible for cloud users in an IaaS environment to load and configure their own firewall or other security virtual appliance to run within the cloud. The software images used for these virtual appliances need to be managed and patched similar to the way the OS, hypervisor, and other applications are managed and patched.
- Logging and audit trails for applications are important for enterprises to understand both application performance and security gaps. Cloud services providers should enable access to their application monitoring and profiling tools, where applicable.
- Authentication mechanisms ("You are who you say you are") are required at both ends of the connection—at the cloud user and cloud service provider levels. The cloud user and operator must agree upon schemes such as authentication with digital certificates and certificate authorities.

- Configuration and updates to the network infrastructure must be audited and tracked. For example, incorrect VLAN configuration on the switches can result in undesired traffic patterns between physical machines and computing resources. It would be useful to log and audit the configuration records for proper security and uptime.
- Because the cloud service is exposed to the outside world, the cloud infrastructure should support security functions such as intrusion detection and prevention, firewalling to prevent disallowed traffic, and *Denial of Service* (DoS) prevention. The cloud service is vulnerable to *Distributed Denial of Service* (DDoS) attacks—which can effectively choke its access lines, resulting in cloud users being locked out of the cloud service. Network-based DDoS prevention is a possible solution—with one of the techniques involving distribution of the cloud infrastructure to specific geographic areas and the ability to redirect cloud users in case of DDoS lockouts.

Virtualization and Security

Two options are under discussion for security in the context of virtualization. Both are useful in building out security-enabled cloud infrastructures. One option involves plug-ins to the hypervisor so that packets destined to the VMs are captured and processed by the security plug-ins. This setup enables application of security functions to the packet before it gets to the VMs. A second option is to make a specific VM handle the security functions without changing or adding to the hypervisor. The hypervisor plug-in option has the advantage of performance and initial isolation, whereas the separate VM option has the advantage of keeping the hypervisor simple and extrapolating the model that exists in physical server infrastructure. Note that these options are not mutually exclusive.

VM migration is another area where security is an important consideration. The hypervisor is responsible for the two-way communication, with the hypervisor on the destination physical machine to accomplish the migration. It is important that the connection between the source and destination hypervisors is authenticated and encrypted during the course of this migration. In addition, VM migration introduces the possibility of a DoS attack because a rogue hypervisor could overwhelm a destination machine by migrating a large number of VMs to the destination machine. Policies and logic are required at the hypervisor level to ensure that these vulnerabilities are addressed. In addition, network-based throttling might be required so that live migration does not cause congestion, which might happen if a large number of VMs need to be migrated to a destination machine at the same time.

Standards Bodies Involved in Cloud Computing

Numerous standards bodies are involved in cloud computing, addressing aspects of interoperability, virtualization migration formats, and security. Some of the organizations involved have established liaisons with the other *Standards Development Organizations* (SDOs) so that there is no duplication of effort.

The *Desktop Management Task Force* (DMTF) has specified a portable format for packaging the software to run as a VM. Known as the *Open Virtualization Format* (OVF), this package format is seeing increased use. The VM can be written onto a disk or external storage and can be moved from one physical machine to another. The DMTF has also formed a group called the *Open Cloud Standards Incubator,* which focuses on standardizing the interactions between cloud environments, including the development of resource management, packaging formats, and security.

The *Cloud Security Alliance* (CSA) is a new group formed to address security aspects of cloud computing with a focus on security assessment and management. The initial part of the effort is on developing an *Audit, Assertion, Assessment and Assurance* (API) set (A6).

The *Organization for the Advancement of Structured Information Standards* (OASIS) sees cloud computing as an extension of the *Service-Oriented Architecture* (SOA) used today in IT environments. The areas for standardization include security and policy, content format control, registry and directory standards, as well other SOA methods.

The *Storage Networking Industries Association* (SNIA) has a Cloud Storage *Technical Working Group* (TWG) that works on storage-related problems related to implementation in a cloud. The TWG has developed an interface known as the *Cloud Data Management Interface* (CDMI), which clients will use for control and configuration of the cloud.

Some Perspectives on Cloud Computing

In this section we outline and provide some perspective on cloud-computing topics that have seen interest (and some heated discussion). This list is not intended to be comprehensive but to provide a quick snapshot. Though this section has a degree of subjectivity, it is directed only to providing a broader perspective.

- *Cloud computing and SOA:* Some view cloud computing as a specific deployment case of an SOA—and this view is more popular than the one that says that cloud computing is the evolution of SOA. David Linthicum outlines that these views are complementary in that cloud-computing services will most likely be defined through SOA. IaaS provides a new variant because you can now access raw compute and storage resources as a service. Independent of the argument that "We have seen this before," there is value to defining and invoking available services in the cloud.

- *Server virtualization schemes:* Comparisons are sometimes made based on how vendor products approach virtualization—type 1 versus type 2—and full versus paravirtualization. These approaches have pros and cons. The final decision often hinges on total costs, so it might be useful to move forward from this debate. Incidentally, vendors provide several useful tools for VM backup, recovery, fault tolerance, load management, and so on, and these tools work equally well for the various approaches to virtualization. It may be argued that these tools and features such as VM migration and the associated costs are more useful areas for comparison.
- *Other types of virtualization:* This article has deliberately omitted discussion of other types of virtualization, including desktop, application, and presentation virtualization. Some of these schemes (server-hosted desktop virtualization is one example) are affected by the cloud, specifically in the areas of network connectivity, authentication, and quality of experience. In general, any thin-client experience is affected by the cloud or data center because most of the work is done at the servers. From a cloud perspective, these types of virtualization schemes are considered to be applications that need to run reliably and consistently.
- *Data transfer and network bandwidth:* IaaS has provided a flexible model, in which you are charged based on compute power usage, storage consumed, and the duration of usage. However, there is another important factor—data needs to be sent back and forth between the cloud user and cloud service provider. Several IaaS providers charge for the amount of data transferred over the link. These charges can quickly add up if your applications are very chatty and require a lot of back-and-forth data traffic. Another concern here is the amount of time the initial upload or download can consume—for example, when you want to move a large number of your files to the IaaS provider's storage, you can tie up the link for hours. In fact, one provider has a model where cloud users can send storage media through a postal or package service for upload to the cloud provider's storage arrays.
- *WAN acceleration for the cloud:* Continuing on the previous point, chatty protocols and applications can benefit from WAN acceleration devices that can be used on both ends of a WAN link to cache and locally serve enterprise applications. These devices are not specific to the cloud—they have been used for several years for application performance improvement when a WAN link is involved. Recently, virtual network appliances for WAN acceleration are seeing deployment—here the WAN acceleration is performed by an individual VM instead of a dedicated appliance.
- *VM migration:* This article outlined some of the concerns with VM migration with respect to Layer 2 and Layer 3 topologies. Another consideration is the amount of data that needs to be moved when a VM is migrated across a network. It can potentially be in the range of gigabytes, depending upon the VM and the included operating environment.

Live migration implements this transfer in an incremental fashion so that the demand on the network is spread out. However, snapshot migration (where a VM is suspended or frozen and migrated over the network in full) can cause a surge of data on the network, leading to application performance problems for other VMs and physical machines. Throttling the amount of data that can be sent in a specific period of time, bandwidth reservation and policing at the intermediate network devices is highly desirable in such situations.

- *Management:* The current management paradigms for the cloud components are quite discrete and provide a strong level of control. For example, it is possible to log in to the *Command-Line Interface* (CLI) of a specific switch in the data center for configuration and control of the switch parameters. Similarly, it is possible to use the management console provided by the virtualization vendor to configure individual parameters for the hypervisors and VMs (for example, when to initiate VM migration to a different physical machine). Efforts are being made to unify management schemes not just through partnerships between the individual vendors but also with machine-readable interfaces (*Extensible Markup Language* [XML] being a baseline) across the multiple types of equipment and software in the cloud. Enterprise users are unlikely to accept point solutions or tools that require extensive user interaction in the long term.
- *Energy considerations:* One of the benefits of virtualization is the use of a lower number of physical servers to realize a specific function. It follows that overall energy consumption would be reduced because you have fewer servers. Although this fact may indeed be true, it would be good to characterize and monitor the effective energy savings for a specific application ("Your mileage may vary"). For example, the load on each server and the associated I/O and storage traffic may lead to higher power requirements on an individual server basis. Other considerations include the hardware infrastructure of the cloud data center because the power and cooling assumptions per rack are based on average server load.
- *Legal and regulatory considerations:* James Urquhart has compiled a set of criteria for workload migration across multiple locations, one of which is "Follow the law." Consider the case of a cloud services provider or operator that has data centers in two separate countries. The operator might use the data centers for workload migration as well as load balancing. A problem might arise if the laws in one of the countries impose limitations on what can and cannot be done at the data center. Scenarios include access to all data stored at this data center by authorities or the ability to examine all transactions on the wire at the data center. Workload migration policy statements have to be provided to cloud users so that they understand what they are signing up to. Alternatively, they might be provided the ability to set preferences for workload migration. This area is potentially worrisome, so it is important that cloud users are aware of their specific situation.

Conclusion

This article has served as a vendor-neutral primer to the area of cloud computing. In Part 1, we provided an introduction to the still-evolving area of cloud computing, including the technologies and some deployment concerns. In Part 2, we provided a more detailed look at the networking factors in the cloud, security aspects, and cloud federation. We also highlighted some areas that are seeing increased attention with cloud-computing proponents and vendors.

The area of cloud computing is very dynamic and offers scope for innovative technologies and business models. Ongoing work with respect to solutions is substantial, in the vendor research labs and product development organizations as well as in academia. It is clear that cloud computing will see significant advances and innovation in the next few years.

Protocol Basics: Secure Shell Protocol

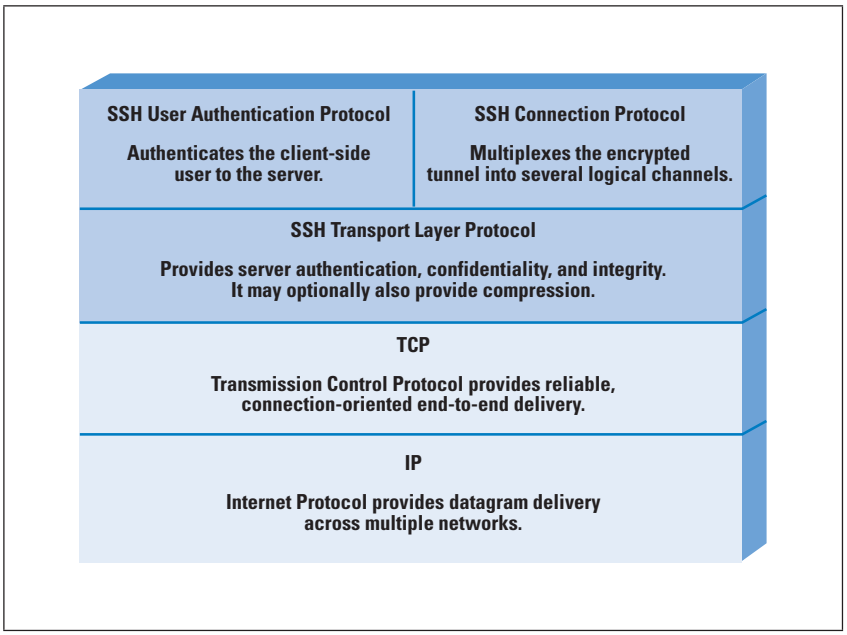
by William Stallings

Secure Shell (SSH) Protocol is a protocol for secure network communications designed to be relatively simple and inexpensive to implement. The initial version, SSH1, focused on providing a secure remote logon facility to replace Telnet and other remote logon schemes that provided no security[4]. SSH also provides a more general client-server capability and can be used to secure such network functions as file transfer and e-mail. A new version, SSH2, provides a standardized definition of SSH and improves on SSH1 in numerous ways. SSH2 is documented as a proposed standard in RFCs 4250 through 4256 [1–3], [5–8].

SSH client and server applications are widely available for most operating systems. It has become the method of choice for remote login and X tunneling and is rapidly becoming one of the most pervasive applications for encryption technology outside of embedded systems. SSH is organized as three protocols that typically run on top of TCP (Figure 1):

- *Transport Layer Protocol:* Provides server authentication, data confidentiality, and data integrity with forward secrecy (that is, if a key is compromised during one session, the knowledge does not affect the security of earlier sessions); the transport layer may optionally provide compression
- *User Authentication Protocol:* Authenticates the user to the server
- *Connection Protocol:* Multiplexes multiple logical communications channels over a single underlying SSH connection

Figure 1: SSH Protocol Stack



Transport Layer Protocol

Server authentication occurs at the transport layer, based on the server possessing a public-private key pair. A server may have multiple host keys using multiple different asymmetric encryption algorithms. Multiple hosts may share the same host key. In any case, the server host key is used during key exchange to authenticate the identity of the host. For this authentication to be possible, the client must have presumptive knowledge of the server public host key. RFC 4251 dictates two alternative trust models that can be used:

1. The client has a local database that associates each host name (as typed by the user) with the corresponding public host key. This method requires no centrally administered infrastructure and no third-party coordination. The downside is that the database of name-to-key associations may become burdensome to maintain.
2. The host name-to-key association is certified by a trusted *Certification Authority* (CA). The client knows only the CA root key and can verify the validity of all host keys certified by accepted CAs. This alternative eases the maintenance problem, because ideally only a single CA key needs to be securely stored on the client. On the other hand, each host key must be appropriately certified by a central authority before authorization is possible.

Figure 2: SSH Transport Layer Protocol Packet Exchanges

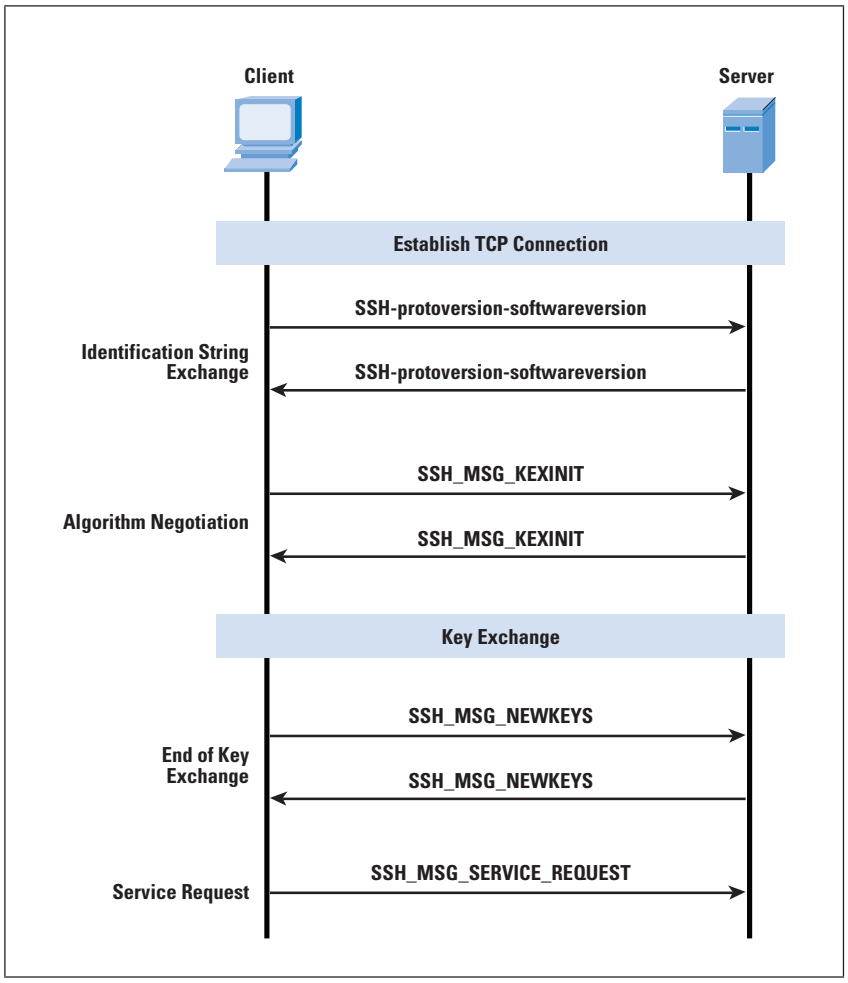


Figure 2 illustrates the sequence of events in the SSH Transport Layer Protocol. First, the client establishes a TCP connection to the server with the TCP protocol and is not part of the Transport Layer Protocol. When the connection is established, the client and server exchange data, referred to as packets, in the data field of a TCP segment. Each packet is in the following format (Figure 3):

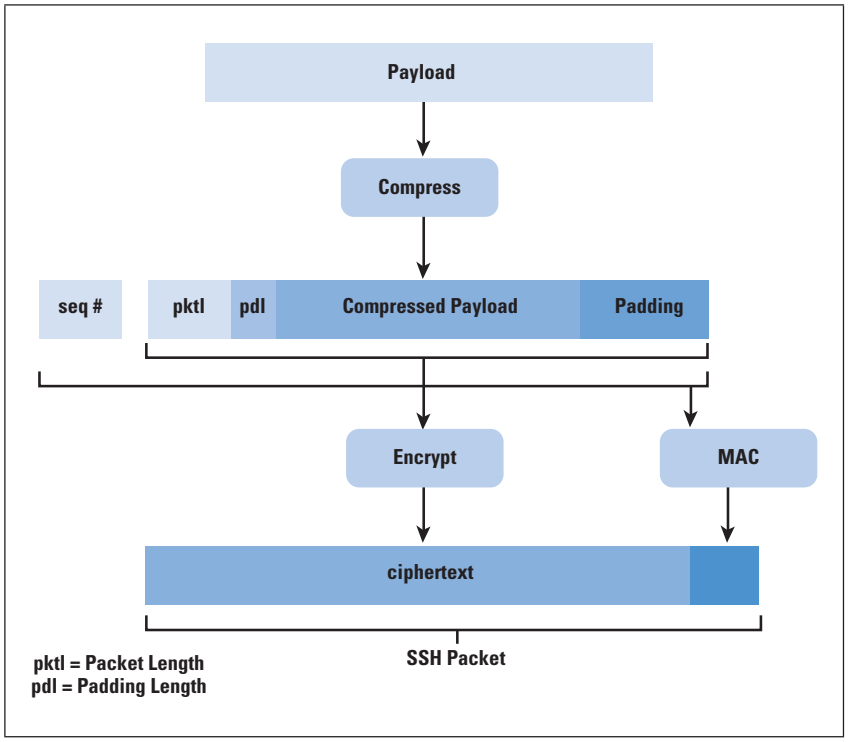
- *Packet length:* Packet length is the length of the packet in bytes, not including the packet length and Message Authentication Code (MAC) fields.
- *Padding length:* Padding length is the length of the random padding field.
- *Payload:* Payload constitutes the useful contents of the packet. Prior to algorithm negotiation, this field is uncompressed. If compression is negotiated, then in subsequent packets this field is compressed.
- *Random padding:* After an encryption algorithm is negotiated, this field is added. It contains random bytes of padding so that that total length of the packet (excluding the MAC field) is a multiple of the cipher block size, or 8 bytes for a stream cipher.
- *Message Authentication Code* (MAC): If message authentication has been negotiated, this field contains the MAC value. The MAC value is computed over the entire packet plus a sequence number, excluding the MAC field. The sequence number is an implicit 32-bit packet sequence that is initialized to zero for the first packet and incremented for every packet. The sequence number is not included in the packet sent over the TCP connection.

Figure 3: SSH Transport Layer Protocol Packet Formation



After an encryption algorithm is negotiated, the entire packet (excluding the MAC field) is encrypted after the MAC value is calculated.

The SSH Transport Layer packet exchange consists of a sequence of steps (Figure 2). The first step, the *identification string exchange*, begins with the client sending a packet with an identification string of the form:

SSH-protoversion-softwareversion SP comments CR LF

where SP, CR, and LF are space character, carriage return, and line feed, respectively. An example of a valid string is **`SSH-2.0-billsSSH_3.6.3q3<CR><LF>`**. The server responds with its own identification string. These strings are used in the Diffie–Hellman key exchange.

Next comes *algorithm negotiation*. Each side sends an **`SSH_MSG_KEXINIT`** containing lists of supported algorithms in the order of preference to the sender. Each type of cryptographic algorithm has one list. The algorithms include key exchange, encryption, MAC algorithm, and compression algorithm. Table 1 shows the allowable options for encryption, MAC, and compression. For each category, the algorithm chosen is the first algorithm on the client's list that is also supported by the server.

Table 1: SSH Transport Layer Cryptographic Algorithms

Cipher	
3des-cbc*	Three-key Triple Digital Encryption Standard (3DES) in Cipher-Block-Chaining (CBC) mode
blowfish-cbc	Blowfish in CBC mode
twofish256-cbc	Twofish in CBC mode with a 256-bit key
twofish192-cbc	Twofish with a 192-bit key
twofish128-cbc	Twofish with a 128-bit key
aes256-cbc	Advanced Encryption Standard (AES) in CBC mode with a 256-bit key
aes192-cbc	AES with a 192-bit key
aes128-cbc**	AES with a 128-bit key
Serpent256-cbc	Serpent in CBC mode with a 256-bit key
Serpent192-cbc	Serpent with a 192-bit key
Serpent128-cbc	Serpent with a 128-bit key
arcfour	RC4 with a 128-bit key
cast128-cbc	CAST-128 in CBC mode

MAC Algorithm	
hmac-sha1*	HMAC-SHA1; Digest length = Key length = 20
hmac-sha1-96**	First 96 bits of HMAC-SHA1; Digest length = 12; Key length = 20
hmac-md5	HMAC-SHA1; Digest length = Key length = 16
hmac-md5-96	First 96 bits of HMAC-SHA1; Digest length = 12; Key length = 16

Compression Algorithm	
none*	No compression
zlib	Defined in RFCs 1950 and 1951

** = Required*
*** = Recommended*

The next step is *key exchange*. The specification allows for alternative methods of key exchange, but at present only two versions of Diffie–Hellman key exchange are specified. Both versions are defined in RFC 2409 and require only one packet in each direction. The following steps are involved in the exchange. In this, C is the client; S is the server; p is a large safe prime; g is a generator for a subgroup of GF(p); q is the order of the subgroup; `V_S` is the S identification string; `V_C` is the C identification string; `K_S` is the S public host key; `I_C` is the C `SSH_MSG_KEXINIT` message; and `I_S` is the `S SSH_MSG_KEXINIT` message that was exchanged before this part began. The values of p, g, and q are known to both client and server as a result of the algorithm selection negotiation. The hash function hash() is also decided during algorithm negotiation.

1. C generates a random number x ($1 < x < q$) and computes $e = g^x \bmod p$. C sends e to S.
2. S generates a random number y ($0 < y < q$) and computes $f = g^y \bmod p$. S receives e. It computes $K = e^y \bmod p$, H = hash(V_C || V_S || I_C || I_S || K_S || e || f || K), and signature s on H with its private host key. S sends (K_S || f || s) to C. The signing operation may involve a second hashing operation.
3. C verifies that `K_S` really is the host key for S (for example, using certificates or a local database). C is also allowed to accept the key without verification; however, doing so will render the protocol insecure against active attacks (but may be desirable for practical reasons in the short term in many environments). C then computes $K = f^x \bmod p$, H = hash(V_C || V_S || I_C || I_S || K_S || e || f || K), and verifies the signature s on H.

As a result of these steps, the two sides now share a master key K. In addition, the server has been authenticated to the client, because the server has used its private key to sign its half of the Diffie–Hellman exchange. Finally, the hash value H serves as a session identifier for this connection. When computed, the session identifier is not changed, even if the key exchange is performed again for this connection to obtain fresh keys.

The *end of key exchange* is signaled by the exchange of `SSH_MSG_NEWKEYS` packets. At this point, both sides may start using the keys generated from K, as discussed subsequently.

The final step is *service request*. The client sends an `SSH_MSG_SERVICE_REQUEST` packet to request either the User Authentication or the Connection Protocol. Subsequent to this request, all data is exchanged as the payload of an SSH Transport Layer packet, protected by encryption and MAC.

The keys used for encryption and MAC (and any needed IVs) are generated from the shared secret key *K*, the hash value from the key exchange *H*, and the session identifier, which is equal to *H* unless there has been a subsequent key exchange after the initial key exchange. The values are computed as follows:

- Initial IV client to server: HASH(*K* || *H* || "A" || session_id)
- Initial IV server to client: HASH(*K* || *H* || "B" || session_id)
- Encryption key client to server: HASH(*K* || *H* || "C" || session_id)
- Encryption key server to client: HASH(*K* || *H* || "D" || session_id)
- Integrity key client to server: HASH(*K* || *H* || "E" || session_id)
- Integrity key server to client: HASH(*K* || *H* || "F" || session_id)

where HASH() is the hash function determined during algorithm negotiation.

User Authentication Protocol

The *User Authentication Protocol* provides the means by which the client is authenticated to the server.

Three types of messages are always used in the User Authentication Protocol. Authentication requests from the client have the format:

byte	**`SSH_MSG_USERAUTH_REQUEST (50)`**
string	username
string	service name
string	method name
....	method-specific fields

where *username* is the authorization identity the client is claiming, *service name* is the facility to which the client is requesting access (typically the SSH Connection Protocol), and *method name* is the authentication method being used in this request. The first byte has decimal value 50, which is interpreted as **`SSH_MSG_USERAUTH_REQUEST`**.

If the server either rejects the authentication request or accepts the request but requires one or more additional authentication methods, the server sends a message with the format:

byte	**`SSH_MSG_USERAUTH_FAILURE (51)`**
name-list	authentications that can continue
boolean	partial success

where the *name-list* is a list of methods that may productively continue the dialog. If the server accepts authentication, it sends a single-byte message, **`SSH_MSG_USERAUTH_SUCCESS (52)`**.

The message exchange involves the following steps:

1. The client sends a `SSH_MSG_USERAUTH_REQUEST` with a requested method of none.
2. The server checks to determine if the username is valid. If not, the server returns `SSH_MSG_USERAUTH_FAILURE` with the partial success value of false. If the username is valid, the server proceeds to step 3.
3. The server returns `SSH_MSG_USERAUTH_FAILURE` with a list of one or more authentication methods to be used.
4. The client selects one of the acceptable authentication methods and sends a `SSH_MSG_USERAUTH_REQUEST` with that method name and the required method-specific fields. At this point, there may be a sequence of exchanges to perform the method.
5. If the authentication succeeds and more authentication methods are required, the server proceeds to step 3, using a partial success value of true. If the authentication fails, the server proceeds to step 3, using a partial success value of false.
6. When all required authentication methods succeed, the server sends a `SSH_MSG_USERAUTH_SUCCESS` message, and the Authentication Protocol is over.

The server may require one or more of the following authentication methods:

- *publickey:* The details of this method depend on the public-key algorithm chosen. In essence, the client sends a message to the server that contains the client's public key, with the message signed by the client's private key. When the server receives this message, it checks to see whether the supplied key is acceptable for authentication and, if so, it checks to see whether the signature is correct.
- *password:* The client sends a message containing a plaintext password, which is protected by encryption by the Transport Layer Protocol.
- *hostbased:* Authentication is performed on the client's host rather than the client itself. Thus, a host that supports multiple clients would provide authentication for all its clients. This method works by having the client send a signature created with the private key of the client host. Thus, rather than directly verifying the user's identity, the SSH server verifies the identity of the client host—and then believes the host when it says the user has already authenticated on the client side.

Connection Protocol

The SSH Connection Protocol runs on top of the SSH Transport Layer Protocol and assumes that a secure authentication connection is in use. That secure authentication connection, referred to as a *tunnel,* is used by the Connection Protocol to multiplex a number of logical channels.

RFC 4254, "The Secure Shell (SSH) Connection Protocol," states that the Connection Protocol runs on top of the Transport Layer Protocol and the User Authentication Protocol. RFC 4251, "SSH Protocol Architecture," states that the Connection Protocol runs over the User Authentication Protocol. In fact, the Connection Protocol runs over the Transport Layer Protocol, but assumes that the User Authentication Protocol has been previously invoked.

All types of communication using SSH, such as a terminal session, are supported using separate channels. Either side may open a channel. For each channel, each side associates a unique channel number, which need not be the same on both ends. Channels are flow-controlled using a window mechanism. No data may be sent to a channel until a message is received to indicate that window space is available.

The life of a channel progresses through three stages: opening a channel, data transfer, and closing a channel.

When either side wishes to open a new channel, it allocates a local number for the channel and then sends a message of the form:

byte	**SSH_MSG_CHANNEL_OPEN**
string	channel type
uint32	sender channel
uint32	initial window size
uint32	maximum packet size
....	channel type specific data follows

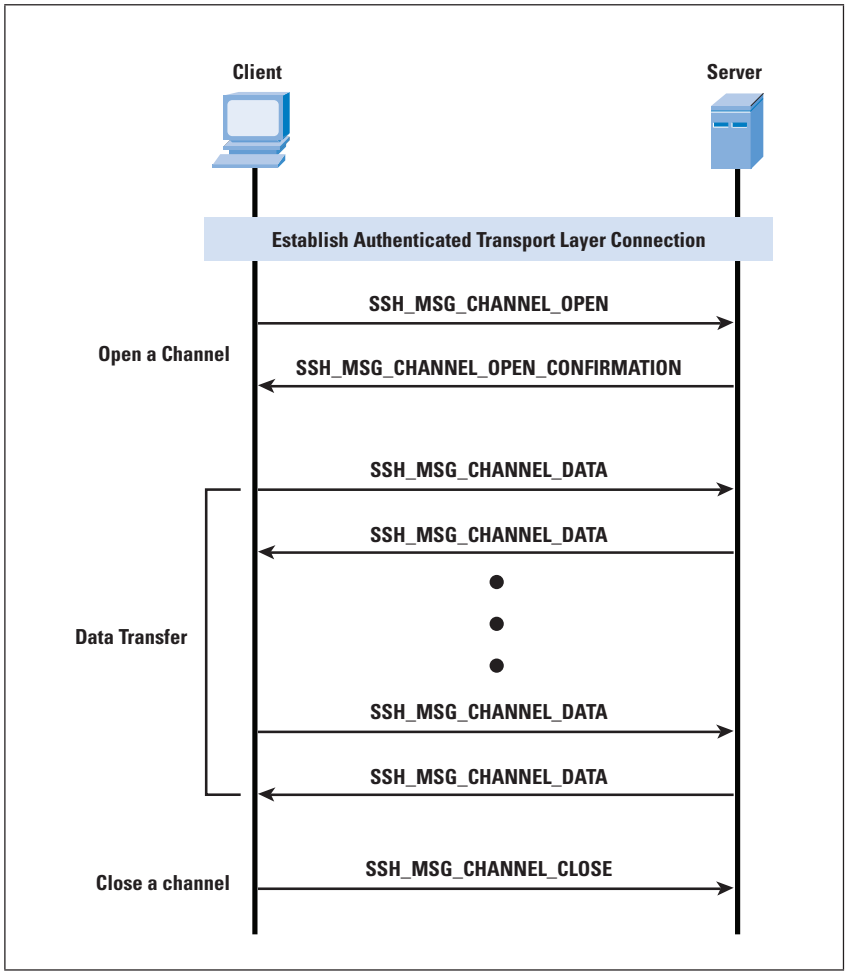
where *uint32* means unsigned 32-bit integer. The *channel type* identifies the application for this channel, as described subsequently. The *sender channel* is the local channel number. The *initial window size* specifies how many bytes of channel data can be sent to the sender of this message without adjusting the window. The *maximum packet size* specifies the maximum size of an individual data packet that can be sent to the sender. For example, one might want to use smaller packets for interactive connections to get better interactive response on slow links.

If the remote side is able to open the channel, it returns a **SSH_MSG_CHANNEL_OPEN_CONFIRMATION** message, which includes the sender channel number, the recipient channel number, and window and packet size values for incoming traffic. Otherwise, the remote side returns a **SSH_MSG_CHANNEL_OPEN_FAILURE** message with a reason code indicating the reason for failure.

After a channel is open, *data transfer* is performed using a **SSH_MSG_CHANNEL_DATA** message, which includes the recipient channel number and a block of data. These messages, in both directions, may continue as long as the channel is open.

When either side wishes to close a channel, is sends a **`SSH_MSG_CHANNEL_CLOSE`** message, which includes the recipient channel number. Figure 4 provides an example of Connection Protocol Exchange.

Figure 4: Example SSH Connectioin Protocol Message Exchange



Four channel types are recognized in the SSH Connection Protocol specification:

- *session:* Session refers to the remote execution of a program. The program may be a shell, an application such as file transfer or e-mail, a system command, or some built-in subsystem. When a session channel is opened, subsequent requests are used to start the remote program.
- *x11:* This channel type refers to the X Window System, a computer software system and network protocol that provides a GUI for networked computers. X allows applications to run on a network server but be displayed on a desktop machine.
- *forwarded-tcpip:* This channel type is remote port forwarding, as explained subsequently.
- *direct-tcpip:* This channel type is local port forwarding, as explained subsequently.

One of the most useful features of SSH is *port forwarding*. Port forwarding provides the ability to convert any insecure TCP connection into a secure SSH connection. It is also referred to as *SSH tunneling*. We need to know what a port is in this context. A *port* is an identifier of a user of TCP. So, any application that runs on top of TCP has a port number. Incoming TCP traffic is delivered to the appropriate application on the basis of the port number. An application may employ multiple port numbers. For example, for the *Simple Mail Transfer Protocol* (SMTP), the server side generally listens on port 25, so that an incoming SMTP request uses TCP and addresses the data to destination port 25. TCP recognizes that this address is the SMTP server address and routes the data to the SMTP server application.

Figure 5: SSH Transport Layer Packet Exchanges

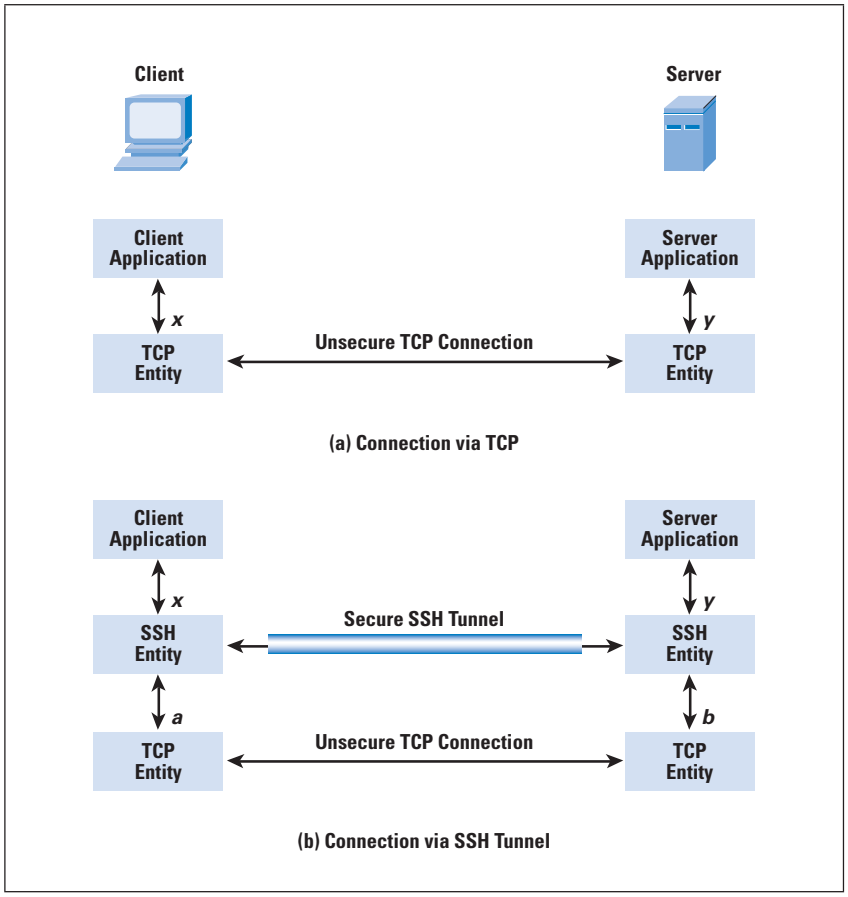


Figure 5 illustrates the basic concept behind port forwarding. We have a client application that is identified by port number *x* and a server application identified by port number *y*. At some point, the client application invokes the local TCP entity and requests a connection to the remote server on port *y*. The local TCP entity negotiates a TCP connection with the remote TCP entity, such that the connection links local port *x* to remote port *y*.

To secure this connection, SSH is configured so that the SSH Transport Layer Protocol establishes a TCP connection between the SSH client and server entities with TCP port numbers *a* and *b*, respectively. A secure SSH tunnel is established over this TCP connection. Traffic from the client at port *x* is redirected to the local SSH entity and travels through the tunnel where the remote SSH entity delivers the data to the server application on port *y*. Traffic in the other direction is similarly redirected.

SSH supports two types of port forwarding: local forwarding and remote forwarding. *Local forwarding* allows the client to set up a "hijacker" process. This process will intercept selected application-level traffic and redirect it from an unsecured TCP connection to a secure SSH tunnel. SSH is configured to listen on selected ports. SSH grabs all traffic using a selected port and sends it through an SSH tunnel. On the other end, the SSH server sends the incoming traffic to the destination port dictated by the client application.

The following example should help clarify local forwarding. Suppose you have an e-mail client on your desktop and use it to get e-mail from your mail server through the *Post Office Protocol* (POP). The assigned port number for POP3 is port 110. We can secure this traffic in the following way:

1. The SSH client sets up a connection to the remote server.
2. Select an unused local port number, say 9999, and configure SSH to accept traffic from this port destined for port 110 on the server.
3. The SSH client informs the SSH server to create a connection to the destination, in this case mailserver port 110.
4. The client takes any bits sent to local port 9999 and sends them to the server inside the encrypted SSH session. The SSH server decrypts the incoming bits and sends the plaintext to port 110.
5. In the other direction, the SSH server takes any bits received on port 110 and sends them inside the SSH session back to the client, which decrypts and sends them to the process connected to port 9999.

With *remote forwarding,* the user's SSH client acts on the server's behalf. The client receives traffic with a given destination port number, places the traffic on the correct port, and sends it to the destination the user chooses.

A typical example of remote forwarding follows: You wish to access a server at work from your home computer. Because the work server is behind a firewall, it will not accept an SSH request from your home computer. However, from work you can set up an SSH tunnel using remote forwarding.

This process involves the following steps:

1. From the work computer, set up an SSH connection to your home computer. The firewall will allow this, because it is a protected outgoing connection.
2. Configure the SSH server to listen on a local port, say 22, and to deliver data across the SSH connection addressed to remote port, say 2222.
3. You can now go to your home computer and configure SSH to accept traffic on port 2222.
4. You now have an SSH tunnel that you can use for remote logon to the work server.

Summary

SSH is one of the most commonly used cryptographic applications. It provides great flexibility and versatility for a wide variety of tasks, including remote administration, file transfer, web development, and penetration testing.

Book Review

Protocol Politics

Protocol Politics: The Globalization of Internet Governance, by Laura DeNardis, MIT Press, 2009, ISBN 978-0-26204257-4.

In *Protocol Politics*, Dr. Laura DeNardis assembles a variety of stories gleaned from official and unofficial *Internet Engineering Task Force* (IETF) records and firsthand accounts, and supplements them with primer-level descriptions of successive generations of Internet addressing and routing protocols to create a broadly accessible overview of the factors that have shaped the present and evolving state of these most central features of Internet technology.

The author, a former enterprise networking consultant and technology analyst, joined the Yale Law School Information Society Project as a Post-Doctoral Fellow in 2006, and became the Executive Director of the program in late 2008. DeNardis approaches the challenge of organizing these disparate materials by adopting an interpretive framework that highlights the role of power—interpersonal as opposed to electrical—as both the primary input and most important output or consequence of the definition, selection, and implementation of Internet protocols.

The book knits together a wealth of important historical information that has to-date remained largely neglected outside of the technical community. Although DeNardis' choice of framing is perfectly legitimate—and in fact quite common within the academic disciplines that delve into the influence of institutions on industries, economies, and society—in this case it leads her to overreach a bit, and arguably to draw a few prominent conclusions that are not well-supported by the balance of available historical evidence.

Organization of the Book

DeNardis employs this interpretive framework across six densely written chapters, the first four of which directly address the significance of power in a different functional context of relevance to the evolution of Internet addressing and routing. The introductory chapter investigates the significance of scarcity and its effect on protocol resource management and *Internet Governance*. Here she devotes considerable space to detailing the critical importance of IP addresses as the single element among Internet protocols that is both indispensable and nonsubstitutable. DeNardis' insightful overview of the general characteristics of IP addresses is somewhat marred by her mixing together of some basic, intrinsic functional properties of addressing (for example, *identifier* and *locator* functions) with various necessary but extrinsic correlates or consequences of those functional properties (for example, universality, external observability), or with contingent features of current IP address usage conventions (for example, indifference to underlying technologies).

In addition, despite the ostensible focus on scarcity in the chapter, no reference is made to that other, equally essential and quantity-constrained feature of the Internet service landscape—that is, the inherently limited, occasionally overtaxed carrying capacity of Internet routing subsystems, particularly the collectively provisioned inter-domain routing system. Overall, *Protocol Politics* provides almost no exposure to the technical, operational, and economic constraints that define the routing environment, much less to the constraints that those factors impose on number resource distribution arrangements. Chapter One closes with an overview of the priorities that justify and define the sphere of Internet Governance which anticipates many of the concluding observations in the book's final chapter on "Opening Internet Governance." Both chapters acknowledge "technical expertise" only as a source of institutional or political legitimacy, without according any special significance to the *content* of such expertise, or why it matters at all. Readers of *Protocol Politics* may thus come away with insufficient appreciation of the fact that before Code can become Law (or anything else), it first must be running code—*and that not every wish is translatable into running code*.[1]

Piercing the Fog of Protocol War

In the three chapters that follow, DeNardis presents her observations about how power shapes and flows from the definition and selection of Internet protocols. Chapter Two covers the first half of this proposition, focusing on the events that followed the December 1990 IETF meeting where, DeNardis suggests, the twin challenges that would shape the development of Internet addressing intersected with the chief institutional impediment that would ultimately reveal the true political nature of Internet standards development.

The first challenge that she identifies is the foreseeable inadequacy of IPv4 as the exclusive addressing resource pool for a rapidly growing and globalizing Internet. In keeping with the overall theme of the book, the second challenge that DeNardis chooses to highlight is the implicitly political challenge of accommodating greater international participation in the U.S.-centric Internet technical coordination and decision-making bodies. Against this backdrop, DeNardis introduces the other chief protagonist in her story, the *International Organization for Standardization* (ISO), which backed the rival *Open Systems Interconnection* (OSI) family of protocols as an alternative, non-TCP/IP-based foundation for the ongoing, global proliferation of data networking. DeNardis details the convoluted, multidimensional deliberations that followed that 1990 IETF meeting, which eventually culminated in 1994 in the formal recognition of IPv6 as "The Next-Generation Internet Protocol."

Chapter Three goes on to explore the implications of both IPv4 and IPv6 for important civil liberties—especially privacy—and how such considerations did and did not, *but hypothetically might have,* influenced the choice and form of the most important features of TCP/IP.

Chapter Four rounds out the central thesis of the book by illustrating how various national-level considerations—especially government-directed foreign and domestic economic policies—have resulted in an increasingly diverse global pattern of IPv6 adoption.

DeNardis' detailed account of the complexities surrounding the *IP Next-Generation* (IPng) debate and its aftermath incorporates a diverse mix of sources, from pointed remarks made on various mailing lists, to conference presentations and official *Internet Architecture Board* (IAB) meeting minutes, and represents a major feat of historical scholarship. That said, her presentation of "relevant historical facts" from the 1990–1994 period is by no means complete, nor is her interpretation of the facts that she does cover or the conclusions that she draws from them immune to criticism. For example, in puzzling over possible hidden forces behind the selection of IPv6, DeNardis states that:

> "If anything, there was market pressure to adopt an OSI rather than TCP/IP-based protocol. The ISO alternative had the political backing of most Western European governments (sic) influential technology companies, and users invested in OSI protocols, and was even congruent with OSI directives of the United States. The selection of IPv6…" (p. 61)

Although these facts may be beyond dispute, they do not represent the full picture. To give one illustration, in 1989, almost 2 years before the date that DeNardis marks as the start of the IETF's lone struggle against the combined forces of Europe, influential carriers and hardware manufacturers, and the U.S. government, an indigenous movement of European network operators emerged and began self-organizing to facilitate the exchange of TCP/IP-based traffic, contact information, and operational tips, and to discuss best practices in areas of networking where individual network-level decisions could have far-reaching effects on internetwork performance.

That organization would go on to become *Réseaux IP Européens Network Coordination Centre* (RIPE NCC), the first independent, transnational registry for Internet Protocol number resources, and the institution that would provide the organizational template for the *Regional Internet Registries* (RIRs) that subsequently sprang up in Asia (APNIC, 1993), North America (ARIN, 1997), Latin America (LACNIC, 2002), and Africa (AFRINIC, 2004). These facts point to a level of active indigenous European support for TCP/IP-based networking that would seem to be at odds with any suggestion of a continent united in support of OSI against a less-attractive standard being pushed by an insular foreign organization.

Thus, regardless of whether DeNardis' concerns about institutions and power relations are well-founded, her intuitions about the division of contestants in the great protocol power struggle clearly are not.[2]

Market Contrast

Another question that DeNardis raises, obliquely but repeatedly, relates to the possibility of "free markets" as an alternative mechanism for defining, selecting, and distributing Internet protocols and the virtual resources that they create.

In no less than a dozen separate passages scattered across each of the chapters in the book, DeNardis sharply contrasts a range of IETF and RIR institutional processes to the workings of the "free market." For example, she observes that the value of IP addresses is unknown because they have never been exchanged in free markets (p. 16); that Internet addresses have never been exchanged in free markets (pp. 23, 190); that the privacy potential of Internet technologies is enhanced by selection pressures from free markets (p. 74); that the IETF refused to countenance an IPng protocol selection made by free markets (p. 51); that the selection of IPv6 happened outside the realm of free markets (p. 69); that widespread adoption of IPv6 is impeded by the absence of a free market for protocols (p. 137); that IETF philosophy holds that it would be inappropriate to exchange protocol resources in free markets (pp. 163, 183–184); that the *Internet Assigned Numbers Authority* (IANA) refused to relinquish IP addresses to free markets (pp. 163, 164); that traditional opposition to the exchange of protocol resources in free markets fortified and centralized the IETF's institutional control (p. 184); and that exchanging IPv4 in free markets has pragmatic appeal, if only as a temporary stopgap (p. 228), although such exchanges might have unintended consequences (p. 229).

Given this frequency of repetition, it is impossible to avoid forming a strong impression of DeNardis' underlying opinion about the intrinsic merits of "free markets" as compared to the seemingly market-antithetical goals and practices of the IETF and the other TCP/IP-centric standards-setting and technical coordination bodies. However, even if one stipulates that "free markets" would by definition represent a superior alternative to the enumerated protocol design and distribution mechanisms, DeNardis never provides any clear indication of where a model for such "free markets" might be found—whether in Europe, the United States, or anywhere else, now or anytime in the past.

Even her own description of that fateful moment in networking history when IPv6 was selected clearly suggests that the alternative to the IETF process that ultimately prevailed was itself neither "free" nor especially market-like:

> "… congruent with OSI directives of the United States. The selection of IPv6, an expansion of the prevailing IPv4 protocol *over such a politically sanctioned OSI alternative* solidified and extended the position of the Internet's traditional standards-setting establishment as the entity responsible for the Internet's architectural direction." (p. 61, emphasis added).

Arguably, the non-inclusion of a pure "free market" example is not merely a coincidence, but rather reflects a more fundamental problem inherent in the concept itself. Further, if one grants that the market mechanism that is *most free* is the one that fosters the broadest participation in those activities that make markets attractive—including openness to participation, exercise of individual choice, competition, accelerated innovation, and wealth creation—then one might interpret the two-plus orders-of-magnitude growth in the number of independent network services providers operating on both sides of the Atlantic since that time as a solid indicator that markets have not suffered too badly from the 1994 decision to extend the lifetime of TCP/IP through IPv6.

Clearly the looming inflection point in IP addressing will provide many irresistible opportunities to revisit that choice in the days ahead. Meanwhile, the question of whether the embrace of an OSI-friendlier IPng by the IETF would have been sufficient to offset the varied negative externalities that might have accompanied such a choice must forever remain unanswered. Would an IETF endorsement have trumped the as-yet incomplete state of OSI standards, as well as OSI's tighter associations with non-standards-based operating systems, proprietary hardware platforms, and the connection-oriented networking technologies favored by then Internet-averse incumbent *Public Switched Telephone Network* (PSTN) operators? Would that choice alone have created or been likely to foster a freer market, or to have led to a more enthusiastic, widespread embrace of a different post-IPv4 addressing format—or alternately would it have led to the appearance of books like *Protocol Politics,* albeit written from the opposite perspective, and possibly a decade sooner? Contrary to the popular adage, hindsight is not 20/20, any more than is our vision of where to go from here.[3]

Beyond the Clash of Idealizations

Writing a book review is an inherently risky undertaking, one that is vulnerable to many of the same human biases and errors that have unquestionably informed both the selection and development of various technical standards, just as they have influenced the embrace, rejection, or modification of various market arrangements throughout history.

Even when people (book reviewers, for example) recognize that real-world decisions and their consequences tend to be irreducibly complex—or perhaps precisely because they recognize that complexity—they nevertheless tend to gravitate toward explanatory frameworks and cognitive models that promise to invest their perceptions and choices with the kind of absolute certitude that is very rarely found outside of the physical world (and only infrequently found there).

The problem, of course, is that many such explanatory frameworks can be found to fit quite nicely with the same set of human experiences, even though some of those models may be mutually orthogonal, and some may be quite mutually and actively antagonistic. In this sense, the juxtaposition of pure, frictionless "free markets" alongside the idea of absolutely pure scientific or technical decision making divorced from all other human considerations, while well-calibrated to inflame passions, represents less a contrast of opposites than a rather less illuminating pairing of two deeply unrealistic ideal types. Distilling a book as rich and informative as *Protocol Politics* down to one possible review-sized essence is much easier to accomplish from just such a privileged vantage point, and no doubt this particular review suffers from the all-too-predictable effects described herein. However, with that caveat firmly established, a few more things about *Protocol Politics* deserve to be mentioned here.

First, *Protocol Politics* is an important book. It is the well-written and informative, and is the first to be written for a general audience that draws on the right historical sources (or at least most of the right ones that remain accessible) to cover this critical period in the development of the Internet's core addressing and routing protocols. Even those who are least likely to be sympathetic to its findings are likely to find *Protocol Politics* to be a thoughtful and engaging read.

Second, IPJ readers and other technologists should not dismiss the inherently political, power-oriented framework that DeNardis employs in *Protocol Politics*. In general, the most honest and effective response to an assertion of *systemic* political or institutional bias is not to claim an equally absolute, otherworldy detachment from the affairs of man, but rather to remind the critic that in a world where all institutions are regarded as manifestations of somebody's will to power, specific targeted criticisms based *solely* on that fact lose all coherence. Would-be institutional critics who espouse such views thus have no choice but to make a positive argument as to which arrangement, among all of the equally power-tainted institutional arrangements that are possible, should be regarded as the preferable outcome, for whom, and why. Judged in this light, this reviewer feels that "the IETF way" still stands up pretty well, foibles and all. There is always room for improvement, but just as in matters of code, a concrete proposal for improvement is worth a thousand critiques of the past.

Finally, the careful reader may notice a pattern within this review, one composed of points highlighted here even though they may not be equally central to the story presented in *Protocol Politics* (for example, about the role of technical expertise in Internet governance, the dynamic limitations of routing system carrying capacity, the possibility of free market alternatives to current Internet address distribution arrangements, and so on).

Each of these points merits special attention because taken together they help to illuminate the existence of an identical set of critiques that have reappeared periodically in the course of another, much older (actually, centuries-old) debate that parallels the as-yet unresolved debates outlined by DeNardis in *Protocol Politics*.

In both instances, the question at issue involves the relative merits of nonmarket, technical expert-based systems as a means of managing resources that are uniquely central to economic growth, and for mitigating the systemic risks that can threaten that growth. In that other debate, arguments in favor of pure free market solutions have generally been dismissed as extreme and unrealistic for more than a century, ever since the last real-world implementation of such a system finally succumbed to its own chronic instabilities and was replaced by a nonmarket coordination arrangement. More recently, however, a resurgence of extreme turmoil in that parallel industry has undermined belief in expert management, if not in the underlying "hard realities" that were supposed to constitute the managers' technical domain of expertise. In turn this turmoil has sparked renewed interest in the long-marginalized pure free market proposals, as well as in alternative remedies involving much tighter industry control by nonmarket authorities.

How the current chapter in either of these parallel stories will play out remains to be written. However, those who are eager to anticipate the kind of language that is likely to play a central role in both outcomes will find that a close reading of *Protocol Politics* provides a wealth of possibilities to consider, and more than a few to keep one up at night.

[1] DeNardis makes several references to the idea that *Code is Law,* which was first articulated by Larry Lessig in *Code and Other Laws of Cyberspace* (1999) [Editor's note: *Code* was reviewed in IPJ Volume 11, No. 3]. Here the phrase is juxtaposed with David Clark's famous paean to "rough consensus and running code," which DeNardis describes as an "articulation of the IETF's core philosophy" (p. 47), and amended with a paraphrasing of an early (c. 1992) observation made by Marshall Rose about a common problem encountered when attempting to implement code to satisfy a non-operationally developed standard. The original staying was, "The problems of the real world are remarkably resilient to administrative fiat."

[2] Several formerly obscure insights on the events of this period were recently illuminated by RIPE co-founders Rob Blokzijl and Daniel Karrenberg, during RIPE's 20th Anniversary Commemoration at the RIPE 58 meeting in Amsterdam (May 2009). Some of these are available at:
http://www.ripe.net/ripe/meetings/ripe-58/content/presentations/Blokzijl-RIPE-20-years.pdf

and

Colitti and Kline Receive First Itojun Service Award

The first *Itojun Service Award* was presented at the recent IETF meeting in Hiroshima, Japan to Lorenzo Colitti and Erik Kline of Google for their outstanding contributions to the development and deployment of IPv6.

The award honours the memory of Dr. Jun-ichiro "Itojun" Hagino, who passed away in 2007, aged just 37. Established by the friends of Itojun and administered by the *Internet Society* (ISOC), the award recognises and commemorates the extraordinary dedication exercised by itojun over the course of IPv6 development.

"The sustained efforts of Lorenzo and Erik have tangibly increased the availability of Web-based services that use IPv6, reflecting the Itojun Service Award's focus on pragmatic contributions in the spirit of serving the global Internet's continued evolution," said Jun Murai of the Itojun Service Award committee and Director of the WIDE Project. "The award aims to recognize how important both the development of IPv6 and related protocols and efforts to advance their deployment are to ensuring the Internet continues to serve as a platform for innovation around the world."

The award, expected to be presented annually, includes a presentation crystal, a US$3,000 honorarium and a travel grant.

Lorenzo Colitti, Network Engineer at Google said, "This is a great honour. Itojun is a legend in the IPv6 community, and the Internet is indebted to him. Without his foundational work, none of what we achieved with IPv6 would be possible—we stand on the shoulders of giants. Itojun has been a source of inspiration, and I regret never being able to meet him, to show him our work, and show him that we too shared his vision of bringing IPv6 to the users of the Internet."

Erik Kline, IPv6 Software Engineer at Google said, "It's humbling to be sharing the Itojun Service Award, having achieved by comparison only a small fraction of the impact of his widely influential body of work. For me personally, Google's IPv6 efforts are not just for the Internet and its future, but also a way to honor his vision, dedication, and passion."

More information on the Itojun Service Award is available at: `http://www.isoc.org/itojun`

ISOC Donation to Support Evolution of W3C Organization

ISOC and the *World Wide Web Consortium* (W3C) recently announced a donation from ISOC for the purpose of advancing the evolution of W3C as an organization that creates open Web standards. Citing strongly aligned views on the value of an open global Internet and support for the current Internet governance and management model, ISOC pledged to support W3C efforts to implement a more agile, inclusive, and flexible organizational structure.

"ISOC and W3C have worked together for years in a number of areas, and have deeply shared values about the Internet's development," said Lynn St. Amour, President and CEO of ISOC. "Our support to the W3C in their transition efforts demonstrates our commitment to ensuring the Internet continues to be a global platform for innovation. What's at stake is the Internet's openness, which is a critical enabler of new products and services to billions of users worldwide."

"ISOC and W3C have a long history of cooperation and the Internet ecosystem has benefited from our shared yet independent voices," said Tim Berners-Lee, W3C Director. "The W3C staff, Members, and community continue to work on making W3C more relevant and valuable to the Web and Internet communities. ISOC support will allow W3C to evolve its structure to ensure we continue to forge solid working relationships with the increasing numbers of developers and users, worldwide."

The two organizations will continue to operate independently, and will maintain their long-standing, informal collaboration. ISOC's pledge of support is for three years, with both organizations working to ensure progress. A FAQ with additional information is available on both the ISOC site and the W3C site, see `http://www.isoc.org` and `http://www.w3.org`

DNSSEC Deployment in the Root Zone

In December 2009, ICANN and VeriSign began to deploy DNSSEC across the root server system and launched a website that provides information about DNSSEC for the root zone. The website is a repository for the documentation relating to the deployment of DNSSEC, and it includes information such as technical status updates and the full timetable for the deployment osf DNSSEC.

The Internet Protocol Journal

March 2010 Volume 13, Number 1

A Quarterly Technical Publication for Internet and Intranet Professionals

In This Issue

You can download IPJ back issues and find subscription information at:
www.cisco.com/ipj

ISSN 1944-1134

From The Editor

Previous articles in IPJ have described *Domain Name System Security Extensions* (DNSSEC), the security system for the *Domain Name System* (DNS). DNSSEC introduces security into the DNS through the use of cryptographic keys and digital signatures. Interest in DNSSEC has grown in recent months, as the *Internet Corporation for Assigned Names and Numbers* (ICANN) and VeriSign have undertaken a phased program to deploy DNSSEC across the root server system in the first half of 2010. In an article by four DNS practitioners, we will explore some side effects of DNSSEC, and examine what happens in two widely used DNS resolver implementations when DNS clients lag behind in synchronizing their local copy of trust keys with the master keys used by the zone administrators to sign their DNS data.

Several articles in IPJ have dealt with various concerns related to scaling of the Internet. In this issue, Paul Francis and Xiaohu Xu describe *Virtual Aggregation,* a new routing technology being developed by the GROW working group of the IETF to reduce the size of the *Forwarding Information Base* (FIB) held in memory by routers.

The *Request For Comments* (RFC) Series has been the main publication channel for Internet standards and related documents for more than 40 years. The RFC Editor function is in the process of being restructured and moved from its original home at the *University of Southern California Information Sciences Institute* (USC/ISI). Leslie Daigle describes the history and future of the RFC Editor mechanism.

Rolling Over DNSSEC Keys

by George Michaelson, APNIC, Patrick Wallström, .SE, Roy Arends, Nominet, Geoff Huston, APNIC

As we are constantly reminded, the Internet can be a very hostile place, and public services are placed under constant pressure from a stream of probe traffic, attempting to exploit any one of numerous vulnerabilities that may be present at the server. In addition, there is the threat of *Denial of Service* (DoS)[1] attacks, where a service is subjected to an abnormally high traffic load that attempts to saturate and take it down. This story starts with the detection of a possible hostile DoS attack on *Domain Name System* (DNS) servers, and narrates the investigation as to the cause of the incident, and the wider implications of what was found in this investigation.

Detecting the Problem

The traffic signature in Figure 1 is a typical signature of an attempted DoS attack on a server, where the server is subjected to a sudden surge in queries. In this case the traffic log is from a secondary DNS Name Server that is authoritative for a number of subdomains of the **`in-addr.arpa`** zone; the traffic surge shown here commenced on December 16, 2009. The traffic pattern shifted from a steady state of some 12 Mbps to a new steady state of more than 20 Mbps, peaking at 30 Mbps.

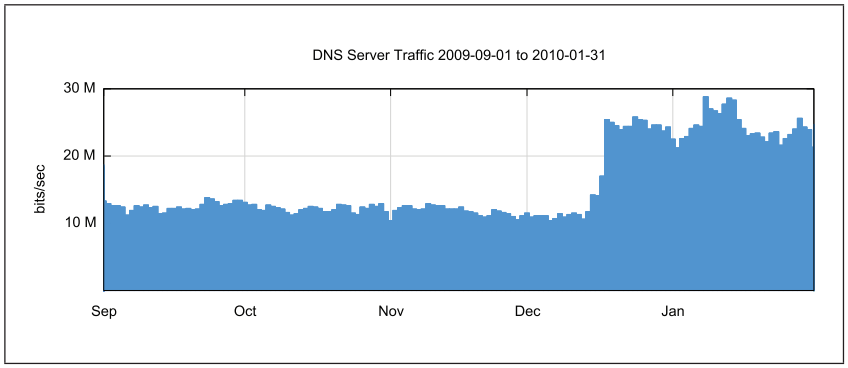

Figure 1: Traffic Load for ***`in-addr.arpa`*** *Server (provided by George Michaelson)*

Because the traffic shown in Figure 1 is traffic passed to and from a Name Server, the next step is to examine the DNS traffic on the Name Server, and in particular look at the rate of DNS queries that are being sent to the Name Server (Figure 2). The bulk of the additional query load is for DNSKEY *Resource Records* (RRs), which are queried as part of the operation of *Domain Name System Security Extensions* (DNSSEC)[2].

Because this zone is a DNSSEC signed zone, DNSKEY queries will cause the server to respond with a DNSKEY RR and the related RRSIG RR in response to each query. This pair of RRs generates a response that is 1,188 bytes in this case. At a peak query rate of some 3,000 DNS queries per second, a traffic response from the server in excess of 35 Mbps will be generated.

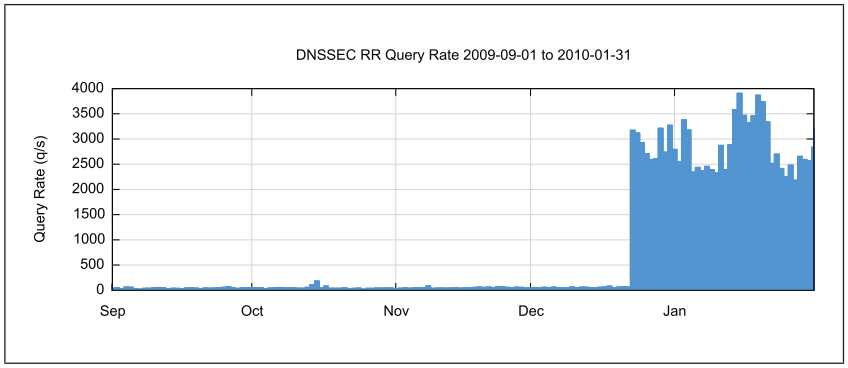

Figure 2: Query Rate for ***in-addr.arpa*** *Server (provided by George Michaelson)*

There are many possibilities as to what is going on here:

- This problem could be caused by a DoS attack directed at the server, with the attacker attempting to saturate the server by flooding it with short queries that generate a large response.
- This problem could be caused by a DNS reflection DoS attack, where the attacker is placing the address of the intended victim or victims in the source address of the DNS queries and attempting to overwhelm the victim with this DNS response traffic.

Although it is good to be suspicious, it is also useful to remember the old adage that we should be careful not to ascribe to malice what could equally be explained by incompetence, so numerous other explanations should also be considered, including:

- This problem could be a DNS resolver problem, where the resolver is not correctly caching the response, and some local event is triggering repeated queries.
- This problem could be a bug in an application where the application has managed to wedge itself in a state of rapid-fire queries for DNSKEY RRs.

The next step is to examine some of these queries more closely, and, in particular, look at the distribution of query source addresses to see if this load can be attributed to a small number of resolvers that are making a large number of queries, or if the load is spread across a much larger set of resolvers. The server in question typically sees on the order of 500,000 to 1,000,000 distinct query sources per day.

Closer inspection of the query logs indicates that the additional load is coming from a relatively small subset of resolvers, on the order of 1,000 distinct source addresses, with around 100 "heavy hitters." In other words, all this DNS traffic is being generated by some 0.01% of the DNS clients. The sequence of queries from one such resolver that is typical of the load being imposed on the server is shown in Figure 3.

Figure 3: DNS Query Sequence Packet Capture

1. Client requests the Delegation Signer (DS) records for the `211.89.in-addr.arpa` zone.
2. Reply says "no such delegation," and sends *DNSSEC Signature* (RRSIG) and *Next-Secure record* (NSEC) from the parent zone, and surrounding records.
3. Client requests DNSKEY from the parent zone.
4. Server sends DNSKEY and RRSIG set for the parent zone.

Having established an initial query state and the DNSKEY and signature set over the original request, the client then paradoxically repeatedly re-queries the parent-zone DNSKEY state. This process is elided as follows because the query and response do not differ during this exchange:

5. Client repeats the DNSKEY request.
6. Server repeats the DNSKEY and RRSIG response.
7. Client repeats the DNSKEY request.
8. Server repeats the DNSKEY and RRSIG response.

This exchange of DNSKEY request and DNSKEY and RRSIG response is repeated a further 6 times.

If this additional query load had appeared at the server over an extended period of time, it would be possible to ascribe this problem to a faulty implementation of a DNS resolver, or a faulty client application. However, the sudden onset of the additional load tends to suggest that something else is happening. The most likely explanation is that some external "trigger" event exacerbated a latent behavioral bug in a set of DNS resolver clients. And the most likely external trigger event is a change of the contents of the zones being served.

So we can now refine our set of possible causes to concentrate consideration on the possibility that:

- Something changed in the zones being served by this secondary server that triggered a pathological query response from a set of resolvers.

And indeed the contents of the zones did change on the day when the traffic profile changed, with a key change being implemented on that day.

DNSSEC Key Management

It is considered good operational practice to treat cryptographic keys with a healthy level of respect. As RFC 4641[3] states: "The longer a key is in use, the greater the probability that it will have been compromised through carelessness, accident, espionage, or cryptanalysis." Even though the risk is considered slight if you have chosen to use a decent key length, RFC 4641 recommends, as good operational practice, that you "roll" your key at regular intervals. Evidently it is a popular view that fresh keys are better keys.

The standard practice for a "staged" key rollover is to generate a new key pair, and then have the two public keys coexist at the publication point for a period of time. This practice allows relying parties, or clients, some period of time to pick up the new public key. Where possible during this period, signing is performed twice, once with each key, so that the validation test can be performed using either key. After an appropriate interval of parallel operation, the old key pair can be deprecated and the new key can be used exclusively for signing.

This key rollover process should be a routine procedure, without any intended side effects. Resolvers that are using DNSSEC should refresh their local cache of zone keys in synchronization with a published schedule of key rollover, and ensure that they load a copy of the new key within the period when the two keys coexist. In this way when the old key is deprecated, responses from the zone servers can be locally validated using the new key.

The question here is why did this particular key rollover for the signed zone cause the traffic load at the server to spike? And why is the elevated query rate sustained for weeks after the key rollover event? The key had changed 6 months earlier and yet the query load prior to this most recent key change was extremely low.

DNSSEC DNS Resolver Behavior with Outdated Trust Keys

It is possible to formulate a theory as to what is going on from this collection of information. It could be that one or more DNS resolver clients has been using a local *Trust Anchor* that has been manually downloaded from the zone administrator prior to the most recent key rollover, but has not been updated since. When the key rollover occurred in December 2009, these clients could no longer validate the response with their locally stored Trust Anchors.

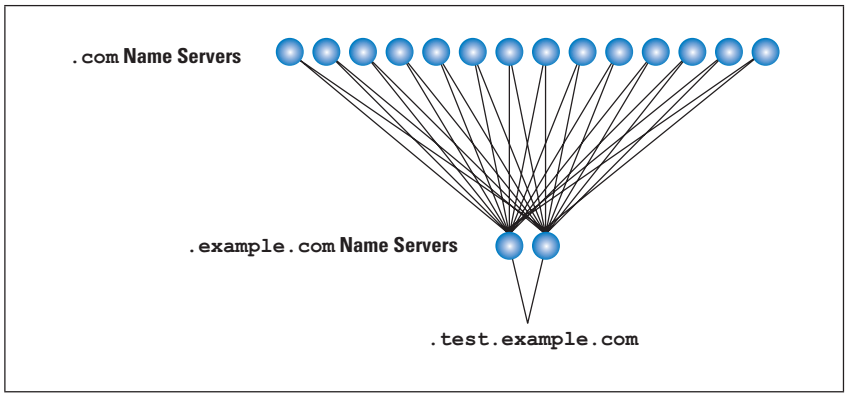
Upon detecting an invalid signature in the response, the client appears to have reacted as if there were a "man-in-the middle" injection attempt, and immediately repeated the request in an effort to circumvent the supposed attack by rapidly repeating the query. If this instance were really a man-in-the-middle injection attack, this response would be plausible, because there is the hope that the query will still reach the authoritative server and the client will receive a genuine response that can be locally validated.

Why does the client really perform this repeated query pattern? In this case the contributory factor is the use of multiple name servers in the DNS. When the DNS client performs a key validation, it performs a bottom-up search to establish the trust chain from the initial received query to a configured Trust Anchor.

Example DNSSEC Validation

As a hypothetical example, assume a TXT RRset for **test.example.com** in a signed **example.com** zone. The zone **example.com** resides on two Name Server addresses. The **example.com** zone has a *Key Signing Key* (KSK), which is referred to by the DS record in the **.com** zone. The **.com** zone is signed, and it resides on 14 addresses (11 IPv4 and 3 IPv6). The **.com** zone has a KSK, which is referred to by a Trust Anchor in the local configuration of the resolver (Figure 4).

Figure 4: Example Configuration



Assume that the locally held Trust Anchor for **.com** in the resolver has become stale. That is, the DS record for **.com** in the root zone validates, but there are no DNSKEYs in **.com** that match the DS record in the root zone.

When a client is resolving a query relating to **test.example.com**, the following search occurs:

- *Berkeley Internet Name Domain* (BIND)[9] resolves the **test.example.com** RRset. It attempts to validate it. To do so, it needs the **example.com** DNSKEY RRset.
- It resolves the DNSKEY RRset for **example.com** from a Name Server of **example.com**. It attempts to validate it. To do so, it needs the **example.com** DS RRset.
- It resolves the DS RRset for **example.com** from a Name Server of **.com**. It attempts to validate it. To do so, it needs the **.com** DNSKEY RRset.
- It resolves the DNSKEY RRset for **.com** from a Name Server of **.com**. It attempts to validate it with the locally configured Trust Anchor.

However, the resolver cannot validate the **.com** DNSKEY RRset because it does not have the proper Trust Anchor for it. It queries all remaining 13 **.com** servers for the DNSKEY RRset for **.com**. Then the resolver still does not have the proper **.com** DNSKEY, and tracks back one level:

- It resolves the DS RRset for **example.com** from the next authoritative Name Server. It attempts to validate it. To do so, it needs the **.com** DNSKEY RRset. The search goes forward again.
- It resolves the DNSKEY RRset for **.com**. It attempts to validate it with the locally configured Trust Anchor.

Because the DNSKEY RRset for **.com** has not changed, this attempt will fail as well.

The complete in-depth first search consists of:

- TXT records on 2 **example.com** servers, signed by:
- DNSKEY records on 2 **example.com** servers, referred to by:
- DS records on 14 **.com** servers, signed by:
- DNSKEY records on 14 **.com** servers.

When all possible paths are exhausted, the client will have sent the following:

- 784 (2 × 2 × 14 × 14) **.com** DNSKEY requests to 14 **.com** Name Servers
- 56 (2 × 2 × 14) **example.com** DS requests to 14 **.com** Name Servers
- 4 (2 × 2) **example.com** DNSKEY requests to 2 **example.com** Name Servers

In other words, in this example scenario with stale Trust Anchor keys in a local client's resolver, a single attempt to validate a single DNS response will cause the client to send a further 844 queries, and each **.com** Name Server to receive 56 DNSKEY RR queries and 4 DS RR queries.

The breadth and level of the search is important here, because the longer the validation chain and the more the number of authoritative Name Servers for those zones that lie on the validation chain path, the more queries that will be sent in an effort to validate a single initial response. In this example, the level of search is three deep, and terminates at **.com**. If the **.com** zone were signed by the root Name Servers and the client were using a stale root zone key, then the 20 distinct root zone server addresses (13 in IPv4 and 7 IPv6 addresses) would also be queried:

- 313,600 (2 × 2 × 14 × 14 × 20 × 20) root DNSKEY requests to 20 root Name Servers
- 15,680 (2 × 2 × 14 × 14 × 20) **.com** DS requests to 20 root Name Servers

It is worthwhile noting in this context that reverse trees and enum trees in the **.arpa** zone are longer on average. Though delegations in those subtrees might span several labels, it is not uncommon to delegate per label. Note also that the entire effort is done per incoming query—the entire search is repeated for each query.

Though this example shows an enormous query load, there are a few ceilings. In commonly used validating resolvers, such as BIND 9.7rc2, every search is performed in serial, and each search is halted after 30 seconds.

The *Unbound* client[4] also appears to have a similar request behavior, although it is not as intense because of the cache management in this implementation. Unbound will "remember" the query outcome for a further 60 seconds, so repeated queries for the same name will revert to the cache. But the DNSSEC key validation failure is per zone, and further queries for other names in the same zone will still exercise this re-query behavior. In effect, for a zone that has sufficient "traffic" of DNS load in subzones or instances inside that zone, the chain of repeated queries is constantly renewed and kept alive.

If one such client failed to update its local trusted key set, then the imposed server load on DNSSEC key rollover would be slight. However, if a larger number of clients were to be caught out in this manner, then the load signature of the server would look a lot like Figure 2. The additional load imposed on the server comes from the size of the DNSKEY and RRSIG responses, which are 1,188 bytes per response in the specific failure case that triggered this investigation.

So far we've been concentrating attention on the **`in-addr.arpa`** zone, where the operational data was originally gathered. However, it appears that this problem could happen to any DNSSEC signed domain where the zone keys are published so as to allow clients to manually load them as trust points, and where the keys are rolled on a regular basis.

It is likely that one possible cause for this situation is in the way in which some DNSSEC distributions are packaged with operating systems. For example, the *Fedora*[5] Linux distribution has bundled numerous trust keys with its packaging of a DNS resolver client and local Trust Anchor key set. When the keys associated with sub zones of **`in-addr.arpa`** rolled over in December 2009, users of this version of the Fedora Linux distribution would have been caught with stale trust keys.

So there appears to be a combination of three factors that are causing this situation:

- The use of prepackaged DNSSEC distributions that included preloaded keys in the distribution
- The use of regular key rollover procedures by the zone administrator
- Some implementations of DNS resolvers that react aggressively when there is a key validation failure by performing a rapid sequence of repeat queries, with either a very slow, or in some cases no apparent back-off in query load

This combination of circumstances makes the next scheduled key rollover for **in-addr.arpa**, scheduled for June 2010, appear to be quite an "interesting" event. If there is the same level of increase in use of DNSSEC with manually managed trust keys over this current 6-month interval as we've seen in the previous 6 months, and if the same proportion of clients fails to perform a manual update prior to the next scheduled key rollover event, then the increase in the query load imposed on **in-addr.arpa** servers at the time of key rollover promises to be truly biblical in volume.

Signing the DNS Root

There is an end in sight for this situation for the subzones of **in-addr.arpa**, and for all other such subzones that currently have to resort to various forms of distribution of their zone keys. The *Internet Corporation for Assigned Names and Numbers* (ICANN) has announced that on July 1, 2010, a signed root zone for the DNS will be fully deployed[6]. Assuming that the **.arpa** and **in-addr.arpa** zones will be DNSSEC-signed in a similar time frame, the situation of escalating loads being imposed on the servers for delegated subdomains of **in-addr.arpa** at each successive key rollover event will be curtailed. It would then be possible to configure the client with a single trust key, the public key signing key for the root zone, and allow the client to perform all signature validation without the need to manually manage other local trust keys.

There are two potential problems with this scenario.

The first is that for those clients that fail to remove the local Trust Anchor key set, these repeated queries may not go away. When there are multiple possible chains of trust, the resolver will attempt to validate using the shortest validation chain. As an example, if a client has configured the DNSKEY for, say, **test.example.com** into its local Trust Anchor key set, and it then subsequently adds the DNSKEY for **example.com**, the resolver client will attempt to validate all queries in **test.example.com** and its subzones using the **test.example.com** DNSKEY.

A more likely scenario is where an operator has already added local Trust Anchor keys for, say, **.org** or **.se**. When the root of the DNS is signed, the operator may also add the keys for the root to the local Trust Anchor set. If the operator fails to remove the local copies of the **.org** and **.se** Trust Anchor keys, in the belief that this root key value will override the **.org** and **.se** local keys, then the same validation failure behavior will occur. In such a case, when the local keys for these second-level domains become stale, their resolver will exhibit the same re-query behavior, even when they maintain a valid local root Trust Anchor key.

As a side note, the same behavior may occur when *DNSSEC Lookaside Validation* (DLV) is used. If the zone key management procedures fall out of tight synchronization with the DLV repository, it is possible to open a window where the old key remains in the DLV repository, but is no longer in the zone file. This situation can lead to a window of vulnerability where the keys in the DLV repository are unable to validate the signed information in the zone file, a situation that, in turn, introduces the same problem with re-query.

The second potential problem lies with the phase-in approach of signing the root. The staged rollout of DNSSEC for the root zone envisages a sequenced deployment of DNSSEC across the root server clusters, and through this sequence the root will be signed with a key that has no valid published public part, creating a *Deliberately Unvalidatable Root Zone* (DURZ).

What happens when a client installs this key in its local Trust Anchor set and performs a query into the root zone?

As an experiment, this DURZ key was installed into an instance of BIND 9.7.0rc2, with a single upstream root, pointing at the "L" root, the only instance of the 13 authoritative root servers enabled with DNSSEC signed data in February 2010. On startup the client made 13 consecutive DNSKEY requests, one to each of the root zone server addresses. When the client started its first query in a subzone, the client issued a further 156 DNSKEY queries in a period of 19 seconds, making 12 queries to each of the 13 root zone server addresses.

This scenario should sound familiar, because it is precisely the same query pattern as happened with the **`in-addr.arpa`** servers and the **`.se`** servers, although the volume of repeated DNSKEY queries is somewhat alarming. When the client receives a response from a subdomain that needs to be validated against the root, and when the queries to the root are not validatable against the local trust key, the client goes into a sequence of repeated queries that explore each potential validation path. Anchoring the local resolver with a key state that invalidates the signatures of all authoritative servers of the zone—but authoritatively (absent DNSSEC) confirms them as valid servers of the zone—places the client instance in an unresolvable situation: no authoritative Name Server that it can query has a signature that the client can validate, but the root zone informs it that only these Name Servers can be used.

Further tests of this behavior show that the client does not cache the outcome that the DNSKEY cannot be validated for a zone, and the client reinitiates this spray of repeated queries against the zone Name Servers when a subsequent DNSSEC query is made in a subzone. Therefore the behavior is promiscuous in two distinct ways. First it is evident that any Name Server so queried is repeatedly queried. Second, it is evident that all Name Servers of a zone are queried. The other part of the client response is not to cache validation failure for the zone in case this repeated query phase does not provide the client with a locally validated key.

After all, the data is provably false, so caching it would be to retain something that has been "proven" to be wrong.

The emerging picture is that misconfigured local trust keys in a DNS resolver for a zone can cause large increases in the DNS query load to the authoritative Name Servers of that zone, where the responses to these additional queries are themselves large, of the order of 1,000 bytes in every response. This situation can occur for any DNSSEC signed zone.

The conditions for the client to revert to a rapid re-query behavior follow:

- The *DNSSEC OK* (DO) bit is honoured by the server.
- The DNS data appears to be signed.
- The signature check fails.
- The client does not cache the validation failure for this zone.

The conditions being set up for the DURZ approach for signing the root follow:

- The DO bit is honoured by the server.
- The DNS data appears to be signed.
- The signature check fails.
- The client does not cache the validation failure for this zone.

What is to stop the DNS root servers from being subjected to the same spike in the query load?

The appropriate client behavior for this period of DNSSEC deployment at the root is not to enable DNSSEC validation in the resolver. Although this advice is sound, it is also true that many resolvers have already enabled validation in their resolvers, and are probably not going to turn off for the next 6 months while the root servers gradually deploy DNSSEC using DURZ.

But what load will appear at the root servers if a subset of the client resolvers starts to believe that these unvalidatable root keys should be validated?

What If…?

The problem with key rollover and local management of trust keys appears to be found in around 1 in every 1,500 resolvers in the **`in-addr.arpa`** zones. With a current client population of some 1.5 million distinct resolver client addresses each day for these **`in-addr.arpa`** zones, there are some 1,000 resolvers who have lapsed into this repeated query mode following the most recent key rollover of December 2009. Each subzone of **`in-addr.arpa`** has six Name Server records, and all servers see this pathological re-query behavior following key rollover.

The root servers see a set of some 5 million distinct resolver addresses each day, and a comparable population of nonupdated resolvers would be on the order of some 3,000 resolvers querying 13 zone servers, where each zone server would see an incremental load of some 75 Mbps.

Because the re-query behavior is caused by the client's being forced to reject the supposedly authoritative response because of an invalid key, and because DURZ is by definition an invalid key, the risk window for this increased load is the period during which DURZ is enabled, which for the current state of the root signing deployment is from the present date until July 2010. Because not all root servers have DNSSEC content or respond to the DO bit—and therefore do not return the unvalidatable signatures—the risk is limited to the set of DNSSEC-enabled roots, which is increasing on a planned, staged rollout. It has been reported that a decision to delay deployment of the DNSSEC/DURZ sign state to the "A" root server instance was made because this root server receives a noted higher query load for the so-called "priming" queries, made when a resolver is reinitialized and uses the offline root "hints" file to bootstrap more current knowledge. It is therefore likely that the "A" root server would also see increased instances of this particular query model, if the priming query is implicated in this form of traffic.

Arguably, this situation is unlikely. For most patterns of DNS query, failure to validate is immediately apparent. After all, where previously you receive an answer, you now see your DNS queries time out and fail.

However, because the typical situation for a client host (including *Dynamic Host Configuration Protocol* [DHCP] initialized hosts in the customer network space, the back office, etc.) is to have more than one listed resolver, there is the possibility of a misconfiguration being unnoticed during the period of a rolling deployment of DNSSEC-enabled services. In this situation if only one of the resolver's "nserver" entries is DNSSEC-enabled, either it is not queried or it is queried, but then passed over by the resolver timeout setting. Users see slower DNS resolution, but can attribute it to network delay or other local problems.

A second argument is that installation of hand-trust material is not normal, so the servers in question will be immediately known because a nonstandard process has to be invoked. Unfortunately, this situation is demonstrably not true. For example, the *Fedora*[5] release of Linux has included a simple DNSSEC-enabling process including a preconfigured trust file covering the reverse-DNS ranges. Because a previous release of this software included now stale keys (which have since been withdrawn in subsequent releases), any instance of *Fedora* for this release state being enabled will not only be unable to process reverse-DNS, it may also invoke this re-query mode of operation that places the server under repeated load of DNSKEY requests.

Because reverse-DNS is the "infrastructure" DNS query that is typically logged, but not otherwise used, unless the server in question is configured to block service on failing reverse (unlikely, given than more than 40 percent of reverse-DNS delegations are not made for the currently allocated IP address ranges), the end user simply might never notice this behavior. The use of so-called "Live CDs" can exacerbate this problem of pre-primed software releases that include key material that falls out-of-date. Even when the primary release is patched, the continued use of older releases in the field is inevitable. So perhaps this second argument is not quite as robust as originally thought.

Lastly, distinct from hand-installed local trust is the use of DNSSEC look-aside validation, which is known as DLV. This DNS namespace is privately managed and has been using the ICANN-maintained *Interim Trust Anchor Repository*, or ITAR. The DLV service is configured to permit resolvers to query it, in place of the root, to establish trust over subzones that exist in a signed state, but cannot be seen as signed from the root downward before the deployment of a signed root. There is now evidence that part of this query space exists, covering zones of interest to this situation. The **`.se`** zone key, for instance, is in the ITAR, as are the **`in-addr.arpa`** spaces signed by the RIPE NCC. Evidence suggests that if the DLV chain is being used and a key rollover takes place, some variants of BIND resolver clients fail to reestablish trust over the new keys until the client is rebooted with a clean cache state. This theory is difficult to confirm because as each resolver is restarted, the stale trust state is wiped out and the local failure is immediately resolved.

Post DURZ

Of course this phase is transitory, and even if there are concerns in terms of DURZ and queries to the root servers, all will be resolved when the root key is rolled to a validatable key on July 1, 2010.

Yes? Maybe not.

The current plan is to roll the root zone Key Signing Key every 2 to 5 years. The implication is that sometime every 2 to 5 years all DNS resolvers will need to ensure that they have fetched a new root trust key and loaded it into their resolver's local trust key cache.

If this local update of the root trust key does not occur, then the priming query for such DNSSEC-enabled resolvers will encounter this problem of an invalid DNSKEY when attempting to validate the priming response from the root servers. The fail-safe option here for the resolver client is to enter a failure mode and shut down, but there is a strong likelihood that the resolver client will try as hard as it can to fetch a validatable DNSKEY for the root before taking the last resort of a shutdown, and in so doing will subject the root servers to this intense repeated query load that we are seeing on the **`in-addr.arpa`** zone.

A reasonable question to ask follows: "Are there any procedural methods to help prevent stale keys from being retained during key rollover?" Reassuringly, the answer is "Yes." There is a relatively recent RFC, "Automated Updates of DNS Security (DNSSEC) Trust Anchors," RFC 5011[7], which addresses this problem.

RFC 5011 provides a mechanism for both signaling that a key rollover needs to take place and forward declaring the use of keys to sign over the new trust set to permit in-band distribution of the new keys. Resolvers are required to be configured with additional keying, and a level of trust is placed on this mechanism to deal with normal key rollover. RFC 5011 does not solve initial key distribution problems, which of course must be made out of band, nor does it attempt to address multiple key failures. Cold standby equipment, or decisions to return to significantly older releases of systems (for example, if a major security compromise to an operating system release demands a rollback) could still potentially deploy resolvers with invalid, outdated keys. However, RFC 5011 will prevent the more usual process failures, and it provides an elegant in-band rekeying method that obviates a manual process of key management that all too often fails through neglect or ignorance of the appropriate maintenance procedures to follow.

It is unfortunate that RFC 5011-compliant systems are not widely deployed during the lifetime of the DURZ deployment of the root, because we are definitely going to see at least one key rollover at the end of the DURZ deployment, and we can expect a follow-up key rollover within a normal operations window. The alternative is that no significant testing of root trust rollover takes place until we are committed to validation as a normal operational activity—a situation that invites the prospect of production deployment across the entire root set while many production operational processes associated with key rollover remain untested. The evidence from past concerns in resolver behavior is that older deployments have a very long lifetime for any feature under consideration, and because BIND 9.5 and older prerelease BIND 9.7 systems can be expected to persist in the field in significant numbers for some years to come, it is likely a significant level of pathological resolver behavior in re-querying the root services by active resolvers will have to be tolerated for some time.

It is also concerning that aspects of the packet traces for the **`in-addr.arpa`** zone suggest that for all key rollovers, albeit at very low levels of query load, some of the resolvers have simply failed to account for the new keys—and may never do so. Therefore, with increasing deployment of key validation, it is possible that a substantial new traffic class that grows, peaks, and then declines, but always declines to a slightly higher value than before, has to be borne, and factored into deployment scaling and planning.

Because this traffic is large—generating a kilobyte of response per query and potentially generally prevalent—it has the capability to exceed the normal response requirements for "normal" DNS query loads by at least one, if not two orders of magnitude. This multiplication factor of load is defined by the size of the resolver space and the number of listed Name Servers for the affected zone.

Mitigation at the server side is possible if this problem becomes a major one. The pattern of re-query here (the sequence of repeated queries for DNSKEY RRs) appears a potential signature for this kind of problem. Given that for any individual server the client times its repeat queries on the reception of the response from the previous query, delaying the response of the server to the repeated query will further delay the client's making its repeated query to this server. If the server were in a position to delay such repeated responses, using a form of exponential increase in the delay timer or similar form of time penalty, then the worst effects of this form of client behavior in terms of threats to the integrity of the ability of the server to service the "legitimate" client load could be mitigated.

Conclusion

It is an inherent quality of the DNSSEC deployment that in seeking to prevent lies, an aspect of the stability of the DNS has been weakened. When a client falls out of synchronization with the current key state of DNSSEC, it will mistake the current truth for an attempt to insert a lie. The subsequent efforts of the client to perform a rapid search for what it believes to be a truthful response could reasonably be construed as a legitimate response, if indeed this instance was an attack on that particular client. Indeed, to do otherwise would be to permit the DNS to remain an untrustable source of information. However, in this situation of slippage of synchronized key state between client and server, the effect is both local failure and the generation of excess load on external servers—and if this situation is allowed to become a common state, it has the potential to broaden the failure state to a more general DNS service failure through load saturation of critical DNS servers.

This aspect of a qualitative change of the DNS is unavoidable, and it places a strong imperative on DNS operations and the community of the 5 million current and uncountable future DNS resolvers to understand that "set and forget" is not the intended mode of operation of DNSSEC-equipped clients.

Extending Router Lifetime with Virtual Aggregation

by Paul Francis, Max Planck Institute for Software Systems, and Xiaohu Xu, Huawei Technologies

Biologists believe that human life is limited by the number of times cells can replicate; noncancerous cells have a kind of internal counter that prevents them from replicating forever. Even if humans are kept healthy in every respect, they will eventually die simply because their cells will cease to replicate. Internet routers also have a finite lifetime. They are built with a fixed amount of hardware memory for storing the forwarding table (the memory structure that tells the router where to forward any IP packet, also called the *Forwarding Information Base* [FIB]). As the Internet global routing table grows, it eventually overflows the FIB, and the router ceases to be able to hold the full routing table. Even if the router is healthy in every respect (all of its hardware components still operate), it can no longer function as a router in the Internet *Default-Free Zone* (DFZ), where no default routes can be used.

In the past, router vendors have been reasonably good at predicting how long FIBs will last because the growth of the global DFZ routing table has stayed fairly predictable. As a result, *Internet Service Providers* (ISPs) can plan their capital budgets, and where necessary use a set of tricks (discussed in the next section) to squeeze additional life out of routers even after their "FIB death." But there are two problems.

First, these tricks work only in limited situations, they require extra configuration, and they can lead to increased traffic loads. Second, and potentially much more serious, the rate of routing table growth may dramatically accelerate in the near future, thus shrinking the lifetime of the installed router base. This expected acceleration is due to the imminent exhaustion of IPv4 addresses. In the past, address authorities such as the *American Registry for Internet Numbers* (ARIN) could assign large contiguous blocks of addresses to ISPs, which in turn assigned smaller blocks to their customers. Therefore, routers in other ISPs' networks need only a single routing table entry—that of the large block—to route to destinations in the ISP. This approach to scaling is called *address aggregation*. There is a fear that, as IPv4 addresses become increasingly unavailable, ISPs will start buying and selling smaller and smaller blocks of IP addresses from each other in an effort to squeeze out as many addresses as possible. These small blocks will appear all over the Internet thus significantly increasing the size of the routing table.

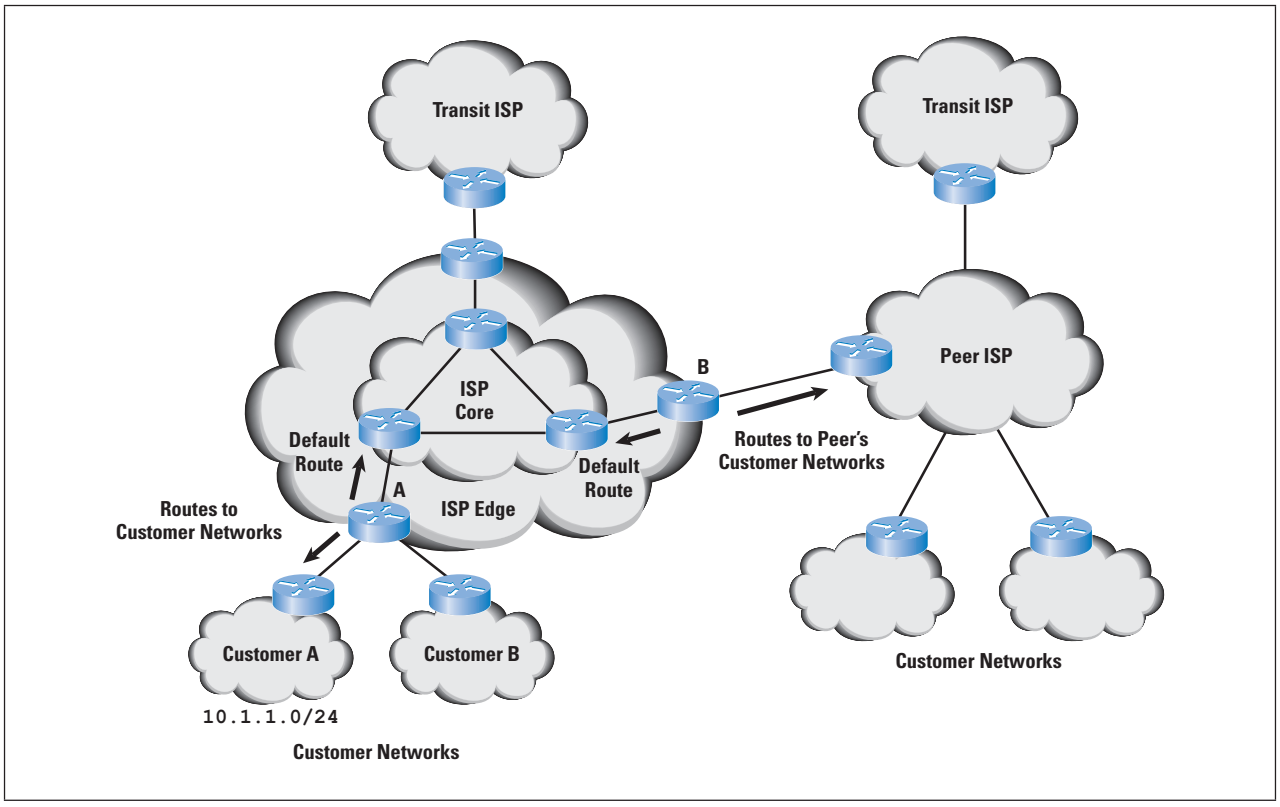
This article describes a new routing technology, called *Virtual Aggregation* (VA), which mitigates these problems. It makes extending the lifetime of old routers much easier, and makes it possible for existing routers to absorb a surge in the routing table size. Virtual Aggregation is a working item in the *Global Routing Operations Working Group* (GROW) working group of the IETF[7], and is documented in `draft-ietf-grow-va`[6] and related drafts.

Tricks for Keeping Old Routers Deployed

ISPs frequently want to extend the usefulness of a router beyond its "FIB death," and there are many tricks for doing just this. The most common is to structure the ISP in a core-edge arrangement. In this setup, a core of routers forms the backbone of the network. Edge routers connect to other networks and feed into the core. In many cases these edge routers do not need to know how to route to everything in the Internet. Rather, they often need to know only what addresses are reachable in their directly connected networks.

For instance, Figure 1 shows an ISP whose edge routers connect to three types of other networks: customer networks, peer ISP networks, and transit ISP networks. Each customer network has only one or a small number of address prefixes. The edge routers connecting customer networks must know what addresses are reachable in the customer networks, but everything else can be "default routed" to the core. Likewise, the routers connected to peer ISPs need to know how to route to the peers' customer addresses. Everything else can be defaulted to the core. The core routers and the edge routers that connect to transit ISPs, however, need to know how to route to everything.

Figure 1: With a core-edge style of deployment, some routers need to keep full routing tables, while others can keep partial routing tables and default route everything else to the ISP core.



A common practice is for ISPs to delegate FIB-dead routers to the customer or peer edges, and to have the core routers filter the routing information given to the edge routers. For instance, router A in Figure 1 learns the addresses reachable in customer network A (say, `20.1.1.0/24`) and conveys them to the ISP core, but the core tells router A only that "everything else" is reachable through it (`0.0.0.0/0`). But what if customer A itself wants the full DFZ routing table? For instance, customer A might be multihomed to some other ISP, and might want to know which Internet destinations are best reachable through each ISP. To do this, it needs to receive the whole routing table from each ISP, a situation that, of course, cannot happen if the core withholds routes from router A.

As another example, what if two peer ISPs later decide that they want to offer transit service to each other? Now additional routes need to be conveyed to the peer-connected edge routers (router B), and this process may not be possible with limited FIB.

Another way an ISP can shrink its routing table is to default route to its transit ISPs. For instance, routers keep track only of how to route to customers and peers, and everything else is defaulted to the transit ISPs. When this default routing is done, even an ISP's core routers do not need the full routing table. A simple approach is for an ISP to send all defaulted packets to the nearest transit ISP. This process, however, may result in many packets taking a longer Internet path than necessary. Reference [1] describes a more complicated approach where the ISP maintains "semidefaults" for different transit networks in order to improve its global routing while reducing routing table size by about half. This approach, however, can be hard to manage.

In addition, any form of ISP-level default (simple or complex) results in sending extra traffic to the transit ISPs. A substantial amount of Internet traffic is targeted to nonroutable prefixes. When an ISP has the full routing table, it can identify this traffic and drop it before sending it to its transit ISPs. When an ISP defaults, it sends this traffic to its transit ISPs, and pays for it.

To summarize, dealing with FIB-dead routers leads to more complex management, limitations in business arrangements with peers and customers, poor paths over the Internet, and increased traffic load.

The Idea of Virtual Aggregation

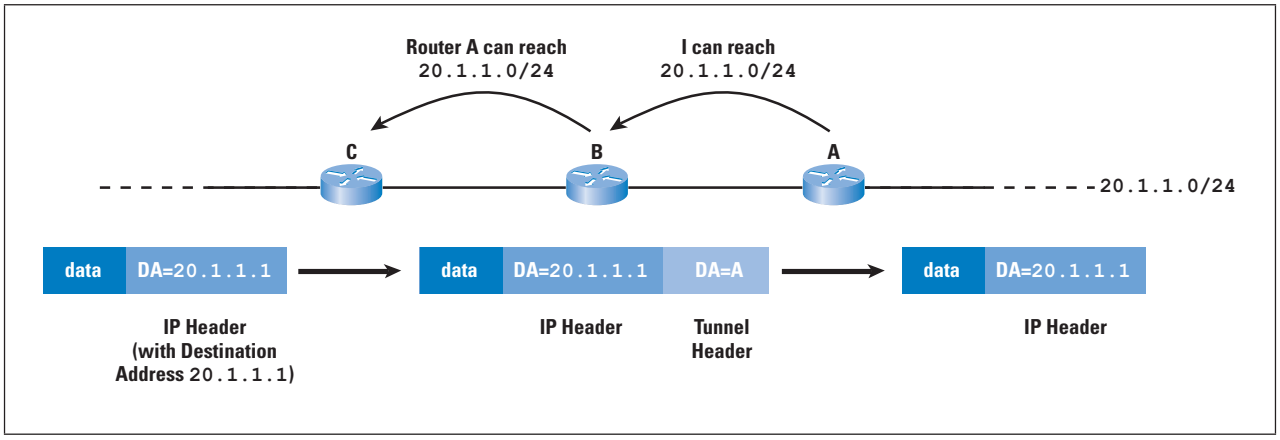
In its simplest form, Virtual Aggregation allows an ISP to use FIB-dead routers as edge routers, in any edge router position (neighbor is a transit provider, a peer, or a customer) without limiting what routing information is exchanged. Configuration requirements are minimal. In a more complex form, Virtual Aggregation allows all ISP routers (not just edge routers) to be FIB-dead routers, without requiring ISP-level default routing.

Virtual Aggregation uses two basic mechanisms, FIB suppression and tunneling. Before discussing FIB suppression, a small amount of background is needed. Internet routers have a "data plane" and a "control plane." The data plane is what forwards packets, and includes such functions as header parsing, FIB lookup, queuing, and packet transmission. The control plane operates the background protocols that gather much of the information needed by the data plane. Examples include routing protocols such as the *Border Gateway Protocol* (BGP) and *Open Shortest Path First* (OSPF), and tunnel establishment protocols such as the *Label Distribution Protocol* (LDP).

The idea of FIB suppression is that the control plane operates as normal, but that certain routing table entries are not loaded into the FIB. This idea exploits the fact that it is (data plane) FIB memory, not control plane routing table memory that is the more severe bottleneck. By allowing the control plane to operate as normal, no changes are required to routing protocols or, for the most part, the management of routing protocols.

Tunneling is used to pass packets through routers that have suppressed FIB entries. The principle is illustrated in Figure 2. Here router A tells router B that it can reach `20.1.1.0/24`. Router B in turn tells router C that router A can reach `20.1.1.0/24`. As a result, router C tunnels packets destined for `20.1.1.0/24` to router A through router B. In other words, it wraps the IP header in another IP or a *Multiprotocol Label Switching* (MPLS) header that first gets the packet to router A. Router A strips that header, and sends the packet toward the destination. Notice that router B can suppress the route to `20.1.1.0/24` from the FIB—it only needs to know how to route the packet to router A. In other words, even though router B fully participates in the control plane, it is able to shrink its FIB through FIB suppression and tunneling.

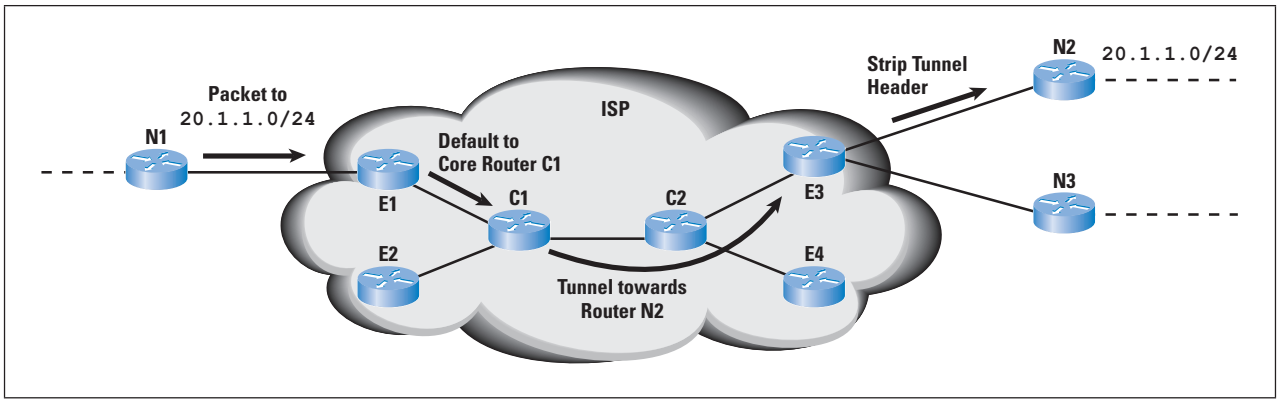
Figure 2: Because router C tunnels the packet to router A, router B does not need to know how to forward packets with addresses in ***`20.1.1.0/24`****.*



Virtual Aggregation in Practice, Simple Version

In the simplest version of Virtual Aggregation, a core-edge configuration is used. The core routers maintain full FIB tables. The edge routers FIB-install at least a default route to the core, and potentially additional routes if there is space in the FIB. This process is illustrated in Figure 3. Here there are two core routers, C1 and C2, and four edge routers, E1, E2, E3, and E4. The edge routers have external neighbors, N1, N2, and N3, as shown.

Figure 3: Packets can be delivered to **`20.1.1.0/24`** *even if none of the edge routers has a FIB entry for* **`20.1.1.0/24`**.



The operation is best explained by example. Suppose that N2 advertises a route to destination `20.1.1.0/24` to E3 using *External BGP* (eBGP) and giving itself as the next hop. E3 in turn advertises this route to the other internal routers using *Internal BGP* (iBGP), with the next hop still as N2. The core routers install this route in their FIBs, with an indication that packets matching the route should be tunneled to the next hop, N2. Assume for now that all edge routers FIB-suppress the entry. When a packet for say `20.1.1.1` arrives at E1 from N1, E1 does not find an entry for `20.1.1.0/24`, but does find the default route `0/0` telling it to forward the packet to its core router C1. C1 looks into its FIB and indeed finds an entry for `20.1.1.0/24` telling it to tunnel the packet to N2. C1 wraps the packet in another header, typically IP or MPLS, addressed to N2. When the packet reaches E3, however, E3 notes that the header directs it to send the packet to N2, strips off the outer header, and sends the packet to N2. E3 can do this without a FIB entry for `20.1.1.0/24`.

MPLS already has all the mechanisms needed to perform this packet forwarding. E3 can use LDP to signal a *Label Switched Path* (LSP) to N2, and *Penultimate Hop Popping* can be used to strip off the MPLS header before forwarding the packet to the external neighbor N2 (as described in section 4.1.4 of [4]).

Alternatively, stacked MPLS label technology can be used; for example, the inner label is signaled with BGP (see "Carrying Label Information in BGP-4"[3]) while the outer label is signaled with LDP. Here E3 sets itself as the next hop for all the routes learned from external neighbors (for example, `20.1.1.0/24`) when advertising them to its iBGP peers, and uses the inner label to identify the external neighbor (see section 4.3, "Label Stacks and Implicit Peering" of [4]). IP-in-IP tunneling can also be used, in this case signaled with softwires BGP attributes[5].

Now let's see what happens if a packet to `20.1.1.1` is received by E3 from external neighbor N3. If E3 has not FIB-installed the route for `20.1.1.0/24`, it uses its default entry and forwards the packet to C2. C2 finds its entry for `20.1.1.0/24`, which instructs it to tunnel the packet to N2. The packet is sent back to E3, which strips off the outer header and delivers the packet to E2. In this case, the packet has traveled an extra hop and back, a process that is not acceptable if done too much. As long as there is space in the FIB, however, routers are free to FIB-install additional routes. A good policy is to always install routes when external neighbors are the next hop. This policy avoids the longer path. In some cases, such as edge routers that connect to transit networks, there may not be enough FIB space to hold all routes from all external neighbors. In this case, the router may FIB-install the routes for which the most traffic is forwarded. Studies have shown that a small number of routes account for majority of the traffic, making Virtual Aggregation a very efficient solution[2].

Note that this simple form of Virtual Aggregation is very easy to configure. Essentially all that is needed is to tell the routers that they are using simple Virtual Aggregation, and to tell them if they are a core or an edge router. The routers can automatically configure everything else. Virtual Aggregation requires configuration of tunnels from every router to every other router, but these configurations also can be automatic. In any event, increasingly these tunnels are created anyway for the purpose of traffic engineering.

Simple Virtual Aggregation solves most of the problems described earlier. It can save FIB on any edge router without having to compromise BGP service to customers or flexibility in using peer networks for some transit. It also allows FIB-dead routers to be used as edge routers with transit ISPs. Finally, it prevents the need for ISP-level default routing to transits, thus avoiding unnecessarily sending unroutable traffic to the transit. And it does all this with much less configuration than is required to operate with FIB-dead routers today.

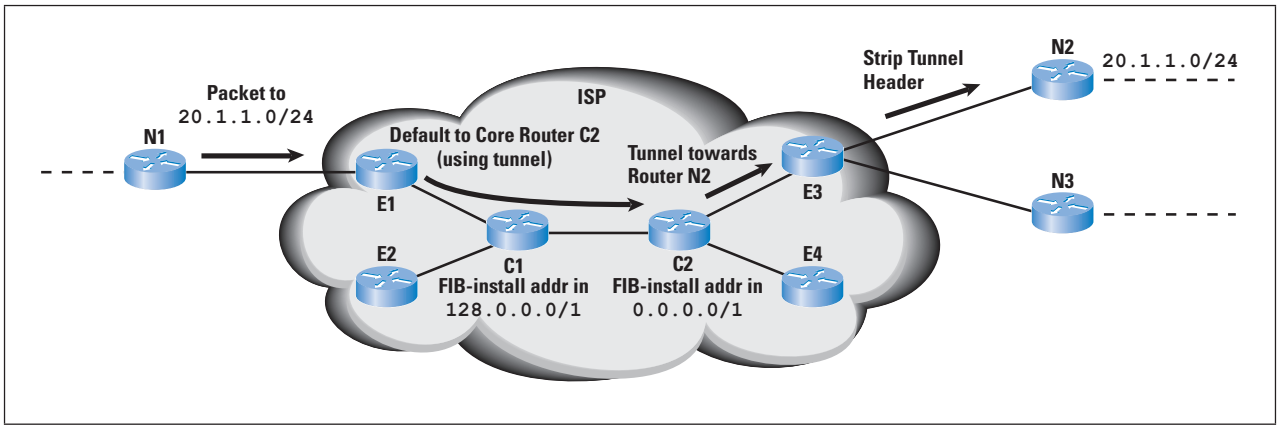
Virtual Aggregation in Practice, Complex Version

The simple version of Virtual Aggregation is satisfactory for edge routers, but it does nothing to reduce FIB size on core routers. What if an ISP wishes to also extend the lifetime of its core routers? Or wants to move away from a core-edge model, and rather connect all edge routers directly through a Layer 2 substrate like MPLS?

What if indeed there is a surge in routing table growth, thus causing ISPs all over the world to suddenly find themselves FIB-starved? There is a version of Virtual Aggregation that allows for FIB reduction in any and all routers in an ISP network.

The basic idea is to divide the address space so that different routers maintain full routes within different parts of the address space. So for instance, rather than have all core routers responsible for all of the address space, you could have half of the core routers responsible for the lower half of the address space, and the other half of the core routers responsible for the upper half of the address space. Figure 4 shows how this setup would look for the simple topology of Figure 3, keeping in mind that this example is rather simplistic.

Figure 4: In a complex version of Virtual Aggregation, even core routers do not need to hold the full routing table.



Assume that C2 FIB-installs only the lower half of the address space (`0.0.0.0/1`) and C1 FIB-installs the upper half (`128.0.0.0/1`). With this arrangement, the edge routers have two defaults instead of one. Packets to addresses in `0.0.0.0/1` are defaulted, through a tunnel, to C2, and packets to addresses in `128.0.0.0/1` are defaulted to C1. These defaults are learned simply by having C1 and C2 advertize their respective default routes with themselves as the next hop in iBGP.

As with the previous example, assume that router N2 advertises a route to `20.1.1.0/24`, with itself as the next hop, to E3. E3 advertises this route to all other routers using iBGP. Only C2, however, FIB-installs this route—C1 suppresses it. When a packet to `20.1.1.1` arrives at E1, it looks in its FIB, finds a matching route to `0.0.0.0/1`, and so tunnels the packet to C2. C2 terminates the tunnel, finds its FIB entry for `24.1.1.0/24`, and tunnels the packet toward N2. E3 uses the tunnel information to know to forward the packet to N2, strips away the tunnel header, and forwards the packet to N2.

Now suppose that a packet for `20.1.1.1` arrives at E3 from N3. Ideally E3 has already automatically FIB-installed the route for `24.1.1.0/24` either because its external neighbor provides the next hop, or because the route is a high-volume destination. In this case, of course, the packet is directly forwarded to N2. However, if E3 has not FIB-installed the route, then its best match is the default to `0.0.0.0/1`, and it tunnels the packet to C2. C2 in turns tunnels the packet back toward N2 through E3 as described before. Worse, if C1 rather than C2 FIB-installed the lower half of the address space, the packet would have detoured all the way to C1. Clearly these routes are not optimal, and so we must ask how nonoptimal would the complex version of Virtual Aggregation be in real ISPs.

The USENIX NSDI paper[2] answers this question for one large transit ISP. In this study, both the topology and the traffic matrix of the ISP are considered. The deployment strategy is substantially more complex than the simplistic example given previously. An upper limit is placed on the maximum increase in latency (5 ms) for any path through the ISP. There is a requirement that within a *Point of Presence* (PoP) at least two routers must cover the same address space. The number and size of address partitions are engineered to spread FIB load evenly. The "additional" routes installed in the FIB are designed to cover high-traffic destinations to the extent possible.

With these requirements in mind, this study found that FIB size could be reduced in all routers by at least an order of magnitude with a negligible increase (1–2%) in overall traffic load due to the occasional extra hops from the detours. This result ultimately translated into an increased router lifetime of easily 10 years.

The management requirements for the complex version are substantially greater than those for the simple version. The address partitions must be chosen, the routers assigned to address partitions must be chosen, and possibly some strategy for deciding what "additional" routes should be FIB-installed is needed. Whether this added configuration and the associated difficulties due to, for instance, misconfiguration are worth the cost savings for extending router lifetime is up to each ISP. Virtual Aggregation at least provides an option that was not previously available.

Status

Virtual Aggregation is a working-group item in the *Global Routing Operations Working Group* (GROW) in the IETF. The primary draft is `draft-ietf-grow-va`[6]. This draft has gone through several revisions, and is very close to its final form. Huawei is currently implementing Virtual Aggregation. A second open-source implementation has been built by Paul Francis' research group for the *Quagga* open-source routing platform, and is still being enhanced.

Acknowledgements

The authors would like to thank the co-authors of the Virtual Aggregation drafts, Hitesh Ballani, Dan Jen, Robert Raszuk, and Lixia Zhang. In particular, it was Robert who suggested the simple version of Virtual Aggregation.

RFC Editor in Transition: Past, Present, and Future

by Leslie Daigle, ISOC

In April 2009, the *Request For Comments* (RFC) Editor published RFC 5540[1], "40 Years of RFCs," which summarized the publication history of the RFC Series. The series has been the technical publication series for Internet technology since long before there was an *Internet Engineering Task Force* (IETF). Although the RFC Series is the publication vehicle for the IETF, it has been, and remains, scoped more broadly than that (refer to RFC 4844[2], "The RFC Series and RFC Editor").The RFC Series is the archival series dedicated to documenting Internet technical specifications, including general contributions from the Internet research and engineering community as well as standards documents.

For the past three of the four decades of the history of the series, the RFC Editor work has been carried out at the *University of Southern California Information Sciences Institute* (USC/ISI). The RFC Editor role now faces another evolutionary step: The work involved in managing the overall series is being split up to recognize the different components of the editing, production, and archiving activities and to lay the groundwork to ensure its continued success, as outlined in RFC 5620[3], "RFC Editor Model (Version 1)."

At the IETF 76 plenary in Hiroshima, Japan, in November 2009, USC/ISI and the role it has played in supporting the RFC Editor over the past 30 years were given special recognition. Some members of the team will move from USC/ISI to the RFC Editor's new home, where they will continue their work. We took the opportunity to talk with current and future RFC Editor staff and advisory board members, including current RFC Editor staff members Bob Braden, Sandy Ginoza, and Alice Hagens, as well as Bob Hinden, who is a member of the RFC Editor advisory board.

The People Behind the RFC Editor

Jon Postel was the first RFC Editor, starting the position in 1969 as an activity to keep track of RFC Series documents. Bob Braden, who was then part of the *Advanced Research Project Agency Network* (ARPANET) research program, told how he got started with the RFC Series: "I wrote my first RFC in the early 1970s, when it was somewhere around RFC 100. I was at that point manager of programming for the Computing Center at the *University of California, Los Angeles* (UCLA), and *Advanced Research Projects Agency* (ARPA) wanted to connect it to ARPANET as a resource." This was all pre-TCP/IP, and Bob's staff had to implement file transfer and Telnet. At the same time, Jon was a graduate student at UCLA, and Bob worked with him as a colleague. It was before Jon got his Ph.D. and moved to SRI in 1973–1974. In 1980, Jon moved to USC/ISI, taking the RFC editorship with him. Joyce Reynolds went to work for Jon at USC/ISI. She did much of the actual editing and became an important part of making the RFC Editor activity viable.

Jon was responsible for quality control, running the operation, and generally being the series editor. When Jon died suddenly in 1998, Bob, who joined USC/ISI in 1986, and Joyce both felt a keen sense of loss. "Jon was a very remarkable guy in many ways," Bob said. "We knew how much the RFC Series meant to Jon, and we volunteered to carry it on."

Sandy Ginoza joined USC/ISI to work on the RFC Editor activity in 1999, just after Jon passed away. Alice Hagens came onboard in 2005, taking on more of the computer-oriented aspects of the work.

RFC Series

Although we tend to reference and read individual RFC documents, it is important to understand that there is significant value in the collection of published RFCs as a *series*. On the importance of the RFC Series, Bob Hinden said, "This community is IETF-focused, but to the larger world not centered around the IETF; it's really the RFCs that are how you build the Internet. One of the things that made the Internet possible was the RFC Series: that you could build things and deploy things without coming to IETF meetings was valuable." Bob went on to outline his own experiences, such as meeting engineers in Taipei, for whom it was the first time they had ever met anyone who had written an RFC. Even the notion of going to an IETF meeting was in another dimension. "The RFC Series is what enables people to build products, networks, and the Internet," he said.

And it is quite an active series. Currently, some 300 documents (10,000 pages) are published every year, and although it might be interesting to review the material to detect trends or arcs of work in the Internet technical community, that type of activity is beyond the current scope of the RFC Editor. Focusing on consistency of the series, Bob Braden wondered, "Will we eventually have good enough statistics from the errata system to gauge our error rate?"

The intent of the RFC Series is to serve the broader Internet community; it is not just for or by the IETF. Sandy's perspective on the value of the *Independent Stream* of RFCs is that "it offers an alternate view than what happens in the IETF and what working groups have decided to take on as part of their chartered activities. It's good to document that work was done, results were generated, lessons learned, etc. 'We tried it; don't do it this way.' We often get asked why it's called RFC when we're not really requesting comments anymore, but that is the genesis, and the Independent Stream keeps some of that alive."

Bob Braden offered his own perspective on the Independent Stream.

"Historically, the RFC Series is supposed to be larger than the IETF, and while Jon was alive, the editor did whatever he thought he ought to do; the community didn't question it much."

However, in the absence of Jon as an authority figure, the community began to ask questions and build its own set of beliefs, eventually coming to believe that RFCs were only for the IETF. That matter was resolved with RFC 4846[4], which explained that there is a separate set of independent submissions that do not come through the IETF.

"It's not a big stream, not a lot of documents, but it is important philosophically," Bob added. "The Internet community is bigger than the IETF."

The RFC Series is, nevertheless, entwined with the IETF and its activities. For instance, the discussion of (IETF) *Intellectual Property Rights* (IPR) has led to an impasse in assigning boilerplate to RFCs that allow the continued publication of the Independent Stream documents. That subject is being worked on and resolved, but it offers an example of some of the complexities—and frustrations—that can arise as part of the RFC Editor process. "The current situation—that the independent submissions cannot be published because we don't know what the boilerplate is—is just terrible," said Bob Braden.

Bob Hinden, who has been tracking the IPR work from the IETF side, agreed and elaborated on some important lessons learned: "The IETF created a process in the IPR working group that focused on trying to provide a solution to what they perceived as a problem. But they lost sight of the complexity and cost of implementing that solution compared with the actual risk of something bad happening. We have learned a lot about doing this in the future. This isn't like a protocol spec where you fix a bug in the finite state machine. This has a real effect on people doing stuff. When you ask for legal opinions you get the answer about how to solve the problem, but that's not the end of the process. You need to balance the cost of solving the problem with the risk of what you're trying to avoid. Lawyers are supposed to give you the lowest-risk answer. You need to follow through with questions about likelihood and consequences. This is all great hindsight, and I hope we can apply it in the future." Hinden also said he believes the current impasse could have been avoided if the new procedure had specified that it go into effect when appropriate supporting conditions were met, instead of on a specific flag day, such as the date of publication of the RFC.

The effects of entwining the RFC Series and the IETF go both ways. For example, the RFC Series recognizes three levels of standards documents: *Proposed, Draft,* and *Full*. The expectation, documented in the IETF standards process, is that standards-track specifications should be published as Proposed and then advanced to Draft and Full as the specification gets tested commercially and acknowledged as appropriately mature to move to the next stage.

In reality, as observed at the IETF 76 plenary, many of the important specifications that form the basis of the operating Internet are still published only as Proposed Standard. Bob Braden explained the history of the standards-track RFC maturity system this way: "Labels were invented whole cloth by the original *Internet Architecture Board* (IAB), who were a bunch of academics. At that point the Internet had not been commercialized—there were no commercial pressures—so we imagined that it made sense to step through progressions in a theoretical world. In the real world, companies are putting out products. There is no financial incentive for people to spend time advancing documents. Plus, the IETF is so large and there are so many working groups that we try to dispatch them as fast as we can; there is no one around to advance a document." There have been, and will continue to be, proposals for moving important, current standards (such as the *Border Gateway Protocol* [BGP]) forward in maturity or for collapsing the maturity scale and labeling system.

On the fun side of the RFC Series, there remains a tradition of "April 1st" RFCs. "That people want to participate in that is cool," said Sandy. "And we get to see the runners-up and the really-not-so-good ideas!"

Alice agreed, adding that "there are high standards for straight-faced satire."

RFC Editor

Traditionally, the RFC Editor has not only populated the series with new (approved) documents but also kept all the threads together in the RFC Series. Describing the origins of the role, Bob Braden pointed out that "Originally, Jon was prince of his kingdom. As RFC Editor, he was an honorary member of the IAB informally called the *Protocol Czar.* He used the RFC Editor position to actively prevent bad ideas from getting pushed. Jon imposed a consistency of style on the document series. You pick up RFC 1001 and compare it with 2001, and they look very similar." Jon believed, and the RFC Editor continues to believe today, that consistency was a worthwhile attribute, promoting stability in the series.

Reflecting back, Bob Braden said, "In discussions over the last five years, people have expressed the view that we don't need an RFC Editor—just take an Internet Draft and publish it. That notion drives me crazy. The implication is that it doesn't matter whether it is good English, correctly referenced, consistent, etc. I can't stand that view." One of the arguments for such an approach to IETF document publishing is that editing can inadvertently alter, and thereby introduce errors to, text. But the RFC Editors understand that.

Alice said changes to text can be problematic, "partly because of the technical content and partly because it is a group process. It's agreed-upon text. The idea is how precious the text is and how a slight change can make a large difference."

Sandy agreed, adding that "for as many changes that get pushed back upon, there are many that make it through the process: for as many people as look at the document before it gets to us, there are things that escape them; there is often missing text, missing words." According to Alice, with working group documents, people often focus on getting the technical ideas right, but nobody has read the text from beginning to end. In addition, many in the community are not native English speakers. It all comes back to the consistency and professionalism of the output of the series.

RFC Editing Process

As the RFC Series has grown, achieving consistency has required the creation and refining of processes. "When Joyce and I took over," said Bob Braden, "we built the website and regularized a lot of things, and the community began to ask, 'Why do you do it that way?'" In response, the editors started publicizing the *Style Manuals* they used. Joyce and Bob generated a lot of rules that have become institutionalized.

Of course, there is continuing evolution. Bob Braden noted that the addition of errata was his idea, although "it has turned out to be a much, much bigger deal than ever imagined, as is often the case," he said, laughing. "Now we're talking about adding image files to solve the problem of incorporating graphics in an ASCII RFC. John Klensin and I generated a plausible solution for that, and we hope to get it installed soon."

It is important to note that there are some edits the RFC Editor will not make. According to Sandy, the RFC Editor tries to ensure consistency of terminology and to make recommendations that improve consistency within a document, both in a technical sense and within the series. "We don't change the active/passive voice," she said.

"We might suggest it, but we are concerned that it would affect the author's intent." Being conservative is critical. Sandy said she was surprised by how "simple grammatical changes can have a serious technical effect; placement of a comma can make a big difference in how people read the document and what they implement."

Working with authors is an important part of making the editing process successful. Innovations such as having the *RFC Editor Help Desk* at IETF meetings and making the AUTH48[5] (final check of the RFC Editor's edits) more of an interactive dialogue have helped build community and create awareness of how to build a better document that conveys the meaning as intended. "It is extremely useful to get discussions started earlier, which lessens problems during AUTH48," said Alice. She added that it has also been useful to have face time with the developers of community-created tools, such as *xml2rfc*[6] and the *Augmented Backus–Naur Form* (ABNF) checker, which have been instrumental in improving RFC production. Office hours, building relationships, and face time "all help make it about working together," said Sandy.

Looking forward, Sandy said she would like to see the RFC editing process (and series) "grow and continue to be more consistent, with better community relations and more transparency so authors can look at our site and better understand the process, instead of thinking their document has gone into a black box."

On the Verge of Major Change

As this article is written, the RFC world is on the brink of major structural change. Following IAB-led community discussion, there is a new model for recognizing the components of activity that make up the RFC activities. ISI is handing off the RFC Editor activity, which will be taken up by separate organizations working together. In February 2010, the IAB appointed Nevil Brownlee as the *Independent Submissions Editor* (ISE) and Glenn Kowack as the Transitional *RFC Series Editor* (RSE). In October 2009, *Association Management Solutions* (AMS) was awarded 2-year contracts to manage the RFC Production Center and the RFC Publisher.

Sandy will be joining AMS as RFC Production Center director and Alice will be joining as senior editor and information technology development project manager. To the question of whether the current RFC advisory board will carry forward in the current format or will change, Bob Braden answered, "The current board serves two functions: It provides a supply of experienced people who review independent submissions, but it also gives the RFC Editor advice on policy matters. Some members of the advisory board are very strong members of the IETF in terms of policy advice. In forming the board, I tended to identify a subset of people within the IETF who have long IETF and publishing experience. In the new world there will be an *RFC Series Advisory Group* (RSAG), which will take over the policy discussions that are currently being conducted by the editorial board. In practice it will be the same people, at least for a while, but with separate duties. That separation is useful."

In considering the change of organizations, Sandy said the biggest thing in moving to AMS is that it is a more service-oriented environment. "In the new model," she said, "it is important that the ISE and RSE be respected individuals who are granted some of the independence the RFC Editor had at ISI."

Alice added that the institutional memory of the RFC Editor function will not be lost with the move to AMS. "Sandy has worked side by side with Bob Braden for 10 years, and much of the process is written down in the document series. I'm confident that the continuity of the series won't be lost by the move to AMS."

Bob Hinden offered another perspective. "I think one of the positive things that has come out of the new model that has gotten lost is this: A lot of people in the IETF didn't understand where the series had come from, or why the IETF chose to use it," he said.

"It is the formalization that there are different streams that have different rules. Before, this was confused with the IETF standards process. Going forward we'll have the opportunity to use the RFC Series for other relevant Internet publication streams that have not been part of IETF. Now we have a framework that would allow that."

Although it is on the verge of major changes, the RFC Series and RFC Editor functions are clearly continuing what has been a long process of constant evolution and change. This transition is just a new chapter in the history of the series.

[Ed.: This article is composed of interviews conducted by Leslie Daigle and Lucy Lynch, and notes compiled by Mat Ford. The original version was published in *The IETF Journal,* Volume 5, Issue 3, January 2010 and has been been updated for use in IPJ. *The IETF Journal* can be obtained from `http://isoc.org/ietfjournal/`]

IETF Outcomes Wiki Launched

As an organization, the *Internet Engineering Task Force* (IETF) measures its success by its publication of RFCs (see previous article). It does not explicitly ask itself whether published work is adopted and used by the greater Internet community. The IETF's dialogue about success started to change with the production of RFC 5218, "What Makes for a Successful Protocol?"[1] which documented case studies and empirical data about some of the factors that appear to correlate with success, in terms of community uptake for IETF work.

Taking a different approach in assessing long-term IETF impact, another tool is now available: A wiki that lets community participants list the success or failure of significant standards. The *Outcomes Wiki*[2] divides listings according to the "areas" used for managing technical work in the IETF, such as Applications or Transport. Outcomes are rated according to a 6-point scale, ranging from "complete failure" to "massive adoption, plus extensive derivative work."

The wiki began in June 2009, as an independent effort among a small set of IETF participants, to test its feasibility and evolve its design. For example, it quickly became clear that the single attribute of success vs. failure needed to be qualified by another attribute that indicates who the work is intended for, called "Target Segment." Work that is intended to support the internal operations of an *Internet Service Provider* (ISP) is not necessarily visible to the billions of Internet users and will, at best, be part of only a few thousand organizations. In terms of Internet scale, that is considered minuscule. However wide adoption of a tool among ISPs can have substantial benefit, and thereby qualify as "massive adoption."

The wiki can serve both as a means of recording the IETF's track record of successes and failures, as well as providing a means of encouraging community dialogue about the quality of different IETF efforts. In addition, it can provide a window onto completed IETF work for the broader Internet community.

Final Phase of Four-byte AS Number Policy Begins in APNIC Region

From 1 January 2010, the *Asia Pacific Network Information Centre* (APNIC) ceased to make a distinction between four-byte only and two-byte only *Autonomous System* (AS) numbers. Instead, all AS numbers are now considered to be four-byte AS numbers.

This change marks the third phase of the transition to four-byte AS numbers. For more information on the implementation phases of the four-byte AS number policy, please see "Policies for Autonomous System number management in the Asia Pacific region," section 6.3, "Timetable for moving from two-byte only AS numbers to four-byte AS numbers," available from:
`http://www.apnic.net/policy/asn-policy.html#6.3`

To learn more about how the transition to four-byte AS numbers may affect your network, see: `http://icons.apnic.net/asn`

Charting the Course for Future Internet Leaders

As the importance of the Internet grows in all aspects of modern life, so too do the challenges of those in positions of leadership and responsibility.

Responding to the need for well-qualified leadership, the *Internet Society* (ISOC) is now accepting applications from people seeking to join the new generation of Internet leaders to address the critical technology, policy, business, and education challenges that lie ahead.

Successful candidates in ISOC's *Next Generation Leaders Program* will gain a wide range of skills in a variety of disciplines, as well as the ability and experience to work with people at all levels of society.

This program, under the patronage of the European Commission, blends course work and practical experience to help prepare young professionals (aged from 20 to 40) from around the world to become the next generation of Internet technology, policy, and business leaders.

"The Internet Society's Next Generation Leaders Program is a unique opportunity to identify potential Internet leaders and help them accelerate their careers," said Bill Graham, responsible for strategic global engagement at ISOC.

The key to the Internet's success lies in the Internet Model of decentralized architecture and distributed responsibility for development, operation, and management. That model also creates important leadership opportunities, especially in those spaces where technology, policy, and business intersect.

"We have designed the Next Generation Leaders Program to prepare young professionals for leadership, bridging the boundaries between business, technical development, policy, and governance on local, regional, and international levels," said Graham.

Full details of the Next Generation Leaders Program are available at:
`http://www.isoc.org/leaders/`

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ contains standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

From The Editor

Protocol changes are never easy, especially when they involve something as fundamental as the *Internet Protocol* (IP). This journal has published numerous articles about the depletion of IPv4 addresses and several articles about IPv6, including methods for a gradual transition from v4 to v6. A lot of energy has gone into the development, promotion, and deployment of IPv6, but in reality only a small fraction of the global Internet currently supports IPv6. Meanwhile, the *Internet Assigned Numbers Authority* (IANA) and the *Regional Internet Registries* (RIRs) will "soon" (12 to 24 months from now is predicted) run out of IPv4 addresses to allocate. Although this situation has some serious implications for new entrants to the *Internet Service Provider* (ISP) market, it does not spell the end of the Internet as we know it. Numerous *Network Address Translation* (NAT) solutions are already widely deployed, and the IETF is discussing other solutions. One example is *Address Sharing* as explained by Geoff Huston in our first article.

Changes to the *Domain Name System* (DNS) are also underway. The *Domain Name System Security Extensions* (DNSSEC) are being gradually deployed in the global Internet. As with any complex technology, implementation of DNSSEC is not without problems. Our second article, by Torbjörn Eklöv and Stephan Lagerholm, is a step-by-step guide for those considering implementing DNSSEC in their network.

By now you will be aware that we have implemented a renewal system for subscribers and will not be automatically extending your subscription unless you contact us via e-mail or use the online tool to renew your subscription. You can find your subscription ID and expiration date either on the back page of your copy or on the envelope that it came in. In order to access your record, click the "Subscriber Services" link on our webpage at `www.cisco.com/ipj`, and enter your e-mail address and the subscription ID. The system will send you a link that allows direct access to your record, and you will be able to update your address and renew your subscription. If you no longer have access to the e-mail you used when you subscribed, or have forgotten your subscription ID, just send a message to `ipj@cisco.com` and we will make the necessary changes for you.

NAT++: Address Sharing in IPv4

by Geoff Huston, APNIC

In this article I examine the topic that was discussed in a session at the 74th meeting of the *Internet Engineering Task Force* (IETF) in March 2009, about *Address Sharing* (the SHARA BOF)[0], and look at the evolution of *Network Address Translation* (NAT) architectures in the face of the forthcoming depletion of the unallocated IPv4 address pool.

Within the next couple of years we will run out of the current supply of IPv4 addresses. As of the time of writing this article, the projected date when the *Internet Assigned Numbers Authority* (IANA) pool will be depleted is August 3, 2011, and the first *Regional Internet Registry* (RIR) will deplete its address pool about March 20, 2012.

Irrespective of the precise date of depletion, the current prediction is that the consumption rate of addresses at the time when the free pool of addresses is exhausted will probably be running at some 220 million addresses per year, indicating a deployment rate of some 170–200 million new services per year using IPv4. The implication is that the Internet will exhaust its address pool while operating its growth engines at full speed.

How quickly will IPv6 come to the rescue? Even the most optimistic forecast of IPv6 uptake for the global Internet is measured in years rather than months following exhaustion, and the more pessimistic forecasts extend into multiple decades.

For one such analysis using mathematical modelling techniques, refer to Jean Camp's work[1]. One of the conclusions from that 2008 study follows: "There is no feasible path which results in less than years of IPv4/IPv6 co-existence. Decades is not unreasonable."

The implication of this conclusion is that we will need to operate a dual-stack Internet for many years to come, and the associated implication is that we will have to make the existing IPv4 Internet span a billion or more new deployed services—and do so with no additional address space.

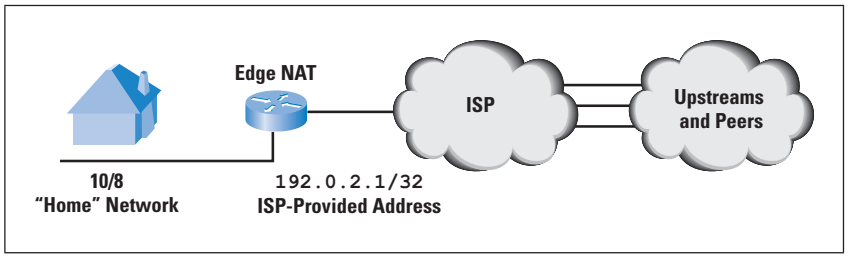
So how are we going to make the IPv4 address pool stretch across an ever-larger Internet?

Given that the tool chest we have today is the only one available, there appears to be only one answer to this question: Use *Network Address Translators,* or NATs.

For a description of how NATs work and some of the terminology used to describe NAT behavior, refer to the article "Anatomy: A Look Inside Network Address Translators," published in this journal[2].

Today NATs are predominately edge devices that are bundled with DSL modems for residential access, or bundled with routing and security firewall equipment for small to midsize enterprise use as an edge device. The generic model of NAT deployment currently is a small-scale edge device that generally has a single external-side public IP address and an internal-side private IP network address (often network 10). The NAT performs address and port translation to map all currently active sessions from the internal addresses to ports on the public IP address. This NAT deployment assumes that each edge customer has the unique use of a public IP address (refer to Figure 1).

Figure 1: Conventional NAT Deployment



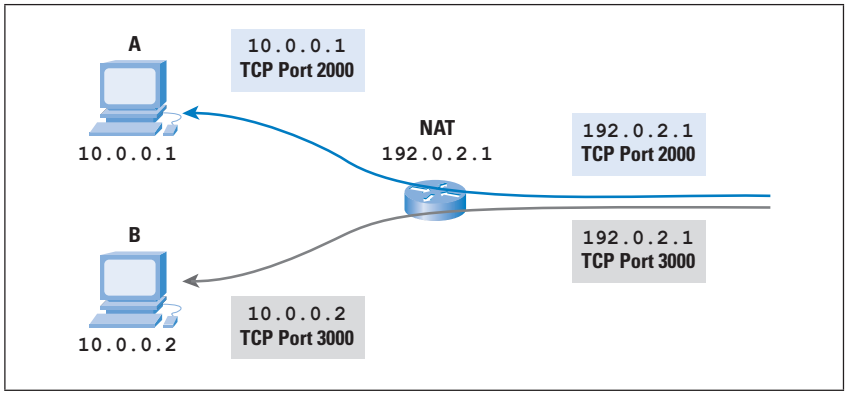
The question provoked by IPv4 address exhaustion is what happens when there are no longer sufficient IPv4 addresses to provide this 1:1 mapping between customers and public IPv4 addresses? In other words, what happens when there are simply not enough IPv4 addresses to allow all customers to have exclusive use of their own unique IPv4 address?

This question has only two possible answers. One is for no one to use IPv4 addresses at all, on the basis that the entire Internet has migrated to use IPv6. But this answer appears to be an uncomfortable number of decades away, so we need to examine the other answer: If there are not enough addresses to go around, then we will have to *share* them.

But isn't sharing IP addresses impossible in the Internet architecture? The IP address in a packet header determines the destination of the packet. If two or more endpoints share the same address, then how will the network figure out which packets go to which endpoint? It is here that NATs and the transport layer protocols, the *Transmission Control Protocol* (TCP) and the *User Datagram Protocol* (UDP), come together. The approach is to use the *port address* in the TCP and UDP header as the distinguishing element.

For example, in Figure 2, incoming TCP packets with TCP port address 2000 may need to be directed to endpoint A, while incoming TCP packets with TCP port address 3000 need to be directed to endpoint B. The incoming TCP packets with a port address of 2000 are translated to have the private IP address of endpoint A, and incoming TCP packets with a port address of 3000 are translated to have the private address of endpoint B.

Figure 2: Address Sharing with NATs



As long as you restrict yourself to applications that use TCP or UDP, you don't rely on receiving *Internet Control Message Protocol* (ICMP) packets, and you don't use applications that contain IP addresses in their payload, then you might expect this arrangement to function.

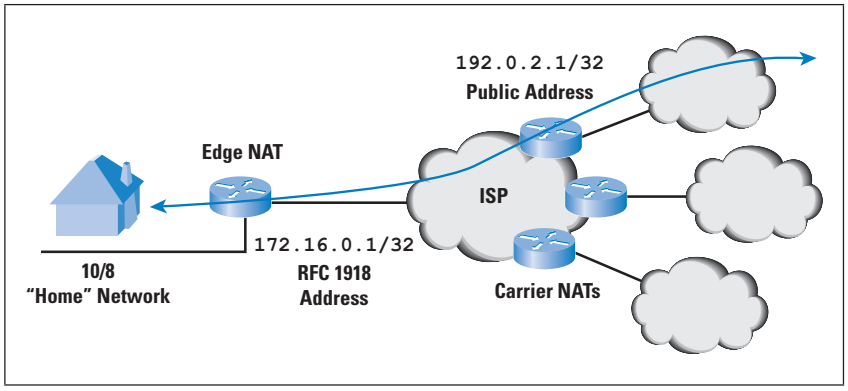
ICMP is a problem because the ICMP packet does not contain a TCP or UDP transport layer. All that a NAT sees in the ICMP packet is its own external address as the destination IP address. To successfully deliver an ICMP packet through a NAT, the NAT needs to perform a more complex function that uses the ICMP-encapsulated IP header to select the original outbound combined IP + TCP header or IP + UDP header in the ICMP payload. The source IP address and transport protocol port address in the ICMP payload are then used to perform a lookup into the NAT binding table and then perform two mappings: one on the ICMP header to map the destination IP address to the internal IP address, and the second on the payload header where the source IP address and port number are changed to the interior-side values, and the checksums altered as appropriate. Now in most cases ICMP really is not critical, and a conservative NAT implementation may elect to avoid all that packet inspection and simply discard all incoming ICMP messages, but one message that is important is the ICMP *packet-too-large-and-fragmentation-disabled* message used in IPv4 *Path MTU Discovery*[3].

Sharing IP addresses is fine in theory, but how can we achieve it in practice? How can many customers, already using NATs, share a single public IP address?

Carrier-Grade NATs

One possible response is to add a further NAT into the path. In theory the *Internet Service Provider* (ISP) could add NATs on all upstream and peer connections, and perform an additional NAT operation as traffic enters and leaves the ISP's network. Variations of this approach are possible, placing the ISP NATs at customer aggregation points within the ISP's network, but the principle of operation of the ISP NAT is much the same.

Figure 3: Carrier NATs



The edge NATs translate between private address pools at each customer's site and an external address provided by the ISP, so nothing has changed there. The change in this model is that the ISP places a further NAT in the path within the ISP network, so that a set of customers is then sitting behind a larger NAT inside the ISP's network, as shown in Figure 3.

This scenario implies that the external address that the ISP provides to the customer is actually yet another private address, and the ISP's NAT performs yet another transform to a public address in this second NAT. In theory this NAT is just a larger version of an existing NAT with larger NAT binding space, higher packet-processing throughputs, and a comprehensive specification of NAT binding behavior. In practice it may be a little more complicated because at the network edge the packet rates are well within the processing capability of commodity processors, whereas in the core of the network there is an expectation of higher levels of robust performance from such units. Because it is intended that such a NAT handle thousands of customers and large numbers of simultaneous data flows and peak packet rates, it requires a performance level well beyond what is seen at the customer edge and, accordingly, such a NAT has been termed a *Carrier-Grade NAT* (CGN), or a *Large-Scale NAT* (LSN).

From the inside of the two NATs, not much has changed with the addition of the CGN in terms of application behavior. It still requires an outbound packet to trigger a binding that allows a return packet through to the internal destination, so nothing has changed there. Other aspects of NAT behavior, notably the NAT binding lifetime and the form of *Cone Behavior* for UDP, take on the more restrictive of the two NATs in sequence. The binding times are potentially problematic in that the two NATs are not synchronized in terms of binding behavior. If the CGN has a shorter binding time, it is possible for the CGN to misdirect packets and cause application-level problems. However, this situation is not overly different from a single-level NAT environment where aggressively short NAT binding times also run the risk of causing application-level problems when the NAT drops the binding for an active session that has been quiet for an extended period of time.

However, one major assumption is broken in this structure, namely that an IP address is associated with a single customer. In this model a single public IP address may be used simultaneously by many customers at once, albeit on different port numbers. This scenario has obvious implications in terms of some current practices in filters, firewalls, "black" and "white" lists, and some forms of application-level security and credentials where the application makes an inference about the identity and associate level of trust in the remote party based on the remote party's IP address.

This approach is not without its potential operational problems as well. For the ISP, service resiliency becomes a critical concern in so far as moving traffic from one NAT-connected external service to another will cause all the current sessions to be dropped, unless the internal ISP network architecture uses a transit access network between the CGNs and the external transit providers. Another concern is one of resource management in the face of potentially hostile applications. For example, an end host infected with a virus may generate a large amount of probe packets to a large range of addresses. In the case of a single edge NAT, the large volumes of bindings generated by this behavior become a local resource management problem because the customer's network is the only affected site. In the case where a CGN is deployed, the same behavior starts to consume binding space on the CGN and, potentially, can starve the CGN of external address bindings. If this problem is seen to be significant, the CGN would need to have some form of external address rationing per internal client in order to ensure that the entire external address pool is not consumed by a single errant customer application. This "rationing" would have the unwanted effect of forcing the ISP to deny access to its customers.

The other concern here is one of scalability. Although the greatest leverage of the CGN in terms of efficiency of usage of external addresses occurs when the greatest numbers of internal edge-NAT-translated clients are connected, there are some real limitations in terms of NAT performance and address availability when an ISP wants to apply this approach to networks where the customer population is in the millions or larger. In this case the ISP is required to use an IPv4 private address pool to number every client. But if all customers use network 10 as their "internal" network, then what address pool can the ISP use for its private address space? One of the few answers that come to mind is to deliberately partition the network into numerous discrete networks, each of which can be privately numbered from the smaller private address pool of `172.16.0.0/12`, allowing for some 600,000 or so customers per network partition, and then use a transit network to "glue" together the partitioned elements, as shown in Figure 4.

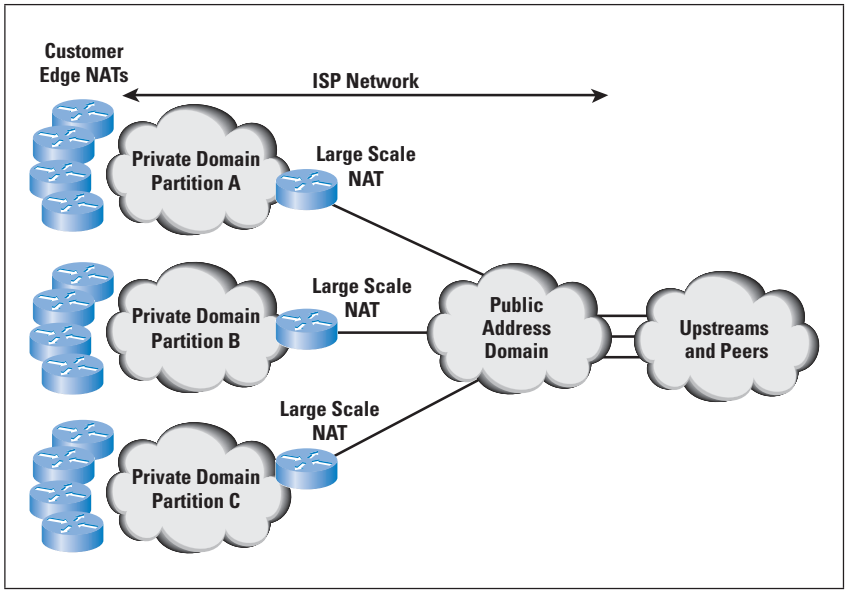


Figure 4: Multiple Carrier NAT Deployment Using Network Partitioning

The advantage of the CGN approach is that for the customer nothing changes. Customers do not need to upgrade their NAT equipment or change them in any way, and for many service providers this motivation is probably sufficient to choose this path. The disadvantages of this approach lie in the scaling properties when looking at very large deployments, and the problems of application-level translation, where the NAT attempts to be "helpful" by performing deep packet inspection and rewriting what it thinks are IP addresses found in packet payloads. Having one NAT do this rewriting is bad enough, but loading them up in sequence is a recipe for trouble!

Are there alternatives?

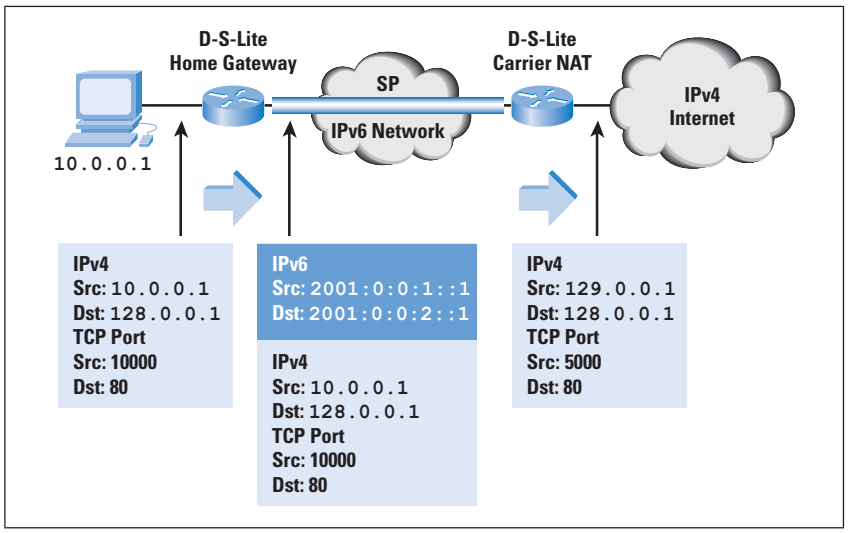
Dual-Stack Lite and Carrier-Grade NATs

One rather elegant alternative is described by Alain Durand and others in an Internet Draft "Dual-stack lite broadband deployments post IPv4 exhaustion"[4]. The assumption behind this approach is that the ISP's network infrastructure needs to support IPv6 running in native mode in any case, so is there a way in which the ISP can continue to support IPv4 customers without running IPv4 internally?

Here the customer NAT is effectively replaced by a tunnel ingress/egress function in the *Dual-Stack Lite Home Gateway*. Outgoing IPv4 packets are not translated, but are encapsulated in an IPv6 packet header, where the IPv6 packet header contains a source address of the carrier side of the home gateway unit and a destination address of the ISP's gateway unit. From the ISP's perspective, each customer is no longer uniquely addressed with an IPv4 address, but instead is addressed with a unique IPv6 address. The customer's interface to the ISP network, the Home Gateway, is configured with this IPv6 address as the customer end of the IPv4-in-IPv6 tunnel, where the other end of the tunnel is the IPv6 address of the ISP's Dual-Stack Lite Gateway unit.

The service provider's Dual-Stack Lite gateway unit performs the IPv6 tunnel termination and a NAT translation using an extended local binding table. The "interior" NAT address is now a 4-tuple of the IPv4 source address, protocol ID, and port, plus the IPv6 address of the home gateway unit, while the external address remains the triplet of the public IPv4 address, protocol ID, and port. In this way the NAT binding table contains a mapping between interior "addresses" that consist of IPv4 address and port plus a tunnel identifier and public IPv4 exterior addresses. This way the NAT can handle a multitude of network 10 addresses, because the addresses can be distinguished by different tunnel identifiers. The resultant output packet following the stripping of the IPv6 encapsulation and the application of the NAT function is an IPv4 packet with public source and destination addresses. Incoming IPv4 packets are similarly transformed, where the IPv4 packet header is used to perform a lookup in the Dual-Stack Lite gateway unit, and the resultant 4-tuple is used to create the NAT-translated IPv4 packet header plus the destination address of the IPv6 encapsulation header (refer to Figure 5).

Figure 5: Dual-Stack Lite



The advantage of this approach is that now only a single NAT is needed in the end-to-end path because the functions of the customer NAT are now subsumed by the carrier NAT. This scenario has some advantages in terms of those messy "value-added" NAT functions that attempt to perform deep packet inspection and rewrite IP addresses found in data payloads. There is also no need to provide each customer with a unique IPv4 address, public or private, so the scaling limitations of the dual-NAT approach are also eliminated. The disadvantages of this approach lie in the need to use a different *Customer Premises Equipment* (CPE) device, or at least one that is reprogrammed. The device now requires an external IPv6 interface and at a minimum an IPv4 or IPv6 tunnel gateway function. The device can also include a NAT if desired, but it is not required in terms of the basic Dual-Stack Lite architecture.

This approach pushes the translation into the middle of the network, where the greatest benefit can be derived from port multiplexing, but it also creates a critical hotspot for the service itself. If the carrier NAT fails in any way, the entire customer base is disrupted. It seems somewhat counter intuitive to create a resilient network with stateless switching environments and then place a critical stateful unit in the middle! So is there an approach that can push this translation back to the edges while avoiding a second NAT in the carrier's network?

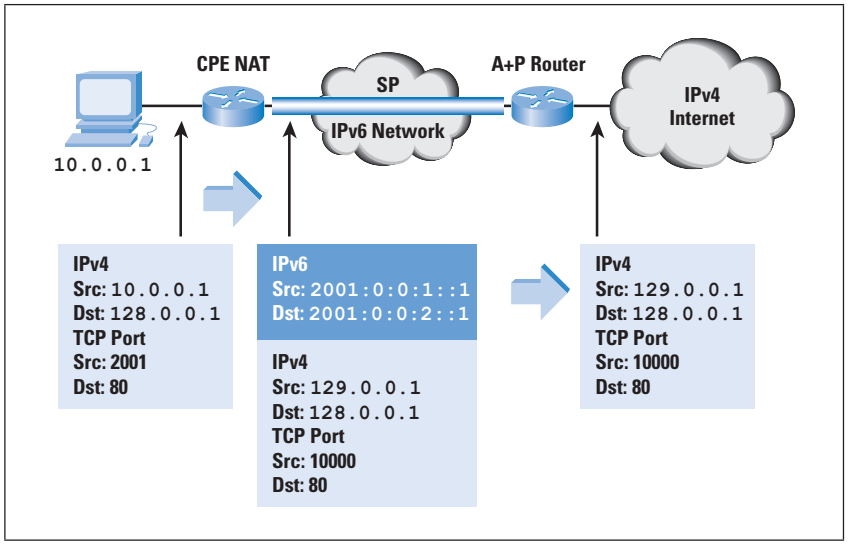
The Address Plus Port Approach

The observation here is that CPE NATs currently map connections into the 16-bit port field of the single external address. If the CPE NAT could be coerced into performing this mapping into 15 bits of the port field, then the external address could be shared between two edge CPE devices, with the leading bit of the port field denoting which CPE device. Obviously, moving the bit marker across the port field would allow more CPE devices to share the one address, but it would reduce the number of available ports for each CPE device in the process.

The theory is again quite simple. The CPE NAT is dynamically configured with an external address, as happens today, and a port range, which is the additional constraint. The CPE NAT performs the same function as before, but it is now limited in terms of the external ports it can use in its NAT bindings to those that lie within the provided port range, because some other CPE may be concurrently using the same external IP address with a different port range.

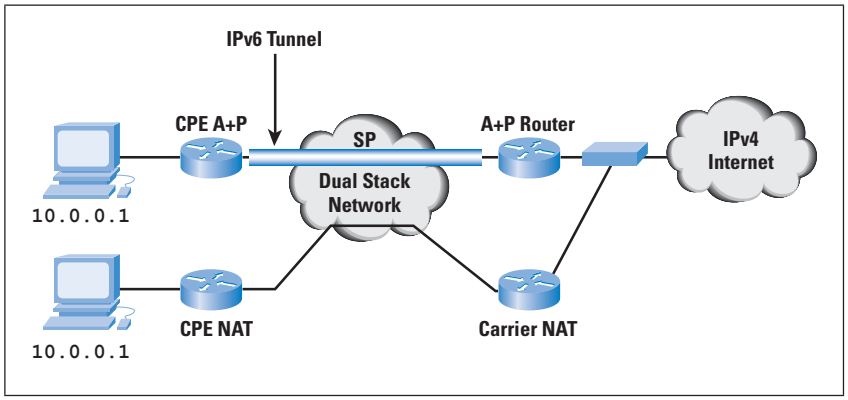
For outgoing packets this limitation implies only a minor change to the network architecture, in that the RADIUS[9] exchange to configure the CPE now must also provide a port range to the CPE device. However, the case of incoming packets is more challenging. Here the ISP must forward the packet based not only on the destination IP address, but also on the port value in the TCP or UDP header. A convenient way to forward the packet is to take the Dual-Stack Lite approach and use an IPv4-in-IPv6 tunnel between the CPE and the external gateway (Figure 6). This gateway, or *Address Plus Port* (A + P) router, needs to be able to associate each address and port range with the IPv6 address of a CPE device, which it can learn dynamically as it decapsulates outgoing packets. Corresponding incoming packets are encapsulated in IPv6 using the IPv6 destination address that it has learned previously. In this manner the NAT function is performed at the edge, much as it is today, and the interior device is a more conventional form of tunnel server.

Figure 6: Address Plus Port Framework



This approach relies on every CPE device being able to operate using a restricted port range, to perform IPv4-in-IPv6 tunnel ingress/egress functions, and to act as an IPv6 provisioned endpoint for the ISP network, which is perhaps an unrealistic hope. Further modifications to this model (Figure 7) propose the use of an accompanying CGN operated by the ISP to handle those CPE devices that cannot support these Address Plus Port functions.

Figure 7: Combined Address Plus Port and Carrier Grade NAT



If the port range assigned to the CPE is from a contiguous range of port values, then this approach could exacerbate some known problems with infrastructure protocols. There are *Domain Name System* (DNS) problems with guessable responses. The so-called "Kaminsky Attack" on the DNS[5, 6] is one such example where the attack can be deflected, to some extent, by using a randomly selected port number for each DNS query. Restricting the port range could mitigate the efficacy of such measures under certain conditions.

However, despite such concerns, the approach has some positive aspects. Pushing the NAT function to the edge has some considerable advantage over the approach of moving the NAT to the interior of the network.

The packet rates are lower at the edge, allowing for commodity computing to process the NAT functions across the offered packet load without undue stress. The ability for an end-user's application to request a particular NAT binding behavior by speaking directly with the local NAT using the *Internet Gateway Device Protocol,* as part of the *Universal Plug and Play* (UPnP)[7] framework, will still function in an environment of edge NATs operating with restricted port ranges. Aside from the initial provisioning process to equip the CPE NAT with a port range, the CPE, and the edge environment is largely the same as in today's CPE NAT model.

That is not to say that this approach is without its negative aspects, and it is unclear as to whether the perceived benefits of a "local" NAT function outweigh the problems associated with this model of address sharing. The concept of port "rationing" is a very suboptimal means of address sharing, given that after a CPE device has been assigned a port range those port addresses are unusable by any other CPE. The prudent ISP would assign to each CPE device a port address pool equal to some estimate of peak demand, so that, for example, each CPE device would be assigned 1,000 ports, allowing a single external IP address to be shared across only 60 such CPE clients. Neither the Carrier-Grade NAT approach nor the Dual-Stack Lite approach attempts this form of rationed allocation, allowing the port address pool to be treated as a common resource, with far higher levels of usage efficiency through dynamic management of the port pool.

The difference here is that in the dynamically managed approach any client can use the currently unused port addresses, whereas in the rationed approach each client has access to a fixed pool of port addresses that cannot be shared with any other client—even when the client does not need them. The difference here parallels the difference in network efficiency between time-division multiplexed synchronous circuits and asynchronous packets at Layer 2 in the network model. In the Address Plus Port framework the leverage obtained in terms of making efficient use of coopting these additional 16 bits of port address into the role of additional bits of client identifier address space is reduced by the imposition of a fixed boundary between customer and ISP use in the port address plan. The central NAT model of a CGN effectively pools the port address range and facilitates far more efficient sharing of this common port address pool across a larger client base.

Alain Durand reported to IETF 74 on a data-collection experiment using a *Cable Modem Termination System* (CMTS) with 8,000 subscribers where the peak port consumption level was 40,000 ports, or a maximum average port consumption of 5 ports per subscriber in each direction. As Alain noted, this average value needs to be compared with the hundreds of ports consumed by a single client browsing a Web 2.0 or *Asynchronous Java and XML* (AJAX) site, but he also noted that a central model of port sharing does yield far higher levels of address-sharing efficiency than the Address Plus Port advanced allocation model.[8]

The other consideration here is that this approach constitutes a higher overhead for the ISP, in that the ISP must support both "conventional" CPE and Address Plus Port equipment. In other words, the ISP must deploy a CGN and support customer CPE using a two-level NAT environment in addition to operating the Address Plus Port infrastructure. Unless customers would be willing to pay a significant price premium for such an Address Plus Port service, it is unlikely that this option would be attractive for the ISP as an additional cost after the CGN cost.

General Considerations with Address Sharing

The basic elements of any such approach to address sharing involve the CPE equipment at the edge, optionally some form of tunneling of traffic between the CPE and the carrier equipment, and carrier-provided equipment at the edge of the carrier's network (refer to Figure 8).

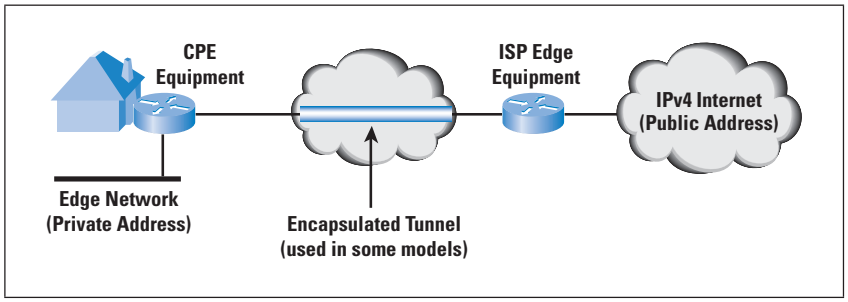


Figure 8: Generic Architecture for Address Sharing

A variety of technical solutions here involve these basic building blocks, so it is not true to say that this challenge is technically significant. But few ISPs have decided to proceed with large-scale deployment of any form of address-sharing technology for their IPv4 network infrastructure. So what is the problem here?

I suspect that the real concern is the consideration of the relevant business model that would guide this deployment. Today's Internet is large. It encompasses some 1.7 billion human users, a larger pool of devices, and hundreds of millions of individual points of control. If we want to change this deployed system, we will need copious quantities of money, time, and unity of purpose. So do we have money, time, and unity of purpose?

Money is missing: It could be argued that we have left the entire IPv6 transition effort to this late stage because of a lack of money. The main advantage of the Internet was that it was cheap. Packet sharing is intrinsically more efficient than circuit sharing, and the shift in functions of network service management from the network to the customer-owned and -operated endpoints implied further cost savings for the network operator. So the Internet model gained ascendency because for consumers it represented a cost-effective choice. It was cheap.

But what does IPv6 offer consumers? For existing Internet consumers it appears that IPv6 does not offer anything that they don't already have with IPv4—it offers mail, the web, various forms of voice services, and games. So consumers are not exactly motivated to pay more for the same services they already enjoy today.

In addition, it would appear that the ISP must carry this cost without incremental revenue from its customer base. But the ISP industry has managed to shave most of its revenue margins in a highly competitive industry, and at the same time lose control of services, their delivery, and their potentially lucrative revenue margins. Thus the ISP industry has been collectively idle in this area not because it cannot see the problem in terms of the imminent exhaustion of IPv4, but because it has little choice because of financial constraints that have prevented it from making the necessary longer-term investments in IPv6. So if the ISP industry has been unwilling to invest in IPv6 so far, then what incentive is there for it to invest in IPv6 and at the same time also invest in these IPv4 address-sharing measures? Is the lure of new, low-margin customers sufficient incentive to make such investments in this carrier-grade equipment? Or is the business case still insufficiently attractive?

Time is missing: The unallocated IPv4 address pool is already visibly waning. Without any form of last-minute rush, the pool will be around for the next 2 years, or until 2012 or so. But with any form of typical last-minute rush, this pool could be depleted in the coming months rather than in the coming years. Can we do what we need to do to get any of these approaches to a state of mass-market deployment in the next few months? All these approaches appear to be at the early stages of a timeline that starts with research and then moves on to development, prototyping, and trials; then to standards activity and industry engagement to orchestrate supply lines for end user equipment, ISP equipment, and definition of operational practices; then to product and service development; and finally, to deployment. For an industry that is the size of the Internet, "technical agility" is now an obsolete historical term. Even with money and unity of purpose this process will take some years, and without money—or even the lure of money—it becomes a far more protracted process, as we have seen already with IPv6 deployment.

And do we have *unity of purpose* here? Do we agree on an approach to address sharing that will allow players to perform their tasks? That will allow consumer product vendors to develop the appropriate product? That will allow application developers to develop applications that will operate successfully in this environment? That will allow the end user platform vendors to incorporate the appropriate functions in the operating system stacks? That will allow ISPs to integrate vendors' productions into their operational environments? Right now it is pretty clear that what we have is a set of ideas, each of which has relative merits and disadvantages, and no real unity of purpose.

It is easy to be pessimistic at this stage, given that the real concerns here appear to be related more to the factors associated with a very large industry attempting to respond to a very challenging change in the environment in which it operates. The question here is not really whether Address Plus Port routing is technically inferior to Dual-Stack Lite, or whether Carrier-Grade NATs are technically better or worse than either of these approaches. The question here is whether this industry as a whole will be able to sustain its momentum and growth across this hiatus. And, from this perspective, I believe that such pessimism about the future of the Internet is unwarranted.

The communications industry has undergone significant technological changes over the years, and this change is one more in the sequence. Some of these transformations have been radical in their effect, such as the introduction of the telephone in the late nineteenth century, whereas others have been more subtle, such as in the introduction of digital technology to telephony in the latter part of twentieth century, replacing the earlier analogue circuit model of telephony carriage. Some changes have been associated with high levels of risk, and we have seen a myriad of smaller, more agile players enter the market to lead the change while the more risk-averse enterprises stand back. On the other hand, other changes require the leverage of economies of scale, and we have seen market consolidation behind a smaller number of highly capitalized players.

My personal opinion is that the Dual-Stack Lite approach is the best one, because it appears to be technically elegant. I suspect, however, that the lowest-common-denominator fall-back position that this somewhat conservative industry will adopt will rely strongly on Carrier-Grade NATs, and the industry is likely to eschew the more complex support mechanisms required by the various permutations of Address Plus Port routing.

Operational Challenges When Implementing DNSSEC

by Torbjörn Eklöv, Interlan Gefle AB, and Stephan Lagerholm, Secure64 Software Corp.

As a reader of *The Internet Protocol Journal*, you are probably familiar with the *Domain Name System* (DNS) "cache poisoning" techniques discovered a few years ago. And you have most likely heard that *Domain Name System Security Extensions* (DNSSEC)[0, 13, 14, 15] is the long-term cure. But you might not know exactly what challenges are involved with DNSSEC and what experience the early adopters have gathered and documented. Perhaps you waited with your own rollout until you could gather more documentation about operational experiences when rolling out DNSSEC.

Stephan Lagerholm and Torbjörn Eklöv are DNS architects with significant DNSSEC experience. Torbjörn lives in Sweden and has helped several municipalities, as well as other organizations, sign their zones. Stephan Lagerholm lives in Dallas, Texas, and has been involved in implementing DNSSEC at several U.S. federal agencies. This article summarizes their experiences, including lessons learned from implementing the technology in production environments, and discusses associated operational concerns.

Background

A plethora of information about DNSSEC and cache poisoning attacks is available on the Internet[16], so we will not repeat it, but we think it is important to state where DNSSEC is today.

During the last few years the number of deployments, as well as the size and importance of the signed domains, has increased significantly. One of the main reasons for adoption of the DNSSEC during the past year was that the U.S. *Office of Management and Budget* (OMB) issued a mandate requiring the signing of the **.gov** domain in the beginning of the year. U.S. federal agencies were mandated to sign their domains by the end of 2009. Some agencies have already implemented the technology, whereas others are still working on it.[1]

Acceptance of DNSSEC technology is also reaching outside of the U.S. government. *Top Level Domains* (TLDs) around the globe have announced DNSSEC initiatives. To mention a few, Afilias signed .org and Neustar recently announced signing of **.us**. Several *County Code TLDs* (ccTLDs), including **.nl** and **.de**, announced that DNSSEC implementation is a work in progress. VeriSign has announced that it is working on signing the largest TLDs, namely **.com** and **.net**. Finally, the *Internet Corporation for Assigned Names and Numbers* (ICANN) along with VeriSign released a timeline for signing the root zone. And of course, the pioneer **.se** is on its fourth year as a signed TLD.

Several vendors have released software and products to support and make the signing of zones easier. A range of different products is now available on the market.

DNS professionals now have a broad choice of technology—from collections of open-source signing scripts to advanced systems with full automation and support for *Federal Information Processing Standard* (FIPS)-certified cryptography.

Operational Challenges

DNSSEC might significantly affect operations unless it is carefully implemented because it requires some changes to the underlying DNS protocol. Those changes are, in fact, the first significant changes that have been made to the DNS protocol since it was invented. Those changes might sometimes fool old systems into believing that the packets are illegal. DNSSEC also introduces new operational tasks such as rolling the keys and resigning the zone. Such tasks must be performed at regular intervals. Furthermore, as with any new technology, there are misconceptions about how to interpret the RFC standard.

The First Bug Reported

Late summer 2007, Torbjörn Eklöv convinced the municipality of Gävle in Sweden of the benefits of DNSSEC. He proudly signed what is believed to be the first municipality zone in the world, **`gavle.se`**. At first, everything worked fine. A week or so later, Gävle received reports from citizens who could not reach the municipality's websites. It turned out that a new version of *Berkeley Internet Name Domain* (BIND) was rolled out by a large service provider and that this version of BIND introduced a rather odd bug that affected DNSSEC. The result of the bug was that home users with some home routers and firewalls could not reach any signed domains.

Some people who heard about the problem at **`gavle.se`** wrongly believed that DNSSEC caused the problem and that DNSSEC is broken. However, this assumption is not true; DNSSEC worked as expected, but a bug in a particular version of BIND caused the problem. The problem triggered some research on how home routers handle DNSSEC. *Stiftelsen för Internetinfrastruktur,* the organization that runs the **`.se`** TLD, issued a report describing how commonly used home routers and firewalls handled the new protocol changes in DNS[2]. Later, Nominet, which administers the **`.uk`** TLD, issued a similar report[3]. In addition, DENIC, which administers the **`.de`** TLD, researched the same subject[4]. The results are all discouraging; only 9 out of 38 tested home gateways supported DNSSEC correctly in the most recent reports.

A *Birds of a Feather* (BoF) session was held at the 76th meeting of the *Internet Engineering Task Force* (IETF) in Hiroshima to discuss the problems involving home gateways[5]. We look forward to seeing progress in this area.

Preparing Your Firewall for DNSSEC

Most problems with DNSSEC are related to firewalls. Make sure to involve your security and networking administrators so that they can make the required changes before taking DNSSEC into production.

Two types of firewall problems are most common:

The first involves the *Transmission Control Protocol* (TCP). There is a misconception among firewall vendors and security administrators that DNS queries use the *User Datagram Protocol* (UDP) and that zone transfers use TCP. Unfortunately, this assumption is not entirely true. DNS queries first try UDP, but revert to TCP if no response is received for the initial UDP query or if the response lacks important information because it is truncated. The possibility of something in the path blocking the response to the initial query is much higher with DNSSEC because of the increased size of the responses.

> *For DNSSEC to work correctly, it is mandatory that you open your firewall for both TCP and UDP over port 53.*

The second problem is related to the *IP Buffer Reassembly* size. The authors of the DNSSEC standard realized that a potential problem might exist with TCP queries. TCP puts a higher burden on the DNS servers. (TCP is much more expensive to process than UDP.) To avoid too much TCP traffic, the authors made the EDNS0 extension mandatory for DNSSEC. EDNS0 is one of the *Extension Mechanisms for DNS* (EDNS), a standard that, among other things, allows a client to signal that it is capable of receiving DNS replies over UDP that are larger than the previous limit of 512 bytes. Some firewalls are not aware of the fact that the EDNS0 standard allows for larger packets and they either block any DNS packet using EDNS0, or block any DNS packet larger than the 512 bytes regardless of the EDNS0 signaling.

Other firewalls allow for the large packets by default, whereas a few vendors require the firewall to be manually configured to do so. Any device in the path that does packet inspection at the application layer must be aware of the EDNS0 standard to be able to make a correct decision about whether to forward the packet or not. ICANN has summarized the status of EDN0 support in some commonly used firewalls[6].

Note that it is not enough to test that your firewall allows large incoming DNS replies by sending DNS queries to the Internet[7]. You must also test that an external source can receive large DNS replies that your DNS server is sending. One way of doing so is to use an open DNSSEC-aware resolver[8, 9].

> *Test and configure your firewall to allow for use of EDNS0 and for DNS packets larger than 512 bytes over UDP.*

Preparing Your Slaves

Setting up DNSSEC involves substantial changes to the master name server so it can sign and serve the signed data. However, it is easy to foresee that the slaves must be upgraded, too. The slaves are much easier to upgrade and operate because they never produce signatures.

They are secondary systems that transfer data from the primary server and respond to DNS queries. But the slaves must understand how to respond to queries requesting signed data.

Slaves must be upgraded to BIND 9.3 or better to understand the *Next Secure* (NSEC)[14] standard. NSEC is a method to provide authenticated denial of existence for DNS resource records. The newer *Next Secure 3* (NSEC3)[10] standard introduces some additional requirements for the slaves. If you use NSEC3, you must upgrade the slaves to BIND 9.6 or later. Version 3 of *Name Server Daemon* (NSD)[17] and any version of *Secure64 DNS Authority/Signer*[18] can do both NSEC and NSEC3. Windows Server 2008 R2 for the x86-64 architecture supports DNSSEC as a master, slave, and validating resolver. However, we recommend limiting the use of the Windows platform to slaves and for domains using NSEC. Our opinion is that it is very hard to implement DNSSEC on Windows, and we suggest that you wait until Microsoft offers a sensible *Graphical User Interface* (GUI) and support for NSEC3. Note that the Itanium version of Windows 2008 R2 supports neither DNS nor DNSSEC.

> *Make sure your slaves can handle the version of DNSSEC you intend to use.*

If the slaves are administered by another party, contact the administrator before you begin DNSSEC implementation. Make sure the slaves are running a version capable of DNSSEC. Stephan helped a large U.S. federal agency sign its domains. The agency used one of the major federal contractors to run its slave servers. After multiple attempts to reach somebody that understood DNS and DNSSEC, Stephan finally learned that the slaves were running BIND 9.2.3 and that the contractor had no plans to upgrade. The only alternative for the agency was to in-source the slaves and run them itself.

> *If your slaves are administered by another party, make sure you know if and what version of DNSSEC that party supports before you start implementing.*

Communicate with Your Parent

TLDs allow you to communicate with them in two ways:

- *Registrant–Registrar–Registry Model:* In this, the most common model, the registrant (**`example.org`**) does not communicate directly with the registry (**`.org`**). Instead, a third-party registrar handles all communication related to DNS and DNSSEC. This model is, for example, used by the **`.se`** and **`.org`** TLDs.
- *Registrant–Registry Model:* This model is normally used by smaller TLDs such as **`.gov`**. It allows direct communication between the registrant (**`agency.gov`**) and the registry (**`.gov`**). The TLD acts as both a registrar and a registry in this model.

Most problems described in the following paragraphs apply to both models, but those involving multiple registries are obviously applicable only to the Registrant–Registrar–Registry model.

Establishing a *Chain of Trust* in DNSSEC involves uploading one or more public keys to the parent. Ultimately the parent publishes a *Delegation Signer* (DS) record, a smaller fingerprint that can be constructed from the DNSKEY record. To upload your keys, you must use a registrar that supports DNSSEC. If your registrar does not support DNSSEC, you need to move your domains to another registrar (or convince your current registrar to start supporting DNSSEC). It usually takes a few days or up to a week to move a domain from one registrar to another.

Make sure that your registrar supports DNSSEC. If it does not, move your domain to a registrar that supports DNSSEC before you begin signing your zone.

Some registrars allow registration under multiple TLDs. However, just because a registrar handles DNSSEC for one TLD does not mean that it handles DNSSEC for all TLDs it serves. For example, several registrars in Sweden support DNSSEC for **`.se`** but not for **`.org`** or **`.us`**.

Make sure that your registrar handles DNSSEC under the TLD in question.

Most registrars offer you the opportunity to use their name server instead of your own. The service is either offered for free or for an additional cost. The registrar typically provides a web interface where you can change your zone data. This service is a good and useful choice if your domains are uncomplicated and small. Larger and more complex domains are better operated on your own servers.

Some registrars that provide this type of service can handle DNSSEC only if you use their name servers and not your own name servers. These registrars can establish the chain of trust with the parent only if the zone is under their control. They lack a user interface for uploading a DS key that you generate on your own name servers.

If you intend to use your own name servers, make sure that your registrar supports this deployment model, and allows you to upload a DS record for further distribution to the registry.

In theory, the child zone system should create the DS record fingerprint and upload it to the parent. In practice, some registrars require you to upload the DNSKEY record to them. They then create the DS record for you. (This practice is bad because the registrar must know the hash algorithm used to construct the DS record, which it might not know.) The DNSKEY record comes in several different formats, depending on the platform you used to create the keys (BIND, Microsoft, NSD, Secure64, etc.). The formats have minor differences, and you might have to convert the DNSKEY into a format that the registrar accepts.

Not everything works smoothly, even with the correct DNSKEY format. The logic at one registrar's website was to deny uploading of DNSKEYs unless the optional *Time To Live* (TTL) field existed. (The TTL value is useless in the DNSKEY context because the parent overrides this value with its own TTL). You may have to manually change your DNSKEY before uploading it to comply with the checks that the registrar performs.

> *If your registrar requires you to upload the DNSKEY, make sure that your solution can generate the requested format. If not, you need to manually change the fields with a text editor.*

As noted previously, some registrars are performing too many checks and irrelevant checks before accepting and creating the secure delegation. Other registrars do not check at all or have limited checks that do not work as expected. For example, some registrars assume that your key is created using a certain algorithm, and they do not double-check it prior to creating a DS record. One registrar created a bogus DS record if you uploaded a DNSKEY with upper-case characters in the domain name. The bogus DS record looked valid, and troubleshooting to find this error took hours.

Another example is keys created with *Webmin*[11], a graphical tool that you can use for signing zones. Webmin defaults to using the less-common *Digital Signature Algorithm* (DSA) for its DNSKEYs. The registrar did not complain when uploading the Webmin key, and it created a bogus DS record by assuming that it was an RSA key.

It is hard for a registrant to do anything about errors at the registrars. The best you can do is to make sure that you upload the correct key with the correct parameters such as algorithm, key length, key-id, etc. If something goes wrong, you might have to change the keys in production. Rolling the keys to the same algorithm and key length is relatively easy—but changing your keys to another algorithm adds extra complexity. It is an interesting exercise to change to another algorithm in production, but it is something we recommend avoiding if possible.

> *Double-check the DNSKEY/DS so that it is created with the correct parameters prior to uploading it.*

Communicate with Your Children

If you have sub-domains in your domain, you must make sure that you can accept and publish the DS records that your children upload to you. This situation is not a problem if you use zone files in text format—you can simply insert the DS record using your favorite editor. But it might be a problem if you are using an *Internet Protocol Address Management* (IPAM) system. In that case make sure that it can insert DS records into the zones that are managed by the system. Some IPAM systems do not support insertion of DS records correctly.

Make sure that your IPAM system can insert DS records into your zones.

A common strategy among organizations with high-availability requirements for their critical servers is to use a global load balancer, which is basically a DNS server that responds differently depending on the status of the service in question. For example, assume a load balancer can respond to a question for `www.example.com` with `192.0.2.1` and `192.0.2.2` if both web servers are up. If `.1` becomes unavailable, the load balancer notices a failure and responds only with `.2`. In order to use a global load balancer, you must delegate `www` as a sub-domain to its own DNS process.

When DNSSEC is implemented, you must make sure that the load balancer can handle DNSSEC (and not that many do); otherwise it is impossible to sign the responses for those resources. Unfortunately, these resources are the most critical ones for your environment and would benefit the most from DNSSEC signing.

Make sure that your load balancers support DNSSEC. If they do not, have an alternative strategy.

Rolling the Keys

You should change the DNSKEYs regularly and when you think the keys are compromised. The process of doing so is called *rolling the keys*. There are normally two different keys in DNSSEC, the *Key Signing Keys* (KSKs) and the *Zone Signing Keys* (ZSKs). Rolling the ZSK is an internal process and does not require communication with the parent. Rolling the KSK, on the other hand, requires the parent to publish a new DS record.[12]

There is no standard yet that describes how the communication between the parent and the child should occur when a key is rolled. Early DNSSEC-capable registrants used a web interface that allowed their registrants to upload and manipulate the DNSSEC information. With a web interface, each domain must be handled separately and there is no easy way to automate the interaction.

The web interface works for a handful of domains but becomes very cumbersome when you have many domains. For those types of organizations, it is important to make sure that there is some kind of *Application Programming Interface* (API) or script access to the registrar. This interface allows the organization to upload new DS records during the rollover in a convenient way.

Make sure that your registrar supports automation through an API if you have many domains.

Scripting with an API as described previously is one way of communicating with the registrar. Another way of achieving the same type of automation is for the parent (or registrar) to monitor the child for any changes to the DNSKEY records.

Note that the chain of trust is still intact during a nonemergency rollover. The parent can securely poll the child and grab the new DNSKEY records and convert them into DS records. The polling from the parent to each signed child needs to occur regularly so that a rollover is picked up quickly. This regularity of polling makes the scheme best for domains with fewer delegations (in the order of thousands, not millions—consider how much bandwidth an hourly polling of 15 million children would require).

Automation is a good thing, but make sure you understand the implications when opting for automatic detection of key rollovers. The automation scripts are not fail-safe. It has been reported that early versions of such scripts under some circumstances wrongly assumed that a key rollover occurred and deleted the DS record, thus breaking the chain of trust.

Understand the implication when opting for automatic detection, addition, and deletion of DS records.

Management of DNSSEC

Without DNSSEC, you are not bound to any particular registrar; you can switch to a new registrar fairly easily. With DNSSEC, this situation changes. First of all, if you let the registrar sign the zone on your behalf, the registrar will be in charge of the key used to sign your zone. Extracting your key so that it can be imported to another registrar is not always straightforward (also remember that there is really no incentive for your previous registrar to help you because you just discontinued its service). An alternative is to unsign the zone before you change registrars, but that option might not always be a viable one. The lack of standards makes it hard to change registrars on a signed domain that is in production.

You must tell your new registrar that you are using DNSSEC, and you must make sure that the registrar supports it. If not, the registrar might accept the transfer but be unable to publish the DNSKEY records. The result would be a DS record published by the registry but no corresponding DNSKEY records at the child, making the zone "security lame" and causing failed validation.

The same types of problems exist if you are running your own name servers. If you change your master server, make sure that you transfer the secret keys as well. Signing with new keys will not work unless you flush out the old keys with rollovers and upload a new DS record to your parent.

Have a plan ready for how to transfer your keys to a new master server.

Timers

It is important to adjust your signature validity periods and the *Start of Authority* (SOA) timers so that they match your organizational requirements and operational practices. SOAs expire and signature validity periods all too often are too short.

Unless you are restricted by guidelines saying otherwise, you should strive to set the timers reasonably high. Set the timers so that your zones can cope with an outage as long as the longest period that the system might be unattended.

For example, if you know that your top DNS administrator usually has three weeks of vacation in July, you could consider setting the times so that the zone can survive four weeks of downtime. If you are confident in your signing solution and are monitoring your signatures carefully, you might set it a little bit lower.

Signature lifetime is a trade-off between security (low signature lifetimes) and convenience (high signature lifetimes). Setting a really high signature lifetime is convenient from an operational perspective but is less secure. Some organizations such as the IETF use an excessive signature lifetime of one year (`dig ietf.org DNSKEY +dnssec | grep RRSIG`). This lifetime is clearly not recommended, and they should know better.

> *Carefully set your signature lifetimes and SOA times to reflect your organization's operational requirements and practices.*

A Note on Validation

This article has focused on the authoritative part of DNSSEC. That part includes signing resource records and serving DNS data. The operational challenges with signing data are much greater than the challenges of validating data. To validate data, the only thing you need to do regularly is update your trust anchor file. Make sure you do so. Torbjörn reports several outages when the `.se` DNSKEY used in the `.se` trust anchor expired in January 2010. We look forward to the work being done in this area to automate the process.

Summary

DNSSEC has been deployed and taken in production for several large and critical domains. It is not hard to implement DNSSEC, but doing so introduces some operational challenges. Those challenges exist both during the implementation phase when the zone is being signed for the first time and during the operation of the zone. Make sure you understand the possible effects of implementation and plan ahead. The following checklist summarizes the most important pitfalls with DNSSEC:

- Open your firewall for EDNS0 signaling and allow large DNS packets using UDP and TCP over port 53.
- Check the DNSSEC capabilities of all your masters and slave servers.
- Check the DNSSEC capabilities of your registrar and understand their requirements for the public key you are uploading.
- Make sure your IPAM system can handle secure delegations.

- Plan how to handle load balancers.
- Develop an automation strategy if you have a lot of zones.
- Plan how you will transfer your keys to a new master server if a disaster occurs.
- Implement a policy for DNSSEC timer settings.

Happy signing!

STEPHAN LAGERHOLM is a Senior DNS Architect with Secure64 Software Corporation—a software company offering high-performance DNS server software that makes the DNS trustworthy and secure. Secure64 DNS applications include key management and zone-signing software that make it easy to deploy DNSSEC securely and correctly as well as DNS server software that is always available. Stephan is a DNS and security expert with more than 11 years of international experience in the field. His background includes leadership positions at the largest networking and security system integrator in Scandinavia, and responsibility for designing hundreds of complex IT networks. Stephan is one of the few persons in the United States to have integrated DNSSEC into production environments. Stephan is CISSP-certified and holds a Master of Science degree in Computer Science and Mathematics from Uppsala University in Sweden. E-mail: **Stephan.Lagerholm@secure64.com**

TORBJÖRN EKLÖV is the founder and partner of Interlan Gefle AB, an IT consulting company in Sweden with 20 employees. He is a DNSSEC and IPv6 pioneer. All internal and external services at Interlan use both IPv6 and IPv4, and the company hosts about 200 DNSSEC-signed domains. Torbjörn has worked with Internet communication and security for 15 years, and is the founder and manager of Secure End User Connection (SEC), or Säker KundAnslutning (SKA) in Swedish, an organization that certifies products and broadband networks to protect subscribers from spoofing and hijacking. His favorite homepage is **http://test.ipv6.tk**. You can reach him at **Torbjorn.Eklov@interlan.se**

Book Review

The Art of Scalability

The Art of Scalability: Scalable Web Architecture, Processes, and Organizations for the Modern Enterprise, by Martin L. Abbott and Michael T. Fisher, ISBN-13: 978-0-13-703042-2, Pearson Education, 2010.

It is often claimed that the primary lesson of the Internet is one of "scaling." So the title of this book bodes well for relevance to Internet designers. A reader would likely expect discussion of hashing algorithms, fast-path coding, protocol latencies and chattiness, distributed redundancy design, and similar guidance for handling a billion users. The reader would largely be wrong, although some of the book is dedicated to technical performance. What is easily missed in the title is the word "organizations." It does not mean organization of modules. It means organizations within a *company.*

This book is very much a holistic one. It takes the painfully realistic position that well-designed protocols and software modules matter only if the company structure or team operation is tuned to growing and running a large-scale service. The book is comprehensive and primarily tailored for highly formal management, with substantial, bureaucratic procedures designed to ensure thorough consideration of scalability needs and implications. It is loaded with discussion of many different organizational and technical management tools that assist in making diligent decisions. For most readers and most companies, attempting to apply this level of formality is dramatic overkill. However, knowing about it is not.

The book is 533 pages, with 33 chapters and 3 appendices. The writing style is reasonably clean, but pedantic. Don't expect the type of entertainment-oriented writing that is common these days. The authors' experiences include *eBay* and *PayPal,* so scaling matters have been within their direct work responsibilities. As holds for any book attempting this kind of breadth, from technology design to organization management, discussion frequently is superficial and will be obvious to some readers, while the specific detail will in places be irrelevant to many others. Although these characteristics might be taken as negatives, they actually serve to demonstrate the utility of the book as an introduction and basic reference to the topic of scaling. A quick scan of the book helps the reader see how many different aspects of an organization's activities can aid or hinder large-scale operations. Exploring specific chapters can explain concepts and topics and suggest particular tools to help in planning or analysis.

Organization

Part I, "Staffing a Scalable Organization," comprises six chapters. It provides a tutorial on classic problems in structuring and staffing an organization for growth. Little is taken for granted. So there is guidance about the characteristics needed in a CEO, CFO, or CTO for aiding leadership in working to scale the company and the company's products. It even has a chapter on "Leadership 101."

For the most part, this section is likely to be useful only for readers with no management background, because the material is extremely basic. What distinguishes it is only the constant consideration of the way its topics are relevant to scaling. The likely utility of the section is in helping employees "manage up" so they can interact with management better when seeking support for changes needed to implement or maintain scalable development or operations. On the other hand, an interesting discussion explored why some simple and entirely logical choices for organizing a company work against accountability and scaling.

Part II, "Building Processes for Scale," at nearly 200 pages is 40 percent of the book. Whereas the first part concerned the people, this one concerns what they do. The first half of this part strongly emphasizes processes for anticipating and responding to scaling problems and for judiciously allocating limited resources. Hence there is even a chapter that considers "build versus buy." Technical topics discussed here are conceptual rather than concrete. They concern risk, performance, capacity, and failure recovery. Each is treated as a planning and design concern, with estimates and procedures. A warning: The word "architecture" shows up in the title of several middle paragraphs in this section, but don't be confused. It refers to groups that do architecture, not to the technical details of architecture.

Part III is "Architecting Scalable Solutions." Now at last, techies will start to get their geek fix. But perhaps with more abstraction than they will expect? Again, this book is more about properly organizing things than about algorithms. The section introduces "technology-agnostic design," with consideration of fault isolation and various growth factors, including repeated attention to cost, risk, scalability, and availability. There are chapters on database scaling and the use of caching for performance. The authors are fond of asynchronous and state-free interaction, with the view that it is more robust. The precise reason for this conclusion was not entirely clear to me, but presumably it is because it is easier to recover and retarget an exchange after an outage occurs during an interaction.

Two chapters of this part of the book are devoted to the "AKF Scale Cube," and indeed the Index has a large number of citations to it. (AKF refers to the authors' company.) For this analytic tool, the x-axis "...represents cloning of services and data with absolutely no bias." In other words, these graphs are pure replications of equivalent, parallel components or activities, used to distribute load. The y-axis "... represents a separation of work responsibility by either the type of data, the type of work performed for a transaction, or a combination of both... We often refer to these as service or resource oriented splits." The nature of the z-axis is described as "...biased most often by the requestor or customer... focused on data and actions that are unique to the person or system performing the request." I took this as meaning that the axis divides work according to tailored attributes.

Part IV is the catchall for remaining topics, with some requisite discussion of clouds and grids, application monitoring, and data center planning.

Summary

The book will be useful for architects who need to understand how to scale their own work and how to support their organization for long-term growth. It will also be useful for technical, operations, and other managers who need to understand the technical and operations scaling problems, support their own architects, and work with the rest of their organization to anticipate and satisfy scaling requirements.

Fragments

Call for Candidates for Itojun Service Award

The *Itojun Service Award* is presented every year to an individual or a group who has made outstanding contributions in service to the IPv6 community. The deadline for nominations for this year's award is July 12, 2010. The award will be presented at the 79th meeting of the *Internet Engineering Task Force* (IETF) to be held in November 2010 in Beijing, China.

The Itojun Service Award, established by the friends of Itojun and administered by the *Internet Society* (ISOC), recognizes and commemorates the extraordinary dedication exercised by Itojun over the course of IPv6 development. The award includes a presentation crystal, a US$3,000 honorarium, and a travel grant.

The award is focused on pragmatic technical contributions, especially through development or operation, with the spirit of servicing the Internet. With respect to the spirit, the selection committee seeks contributors to the Internet as a whole; open source developers are a common example of such contributors, although this is not a requirement for expected nominees. While the committee primarily considers practical contributions such as software development or network operation, higher-level efforts that help those direct contributions will also be appreciated in this regard. The contribution should be substantial, but could be immature or ongoing; this award aims to encourage the contributors to continue their efforts, rather than just recognizing well-established work. Finally, contributions of a group of individuals will be accepted as deployment work is often done by a large project, not just a single outstanding individual.

The award is named after Dr. Jun-ichiro "Itojun" Hagino, who passed away in 2007, aged just 37. Itojun worked as a Senior Researcher at *Internet Initiative Japan Inc.* (IIJ), was a member of the board of the *Widely Integrated Distributed Environment* (WIDE) project, and from 1998 to 2006 served on the groundbreaking KAME project in Japan as the "IPv6 Samurai." He was also a member of the *Internet Architecture Board* (IAB) from 2003 to 2005.

For additional information on the award, please visit:
http://www.isoc.org/awards/itojun/

Less than 10% of IPv4 Addresses Remain Unallocated, says NRO

The *Number Resource Organization* (NRO), the official representative of the five *Regional Internet Registries* (RIRs) that oversee the allocation of all Internet number resources, recently announced that less than 10 percent of available IPv4 addresses remain unallocated. This small pool of existing IP addresses marks a critical moment in IPv4 address exhaustion, ultimately impacting the future network operations of all businesses and organizations around the globe.

"This is a key milestone in the growth and development of the global Internet," noted Axel Pawlik, Chairman of the NRO. "With less than 10 percent of the entire IPv4 address range still available for allocation to RIRs, it is vital that the Internet community take considered and determined action to ensure the global adoption of IPv6. The limited IPv4 addresses will not allow us enough resources to achieve the ambitions we all hold for global Internet access. The deployment of IPv6 is a key infrastructure development that will enable the network to support the billions of people and devices that will connect in the coming years," added Pawlik.

The *Internet Protocol* (IP) is a set of technical rules that defines how devices communicate over a network. There are currently two versions of IP, IPv4 and IPv6. IPv6 includes a modern numbering system that provides a much larger address pool than IPv4. With so few IPv4 addresses remaining, the NRO is urging all Internet stakeholders to take immediate action by planning for the necessary investments required to deploy IPv6.

The NRO, alongside each individual RIR, has actively promoted IPv6 deployment for several years through grassroots outreach, speaking engagements, conferences and media outreach. To date, their combined efforts have yielded positive results in the call to action for the adoption of IPv6.

Given the less than 10 percent milestone, the NRO is continuing its call for Internet stakeholders, including governments, vendors, enterprises, telecoms operators, and end users, to fulfill their roles in IPv6 adoption, specifically encouraging the following actions:

- The business sector should provide IPv6-capable services and platforms, including web hosting and equipment, ensuring accessibility for IPv6 users.
- Software and hardware vendors should implement IPv6 support in their products to guarantee they are available at production standard when needed.
- Governments should lead the way by making their own content and services available over IPv6 and encouraging IPv6 deployment efforts in their countries. IPv6 requirements in government procurement policies are critical at this time.
- Civil society, including organizations and end users, should request that all services they receive from their ISPs and vendors are IPv6-ready, to build demand and ensure competitive availability of IPv6 services in coming years.

The NRO's campaign to promote the next generation of Internet Protocol continues to positively impact the Internet community. IPv6 allocations increased by nearly 30% in 2009, as community members continued to recognize the benefits of IPv6.

"Many decision makers don't realize how many devices require IP addresses—mobile phones, laptops, servers, routers, the list goes on," said Raul Echeberria, Secretary of the NRO. "The number of available IPv4 addresses is shrinking rapidly, and if the global Internet community fails to recognize this, it will face grave consequences in the very near future. As such, the NRO is working to educate everyone, from network operators to top executives and government representatives, about the importance of IPv6 adoption," added Echeberria.

IP addresses are allocated by the *Internet Assigned Numbers Authority* (IANA), a contract operated by the *Internet Corporation for Assigned Names and Numbers* (ICANN). IANA distributes IP addresses to RIRs, who in turn issue them to users in their respective regions. "This is the time for the Internet community to act," said Rod Beckstrom, ICANN's President and Chief Executive Officer.

"For the global Internet to grow and prosper without limitation, we need to encourage the rapid widespread adoption of the IPv6 protocol," he added.

The NRO is the coordinating mechanism for the five RIRs. The RIRs—AfriNIC, APNIC, ARIN, LACNIC, and the RIPE NCC—ensure the fair and equitable distribution of Internet number resources (IPv6 and IPv4 addresses and *Autonomous System* (AS) numbers) in their respective regions. The NRO exists to protect the unallocated Internet number resource pool, foster open and consensus-based policy development, and provide a single point of contact for communication with the RIRs.

Learn more about the NRO at **`www.nro.net/media`**

The five RIRs that make up the NRO are independent, not-for-profit membership organizations that support the infrastructure of the Internet through technical coordination. The IANA allocates blocks of IP addresses and ASNs, known collectively as *Internet number resources,* to the RIRs, who then distribute them to users within their own specific service regions. Organizations that receive resources directly from RIRs include *Internet Service Providers* (ISPs), telecommunications organizations, large corporations, governments, academic institutions, and industry stakeholders, including end users. The RIR model of open, transparent participation has proven successful at responding to the rapidly changing Internet environment. Each RIR holds one or two open meetings per year, as well as facilitating online discussion by the community, to allow the open exchange of ideas from the technical community, the business sector, civil society, and government regulators.

The five RIRs are:

- AfriNIC: **http://www.afrinic.net**
- APNIC: **http://www.apnic.net**
- ARIN: **http://www.arin.net**
- LACNIC: **http://www.lacnic.net**
- RIPE NCC: **http://www.ripe.net**

ISOC Funds Projects to Support Internet Access, Security, and Policy Development

The *Internet Society* (ISOC) recently announced it is funding community-based projects around the world addressing issues such as Internet leadership, education, core infrastructure, local governance, and policy development, with a strong focus on currently underserved communities.

"The diversity of projects awarded highlights the profound importance of the Internet in so many aspects of our lives, in all parts of the world," said Jon McNerney, Chief Operating Officer of the Internet Society. "The passion and creativity of those developing the projects within their communities drives the Internet Society's commitment to help bring the benefits of the Internet to people everywhere."

As part of the ISOC *Community Grants Program,* each project will receive up to US$10,000 for efforts that promote the open development, evolution, and use of the Internet for the benefit of all people throughout the world.

Projects funded in this round include:

- Training programs to build digital literacy within safe environments in India and Uganda
- Village-operated telecommunication services in East Timor
- Support for development of core Internet time infrastructure
- Policy and practical action in Kenya to improve online safety for women
- Online support for NGOs in Tunisia and more effective local governance in India
- Promotion of Internet leadership in Ecuador
- Development of important public policy resources in Georgia and Australia

ISOC Community Grants are awarded twice each year. The next round of the program will open on September 1, 2010. Additional information about the Community Grants Program and this round of award-winning projects can be found here:

https://www.isoc.org/isoc/chapters/projects/index.php

https://www.isoc.org/isoc/chapters/projects/awards.php?phase=11

RIPE Community Statement on the Internet Address Management System

At the May 2010 *Réseaux IP Européens* (RIPE) meeting in Prague, Czech Republic, the RIPE community issued the following statement:

"The RIPE community supports all efforts to assist in the deployment of IPv6, especially in developing countries.

However, we note concerns being expressed within the ITU by a few members, most recently in the ITU IPv6 Group, that the current address management system is inadequate.

The RIPE community mandates the RIPE NCC to work with the ITU IPv6 Group, individual ITU members, and the community to clearly identify these concerns and to find ways to address them within the current IP address management system."

This statement will be sent to the *International Telecommunications Union* (ITU) to reiterate the RIPE community's belief that the current address management system works. The RIPE NCC will continue to participate actively in the ITU IPv6 Group and report back to the RIPE community.

For more information see:

http://www.itu.int/ITU-T/othergroups/ipv6/
http://ripe.net/ripe/index.html
http://www.nro.net/documents/nro51.html

Upcoming Events

The *North American Network Operators' Group* (NANOG) will meet in San Francisco, California, June 13–16, 2010.
See **http://nanog.org**

The *Internet Corporation for Assigned Names and Numbers* (ICANN) will meet in Brussels, Belgium, June 20–25, 2010.
See **http://icann.org**

The *Internet Engineering Task Force* (IETF) will meet in Maastricht, The Netherlands, July 25–30, 2010 and in Beijing, China, November 7–12, 2010. See **http://www.ietf.org/**

APNIC, the *Asia Pacific Network Information Centre,* will hold its Open Policy meeting in the City of Gold Coast, Australia, August 24–28, 2010. See **http://www.apnic.net/meetings/30/**

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ contains standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

From The Editor

Technology advances—such as improvements in display technology, battery life, processor capabilities, and communications systems—have all contributed to making *mobile devices* the most important area for Internet growth. In order to fully support these devices, the IETF developed *Mobile IP* many years ago, and it has continued to work on the general area of IP mobility. We have covered some of this work in previous issues of IPJ, and this time we look at *Proxy Mobile IPv6* (PMIPv6), which is being standardized by the IETF. The article is by Ignacio Soto, Carlos J. Bernardos, María Calderón, and Telemaco Melia.

Deployment of IPv6 is progressing, albeit slowly. In several upcoming articles we will examine some transition technologies or implementation details that can make this deployment easier, and above all, transparent, to the end user. In our first article, Dan Wing and Andrew Yourtchenko explain the concept of "Happy Eyeballs" as applied to dual-stack IPv4/IPv6 systems.

Domain Name System Security Extensions (DNSSEC) have recently been applied to the Internet system of root servers. For details, see our "Fragments" section, where you will also find a statement from the *Number Resource Organization* (NRO) regarding the results of a recent IPv6 readiness study.

Once again, please remember to check your subscription expiration date and take the necessary steps if you wish to continue receiving this journal. It's not too late to renew and get back on the distribution list, even if your subscription expired some time ago. You can find your subscription ID and expiration date either on the back page of your copy or on the envelope that it came in. In order to access your record, click the "Subscriber Services" link on our webpage at `www.cisco.com/ipj` and enter your e-mail address and the subscription ID. The system will send you a link that allows direct access to your record, and you can update your address and renew your subscription. If you no longer have access to the e-mail you used when you subscribed or have forgotten your subscription ID, just send a message to `ipj@cisco.com` and we will make the necessary changes for you.

PMIPv6: A Network-Based Localized Mobility Management Solution

by Ignacio Soto, Universidad Politécnica de Madrid; Carlos J. Bernardos, and María Calderón, Universidad Carlos III de Madrid; and Telemaco Melia, Alcatel Lucent Bell Labs

Traditional IP mobility procedures[4] are based on functions residing in both the mobile terminal and the network. Recently, we have been assisting in a shift in IP mobility protocol design, mostly focusing on solutions that relocate mobility procedures from the mobile device to network components. This new approach, known as *Network-Based Localized Mobility Management* (NetLMM), allows conventional IP devices (for example, devices running standard protocol stacks) to roam freely across wireless stations belonging to the same local domain. This property is appealing from the operator's viewpoint because it allows service providers to enable mobility support without imposing requirements on the terminal side (for example, software and related configuration). For this purpose the *Internet Engineering Task Force* (IETF) has standardized *Proxy Mobile IPv6* (PMIPv6)[1].

This article details the Proxy Mobile IPv6 protocol, providing a general overview and an exhaustive description of a few selected functions.

Why Network-Based Localized Mobility?

The ability to move while being connected to a communication network is very attractive for users, as demonstrated by the success of cellular networks. However, while designing the IP stack, mobility was not retained as a requirement and, as a consequence, IP does not natively support mobility. The reason is a very basic design choice adopted in IP, both in IPv4[2] and in IPv6[3], namely that addresses have two roles: they are used as locators and identifiers at the same time.[16]

IP addresses are *locators* that specify, by means of the routing system, how to reach the node (more properly, the *network interface*) that is using a specific destination address. The routing system keeps information about how to reach different sets of addresses that have a common network prefix, thus improving scalability of the system itself. However, IP addresses are also *identifiers* used by upper-layer protocols (for example, the *Transmission Control Protocol* [TCP]) to identify the endpoints of a communication channel. Additionally, names of nodes are translated by the *Domain Name System* (DNS) to IP addresses (which, in that way, play the role of node identifiers).

The linking of these two roles (*locators* and *identifiers*) is appealing because name resolution of the peer with whom we want to communicate and location finding translate to the same problem (that is, no translation mechanism is needed). However, the negative side effect is that supporting mobility becomes difficult.

Mobility implies separating the identifier role from the location one. From the identification standpoint, the IP address of a node should never change, but from the location point of view the IP address should change each time the node moves, showing its current location within the routing hierarchy (that is, the IP subnet to which the node is currently attached).

The IETF has studied the problem of terminal mobility in IP networks for a long time. It has developed IP-layer solutions for both IPv4 (Mobile IPv4[4, 5]) and IPv6 (Mobile IPv6[6]), enabling the movement of terminals and providing transparent service continuity. These solutions, being IP-based, are independent of the Layer 2 technologies. They provide Mobile Nodes with a permanent address (the *Home Address* [HoA]) to be used as identifier, and a temporal address (the *Care-of Address* [CoA]) to be used as locator. The CoA changes in each IP subnet visited by the Mobile Node. An entity in the network, the *Home Agent,* binds both addresses with the help of signaling generated by the Mobile Node. The Home Agent serving a Mobile Node must be placed in the subnet where the Home Address of that Mobile Node is topologically correct (the home network).

Although Mobile IP enables a host to move (that is, change the point of attachment in an IP network) while keeping session continuity, this ability is not sufficient for true mobility. Enabling efficient handoffs is an additional and critical requirement. Because the IP handoff latency is affected by the time required to exchange signaling between the Mobile Node and the Home Agent, a new family of solutions proposes to use a local Home Agent (that is, a Home Agent closer to the Mobile Node) to provide mobility in a local domain; that is, to provide localized mobility support. Changing the point of attachment within the local domain requires only signaling to the local Home Agent, allowing faster signaling messages exchange because it is limited within the local domain. This approach is attractive because users typically move in localized environments (for example, they commute between their living homes and their work places) that can be covered with localized domains. Examples of these types of solutions are "Regional Registrations for IPv4"[7] or "Hierarchical Mobile IPv6 for IPv6"[8]. Note that the term "localized" refers to a particular area from the point of view of the IP network topology, but depending on the access technology, geographically the area can be large, as happens when applying a localized mobility approach to cellular networks.

A common feature of Mobile IP and the localized mobility proposals mentioned previously is that all of them are *host-based*. Mobile Nodes must signal themselves to the network when their location changes and must update routing states in the Home Agent, in the local Home Agent, or in both. This situation also raises the problem of complex security configurations to authenticate those signaling exchanges and modifications of routing states.

Therefore, the IETF decided to work on a solution for NetLMM[10, 11], compounding the advantages of a network-based approach with the benefits of localized mobility management strategies. In NetLMM the network provides mobility support, although the Mobile Node does not participate in IP mobility procedures. That is, network operators can provide mobility support without requiring additional software and complex security configuration in the Mobile Nodes. Thus the deployment of network-based mobility solutions is greatly facilitated. Moreover, the Mobile Node can implement any global mobility solution, because the localized one is transparent and independent from it.

There are several target scenarios for Network-Based Localized Mobility Management[9]:

- Large campus networks with *Wireless Local-Area Network* (WLAN) access: Users move with IP standard devices (that is, no additional hardware or software is required) within a campus that provides WLAN access and mobility support.
- Advanced beyond-third-generation (3G) networks: Cellular operators have been important promoters in the development of the NetLMM solution in the IETF. *Universal Mobile Telecommunications System* (UMTS) and *General Packet Radio Service* (GPRS) networks use a proprietary network-based localized mobility mechanism to provide mobility support for user data traffic (typically IP). This mechanism is based on the GPRS Tunneling Protocol[11], a special-purpose solution developed for *Third-Generation Partnership Project* (3GPP) networks that uses TCP/IP application layer tunnels. A standardized NetLMM protocol for the Internet has important advantages:
  - Reduced costs in network management and in equipment supporting the technology (because of economy of scale)
  - Easier extension of mobility support to other technologies
  - Easier integration with other networks
- Other more-complex scenarios involving network mobility, as in automotive scenarios[12], could benefit from a NetLMM approach to support mobility.

With these advantages in mind, the IETF has standardized a protocol to provide Network-Based Localized Mobility support in IP networks, the *Proxy Mobile IPv6* (PMIPv6) protocol.

Operation of Proxy Mobile IPv6

The main idea of PMIPv6 is that the mobile node is not involved in any IP layer mobility-related signaling. The Mobile Node is a conventional IP device (that is, it runs the standard protocol stack). The purpose of PMIPv6 is to provide mobility to IP devices without their involvement. This provision is achieved by relocating relevant functions for mobility management from the Mobile Node to the network.

PMIPv6 provides mobility support within a localized area, the *Localized Mobility Domain* (LMD) or PMIPv6 domain. While moving within the LMD, the Mobile Node keeps its IP address, and the network is in charge of tracking its location. PMIPv6 is based on *Mobile IPv6* (MIPv6), reusing the Home Agent concept but defining nodes in the network that must signal the changes in the location of a Mobile Node on its behalf.

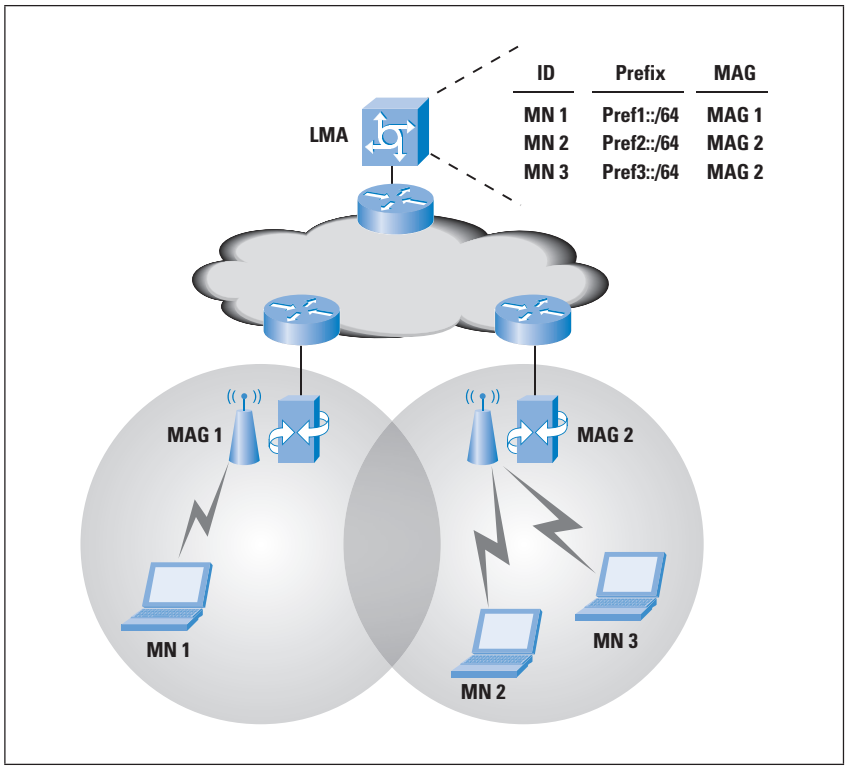

Figure 1: Network Entities in Proxy Mobile IPv6

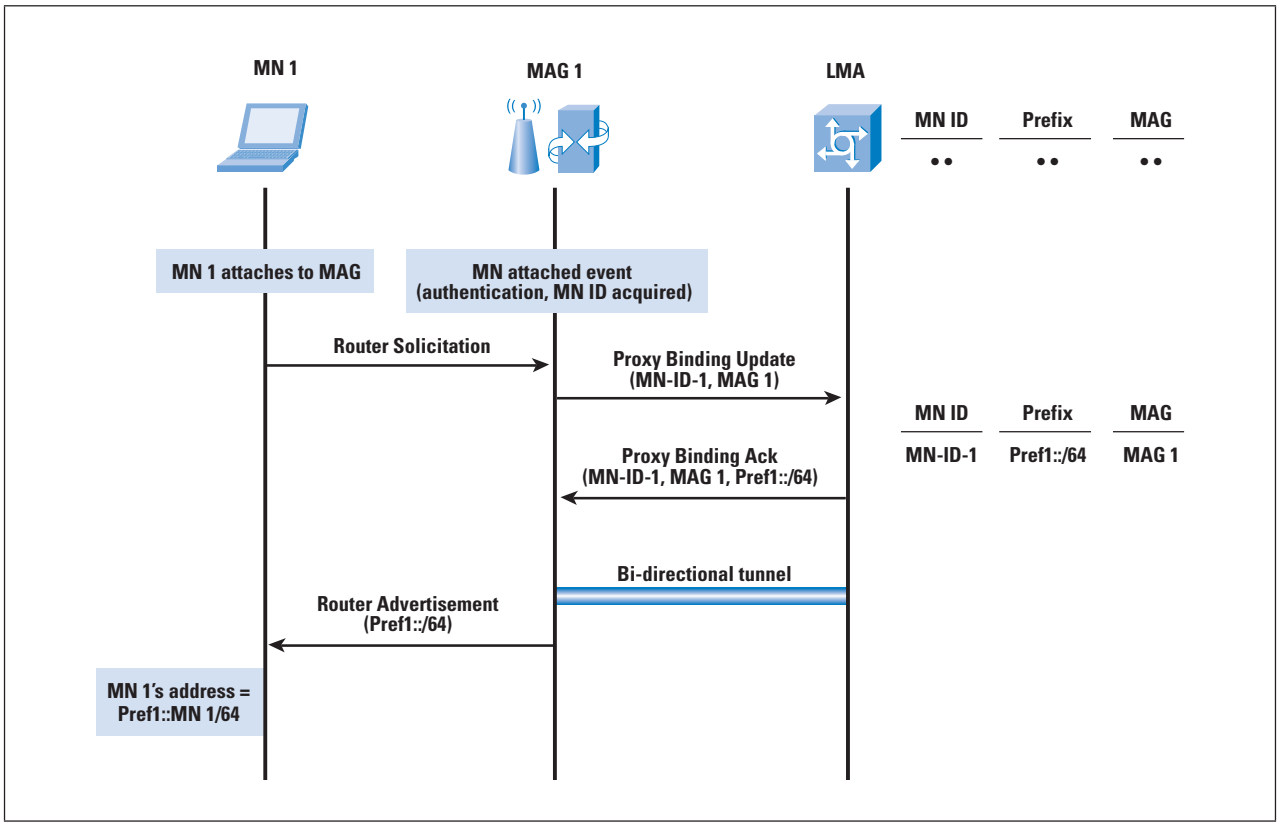
The functional entities in the PMIPv6 network architecture (refer to Figure 1) include the following:

- *Mobile Access Gateway* (MAG): This entity performs the mobility-related signaling on behalf of the Mobile Nodes attached to its access links. The MAG is usually the access router for the Mobile Node, that is, the first-hop router in the Localized Mobility Management infrastructure. It is responsible for tracking the movements of the Mobile Node in the LMD. An LMD has multiple MAGs.
- *Local Mobility Anchor* (LMA): This entity within the core network maintains a collection of routes for each Mobile Node connected to the LMD. The routes point to MAGs managing the links where the Mobile Nodes are currently located. Packets sent or received to or from the Mobile Node are routed through tunnels between the LMA and the corresponding MAG. The LMA is a topological anchor point for the addresses assigned to Mobile Nodes in the LMD, meaning that packets with those addresses as destination are routed to the LMA.

The basic operation of PMIPv6 follows. When a Mobile Node enters a PMIPv6 domain, it attaches to an access link provided by a MAG. The MAG proceeds to identify the Mobile Node, and checks if it is authorized to use the network-based mobility management service. If it is, the MAG performs mobility signaling on behalf of the Mobile Node (see in Figure 2 the signaling when the Mobile Node enters the PMIPv6 domain). The MAG sends to the LMA a *Proxy Binding Update* (PBU) associating its own address with the identity of the Mobile Node (for example, its *Media Access Control* [MAC] address or an identifier related to its authentication in the network). Upon receiving this request, the LMA allocates a prefix to the Mobile Node. Then the LMA sends to the MAG a *Proxy Binding Acknowledgment* (PBA) including the prefix allocated to the Mobile Node. It also creates a *Binding Cache* entry and establishes a bidirectional tunnel to the MAG. The MAG sends *Router Advertisement* messages to the Mobile Node, including the prefix allocated to the Mobile Node, so the Mobile Node can configure an address (stateless autoconfiguration). The Mobile Node can alternatively use stateful address autoconfiguration mechanisms. For simplicity, we assume in the rest of the article that the stateless address autoconfiguration mechanism is used, except when indicated otherwise.

Figure 2: Signaling When a Mobile Node Connects to the PMIPv6 Domain



Whenever the Mobile Node moves, the new MAG updates the location of the Mobile Node in the LMA and advertises the same prefix to the Mobile Node (through Router Advertisement messages), thereby making the IP mobility transparent to the Mobile Node. In this way the Mobile Node keeps the address configured when it first enters the LMD, even after changing its point of attachment within the network, and the LMD appears as a single link from the perspective of the Mobile Node. It should be noted that all the MAGs configure the same link local address for a specific Mobile Node. That is, the Mobile Node will never see a change in its default route configuration.

The bidirectional tunnel between the LMA and the MAG and associated routing states in both LMA and MAG manage the Mobile Node data plane. Downlink packets sent to the Mobile Node from outside of the LMD arrive to the LMA, which forwards them through the tunnel to the serving MAG. The MAG, after decapsulation, sends the packets to the Mobile Node directly through the access link. Uplink packets that originated in the Mobile Node are sent to the LMA from the MAG through the tunnel, and then are forwarded to the destination by the LMA. Traffic originated inside the LMD and directed to a Mobile Node also inside the LMD follows a similar procedure, going through two tunnels from the originating MAG, to the LMA, and then to the destination MAG. It should be noted that PMIPv6 allows a MAG to short-circuit the tunneling in case two mobile nodes directly communicate through any of its interfaces.

Protocol Details

We next describe the PMIPv6 primary functions. Because PMIPv6 is based on the Mobile IPv6 protocol format, we will highlight the differences and extensions to MIPv6. Readers interested in knowing all protocol details should refer to the RFC[1].

Entering a PMIPv6 Domain

The Mobile Node enters the PMIPv6 domain by attaching to an access link. PMIPv6 defines a new functional entity, the MAG, typically residing in the access router. The MAG detects the attachment of the Mobile Node to the access link. The only access link types supported in PMIPv6 are point-to-point links; other types of links can be used as long as they are configured to emulate point-to-point links.

The MAG, upon detecting a Mobile Node attachment, verifies if the Mobile Node is eligible to the network-based mobility management service. Specific procedures to achieve this verification are out of the scope of the PMIPv6 standard. A Mobile Node that uses the mobility support service is identified by the network entities using a *Mobile Node Identifier* (MN-ID). The MN-ID must be stable and unique for the Mobile Node throughout the PMIPv6 domain, but the exact nature of this identifier is not specified. Possible examples are the Mobile Node MAC address or an identifier obtained as part of the Mobile Node authentication procedure.

After the MAG identifies the Mobile Node, authorizes its use of the NetLMM service, and acquires its Mobile Node Identifier, the MAG sends a PBU to the LMA; that is, it sends a registration request on behalf of the Mobile Node to the LMA. The PBU message is based on the MIPv6 *Binding Update* (BU) message with some extensions, but whereas the BU is sent by the Mobile Node, the PBU is sent by the MAG on behalf of the Mobile Node. A flag in the message is used to indicate that it is a PBU and not a BU. The PBU has as source address (and also in the alternate CoA option, if present) the global address configured in the egress interface of the MAG. This address is called *Proxy-CoA* in PMIPv6 terminology and is used by the LMA as locator of the Mobile Node. In the PBU, unlike in the BU, a Home Address destination option is not present; instead a *Mobile Node Identifier Option*[13] has to be included with the Mobile Node Identifier, which is used to identify the Mobile Node throughout the PMIPv6 domain.

The PBU also contains additional information, such as the access link technology, a handoff indicator, the requested lifetime for the registration, and other optional data. The *handoff indicator* is a new mobility option defined in PMIPv6 that allows the MAG to signal the LMA whether the PBU originated upon network attachment or upon handover of a Mobile Node (if known by some unspecified mechanisms), and that information could be useful to support advanced functions such as multihoming. Examples of values of the handoff indicator include: a Mobile Node entering the PMIPv6 domain, a reregistration to update the registration lifetime, a handoff between MAGs, or a handoff between interfaces of the Mobile Node.

Upon sending the PBU, the MAG creates a Binding Update List entry[6] for the Mobile Node. Note that this data structure in Mobile IPv6 is maintained by the Mobile Node to keep track of its bindings, but consequently to the PMIPv6 philosophy, the MAG maintains a *Binding Update List* (BUL) storing the bindings of the Mobile Nodes attached to it. The information in the Binding Update List allows the MAG to link the information about the Mobile Node, the interface in the MAG to which the Mobile Node is connected, and the LMA serving it, among others.

When the LMA receives the PBU sent by the MAG, it first checks that the message is correct according to the PMIPv6 specification, rejecting the registration otherwise. If the LMA accepts the PBU, it has to verify if its *Binding Cache* contains an entry for the Mobile Node identified in the PBU. When a Mobile Node first enters the PMIPv6 domain, the LMA cannot find an entry in its Binding Cache and has to create a new one. The Binding Cache entry is an extended version of the data structure defined for the Binding Cache entries in Mobile IPv6[6].

The entry in the Binding Cache has a flag to indicate that it is a proxy registration, and it links all the information related to the Mobile Node, including its identification and the MAG serving it; that is, the location of the Mobile Node. If there is no entry for the Mobile Node in the Binding Cache (that is, the Mobile Node is entering the PMIPv6 domain), the LMA allocates one or more network prefixes to the Mobile Node. These prefixes are called *Home Network Prefixes,* and it must be noted that at least one network prefix is assigned per Mobile Node.

If the LMA cannot allocate a network prefix to a Mobile Node, it has to reject the registration. The address(es) that the Mobile Node uses while inside the PMIPv6 domain are configured from those Home Network prefixes. The decision of allocating one or more network prefixes depends on a global policy in the PMIPv6 domain or a per-Mobile Node policy. When the registration request is accepted, the LMA creates a *Binding Cache Entry* (BCE) with the accepted values for the registration, including the Mobile Node Identifier, the Proxy CoA (the address of the MAG serving the Mobile Node), and the Home Network prefix(es) allocated to the Mobile Node.

Upon BCE creation, the LMA creates an IPv6-in-IPv6 bidirectional tunnel, if one does not already exist, to the MAG sending the PBU. The LMA sets up forwarding routes through the tunnel for any traffic received that is addressed to the Home Network prefixes of the Mobile Node. Finally, the LMA creates a *Proxy Binding Acknowledgment* (PBA) and sends it to the corresponding MAG. The PBA message is based on the MIPv6 *Binding Acknowledgment* (BA) message with a few more extensions, including a flag that indicates that the message is a Proxy Binding Acknowledgement. The PBA informs the MAG about the registration request result, if it has been rejected (and why, using a status code) or accepted. The PBA contains the Mobile Node Identifier and the Home Network prefixes allocated to the Mobile Node. Unlike the Binding Acknowledgment, the PBA does not include a type 2 routing header (that in the Binding Acknowledgment includes the Home Address of the Mobile Node). Also the PBA is received and processed by the MAG, and not by the Mobile Node.

If the PBA confirms that the registration request has been accepted for the Mobile Node, the MAG creates an IPv6-in-IPv6 bidirectional tunnel, if one does not already exist, to the LMA. The MAG sets up forwarding routes, through the tunnel, for uplink or downlink packets received or sent from or to the Mobile Node. The MAG also updates the Binding Update List entry to reflect the accepted binding registration values.

Upon network attachment and during the PBU or PBA procedure, the Mobile Node can send a *Router Solicitation* in the access link as part of the standard neighbor discovery procedures. The MAG should not reply to this Router Solicitation until the registration in the LMA has been successfully completed. When the MAG receives the PBA indicating a successful registration, the MAG sends a Router Advertisement to the Mobile Node announcing the Home Network prefix(es). The Mobile Node can then apply the stateless address autoconfiguration mechanism or the stateful one (using the *Dynamic Host Configuration Protocol* [DHCP]) according to the indication in the Router Advertisement. For supporting DHCP, a DHCP relay agent has to be present in every MAG in the domain, and the relay agent must include in the link-address field of the *Relay Forward* message an IPv6 address from the Home Network prefix, to indicate to the DHCP server the range of addresses it can assign.

The PMIPv6 specification, as mentioned previously, supports only point-to-point access links with the Mobile Nodes. An interesting use case is to have a broadcast access link and to emulate point-to-point links with the Mobile Nodes to be able to apply the PMIPv6 specification. This case raises the problem of sending Router Advertisements that should be received only by the corresponding Mobile Node, and not by other Mobile Nodes present in the broadcast link. There are several ways to send these advertisements. The Router Advertisements could be sent to the IPv6 link-local address of the Mobile Node that the MAG can learn from the source address of router solicitations sent by the Mobile Node, or by some other unspecified means. Another possibility is to send Router Advertisements to the all-nodes multicast address at the IP layer but to the Link Layer 2 address of the Mobile Node.

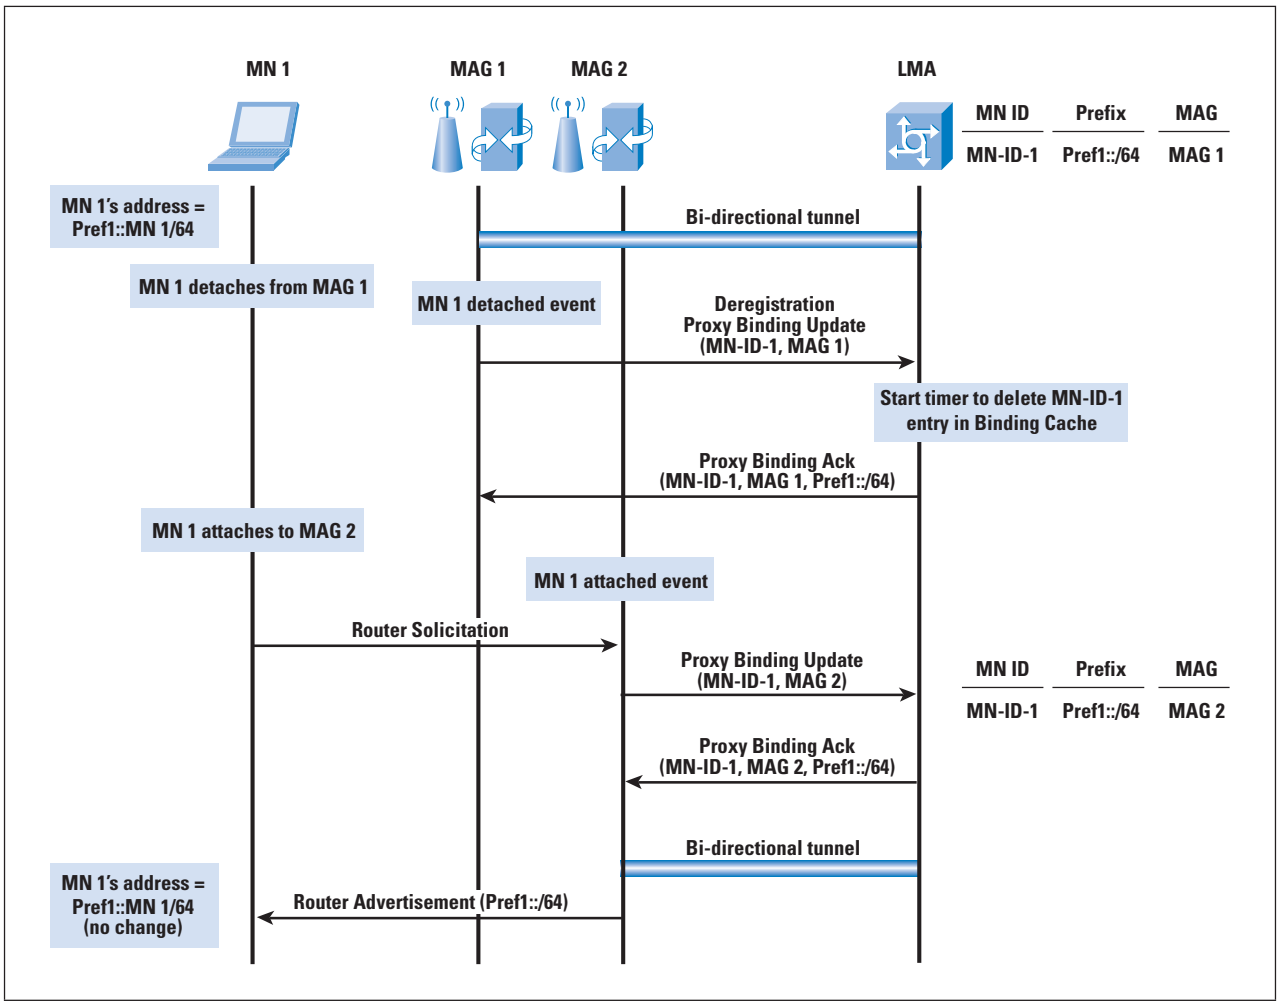
Changing MAG in a PMIPv6 Domain

The complete signaling for supporting the change of attachment by a Mobile Node in a PMIPv6 domain is described in Figure 3.

When a Mobile Node leaves a link, the event is detected by the corresponding MAG. The mechanism for Mobile Node movement detection is not specified in PMIPv6, but some possible options are link-layer events or an *IPv6 Neighbor Unreachability Detection* event. The MAG that detects that the Mobile Node has left the link must send a PBU with a Mobile Node de-registration request to the LMA. Upon receiving a PBA replying to the PBU or after a timer, the MAG deletes all the states associated with a specific Mobile Node.

When the LMA receives a PBU with a de-registration request for a Mobile Node with a valid entry in the Binding Cache, it sends the corresponding PBA and starts a timer. During the period defined by the timer the LMA drops any packets received for the Mobile Node. The use of this timer allows the LMA to receive a PBU from a new MAG updating the location of the Mobile Node. If the PBU is not received during that time, the LMA deletes the state associated with the Mobile Node.

Figure 3: Signaling When a Mobile Node Changes Point of Attachment



In a handoff situation the Mobile Node, after leaving a link, attaches to a new access link associated with a new MAG. The new MAG detects the Mobile Node and sends a PBU to the LMA on behalf of the Mobile Node. The LMA receives and processes the PBU, and detects that there is already a Binding Cache entry for that Mobile Node (the same Mobile Node Identifier). The LMA updates the Binding Cache entry with the new information, in particular with the Proxy CoA (egress IPv6 address) of the new MAG, updating also the tunnel and routing information for handling the traffic from or to the Mobile Node. The LMA sends a PBA to the new MAG in which it includes the Home Network prefix(es) already assigned to the Mobile Node. This scenario allows the new MAG to send a Router Advertisement with the same network prefix information as the Mobile Node received from the previous MAG. As stated before, the Mobile Node does not detect a link change and it keeps the same address(es). To make the change of link completely transparent to the Mobile Node, it must also continue receiving the Router Advertisements from the same link-local and link layer address; otherwise the Mobile Node would detect a change of default router. We describe how this problem is addressed in the next section.

Home Network Emulation and Address Uniqueness

MAGs must ensure that Mobile Nodes do not detect link changes when moving in a PMIPv6 domain; that is, MAGs must provide a home network emulation to the Mobile Nodes. To achieve this emulation, all the MAGs in the PMIPv6 domain must send, to a particular Mobile Node, Router Advertisements with the same network prefix information, as described previously. Additionally, the source IPv6 link-local address and the source link layer address in Router Advertisements sent to a Mobile Node must never change, independently of the MAG sending them. Therefore, the PMIPv6 specification requires all the MAGs to use, in any access link to which a particular Mobile Node attaches, the same link-local and link layer address.

PMIPv6 proposes two ways to meet this requirement:

- Configure a fixed link-local and link layer address to be used in all the access links in a PMIPv6 domain.
- Generate at the LMA the link-local address to be used by MAGs with a particular Mobile Node, and send it to the serving MAG through PMIPv6 signaling messages.

Both of these configuration methods are also helpful to guarantee address uniqueness in the access links of the PMIPv6 domain. The global addresses are always unique because all links are point-to-point and only one Mobile Node uses unicast global addresses over that link. Link-local addresses are used by the MAG and the Mobile Node on the link and a collision is possible. However, because the PMIPv6 specification requires that the link-local address used by the different MAGs with a particular Mobile Node is always the same while the Mobile Node moves across the PMIPv6 domain, the collision problem can happen only when the Mobile Node enters the PMIPv6 domain.

When a Mobile Node enters the domain, we must rely on *Duplicate Address Detection* (DAD) to detect a collision. If we use a globally unique link-local address for all the MAGs in the PMIPv6, then it is easy for the MAGs to respond to DAD requests from Mobile Nodes, because MAGs always know the address they must defend. If the link-local address to be used by the MAG with a Mobile Node is generated in the LMA, then it is desirable that the MAG learns that link-local address (that is, completes the PMIPv6 registration procedure) to defend it before the Mobile Node carries out the DAD procedure. You can ensure the MAG can learn this address by ensuring that the Layer 2 attachment is not completed until finishing the PMIPv6 signaling registration, or by configuring the PMIPv6 registration procedure in such a way that it is likely to be completed before the default waiting time of a DAD procedure.

Security Considerations

As with Mobile IPv6 signaling, PMIPv6 signaling is very sensitive to security threats, because it changes routing states of nodes in the network on behalf of the Mobile Nodes. PMIPv6 specification recommends using *IP Security* (IPsec) to protect the signaling exchanges between the MAGs and the LMA. A security association is needed between MAGs and the LMA, but how it is created is not defined. Two cases are possible:

- The network elements (LMA and MAGs) belong to the same operator.
- The elements belong to different operators with an agreement for roaming support.

In both scenarios, creating the security association is an affordable problem.

Traffic Handling in a PMIPv6 Domain

Traffic sent to any address belonging to a Home Network prefix is received by the LMA, the anchor point for those addresses. The LMA forwards the traffic through the tunnel to the MAG serving the Mobile Node, and the MAG decapsulates the packets and forwards them to the Mobile Node through the access link. Packets sent by the Mobile Node are forwarded by the MAG through the tunnel to the LMA. The LMA decapsulates the packets and forwards them to the destination. If a MAG has data traffic that originated in one of its access links and is destined to another of its access links, it can forward the traffic locally to avoid the forwarding through the LMA. This forwarding is done according to a policy configured in the MAG.

Performance Considerations

PMIPv6 presents two performance advantages compared with MIPv6. First, the LMA is a local network entity, so in principle the delay of sending signaling to the LMA will be lower than sending signaling to a remote Home Agent. And second, because the tunnel required to handle the traffic is terminated in the MAG instead of in the Mobile Node (as happens in MIPv6), we avoid the overhead of having a tunnel (two IP headers) over the radio interface. This overhead avoidance is relevant because bandwidth resources are scarcer over the air interface than in the backhaul network.

IPv4 Support Considerations

PMIPv6 acknowledges the existence of a dual-stack mobile host. To this end there are ongoing efforts to standardize IPv4 support for PMIPv6 operations. The extensions defined in [14] specify how to assign an IPv4 Home Address to a mobile host accessing the PMIPv6 domain. That is, the MAG—upon Mobile Node detection attachment and verification that the Mobile Node is eligible for PMIPv6 service—inserts in the PBU an "IPv4 Home Address Request Option."

The LMA, upon reception of the PBU message, assigns an IPv6 *Home Network Prefix* (HNP) or an IPv4 Home Address by attaching an "IPv4 Home Address Reply Option" to the PBA. How the information is delivered to the Mobile Node depends on the interface between the Mobile Node and the MAG, possible examples being DHCP or *Internet Key Exchange Version 2* (IKEv2). The Mobile Node—independent of the method deployed—configures the HNP and the IPv4 Home address assigned by the LMA, thus supporting both IPv4- and IPv6-based applications.

Conclusions

PMIPv6 is a promising specification that allows network operators to provide localized mobility support without relying on mobility functions or configuration present in the mobile nodes. This reality greatly eases the deployment of the solution.

The IETF is currently working in the *Network-Based Mobility Extensions* (netext) Working Group on extending the PMIPv6 specification to add functions such as enhanced multihoming and intertechnology handoff support, and localized routing for traffic between MAGs to avoid going through the LMA. Additionally, the *Multicast Mobility* (multimob) Working Group is working on the support of multicast in PMIPv6.

Improving User Experiences with IPv6 and SCTP

by Dan Wing and Andrew Yourtchenko, Cisco Systems

To be successful, new technologies must improve the user experience. In the process of finding the best way to deploy a new technology, several approaches are typically conceived, written down, tried, and possibly discarded. This article addresses two such approaches for *Internet Protocol Version 6* (IPv6) and the *Stream Control Transmission Protocol* (SCTP)[10].

Modern web browsers, web servers, and operating systems support IPv4 and IPv6, and several major content providers already support IPv6, including Google, NetFlix, and Facebook. However, their properties are not generally available over IPv6 because of a conflict between IPv6 technology and their business realities.

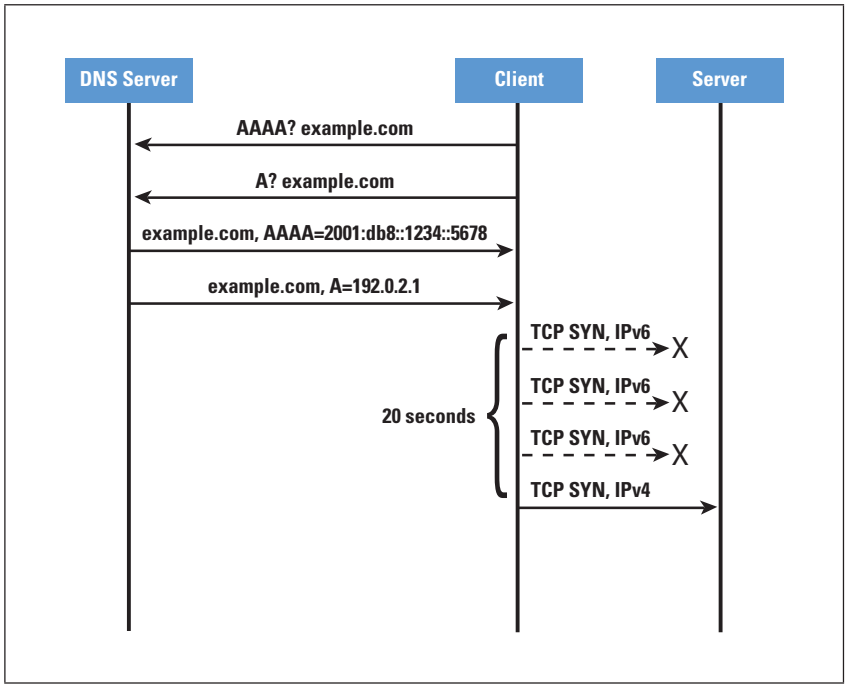
The technology in web browsers and operating systems involves doing *Domain Name System* (DNS) queries for *AAAA* and *A* resource records and then attempting to connect to the resulting IPv6 and IPv4 addresses *sequentially*. If the IPv6 path is broken (or slow), this connection can take a long time before it falls back to trying IPv4. This process is especially painful on typical websites that retrieve objects from different hosts—each failure incurs a delay. The combination of operating system and web browser results in delays from 20 seconds to several minutes if the IPv6 path is broken[2]. The typical message flow of a TCP client is shown in Figure 1. Clearly, this delay is unacceptable to users. Users avoid this delay by disabling IPv6[3] or avoiding IPv6-enabled websites.

The problem of broken IPv6 networks is relatively widespread[6]. Providing content is a business—either directly (for example, streaming movies) or indirectly (for example, selling advertising). If users suffer delays viewing IPv6-enabled content (because of the technology reasons described previously), they will have an incentive to visit other websites. This scenario means lost revenue and is unacceptable to the business. Considering that all of the customers on today's Internet can reach IPv4 content, it is a business risk to enable IPv6 because some customers will suffer delays attempting to view IPv6 websites. Major content providers have been monitoring the situation and have published results[7] showing that the IPv6 failure rate is too high to enable IPv6 *AAAA* for their content.

IPv6 problems have several causes. It is new technology, and monitoring of IPv6 connectivity is not yet on par with that of IPv4 because of single-point tunnels, unmanaged tunnels[11], accidentally misconfigured firewalls, and router and link failures can more easily cause outages on IPv6. Many applications remain IPv4-only, or network administrators are relying on dual-stack equipment to transparently fail over to IPv4 during IPv6 outages.

However, such failover is never transparent to users—it takes many seconds or minutes! To avoid these problems, the content provider has only one choice: don't provide *AAAA* records if users might experience broken or slow IPv6.

Figure 1: Behavior of a Typical Web Browser



To work around that problem, Google implements a white list of DNS servers that it will provide *AAAA* records for[8]. However, in its current incarnation, DNS white listing does not scale well because the *Internet Service Provider* (ISP) has to prove good IPv6 connectivity to Google, and then Google white lists the ISP's DNS servers to receive the *AAAA* records. The scaling problem is that there are thousands of ISPs around the world, and white listing and de-white listing them becomes a tiresome manual task for both ISPs and Google. Furthermore, if every content provider did DNS white listing, ISPs would have to work with several content providers in order to give value to the IPv6 network they have deployed to their subscribers! Content providers have started working together to consolidate requirements for DNS white listing and operate some sort of DNS white-listing service to slightly automate this process[5].

Yet, DNS white listing still does not guarantee a working IPv6 network or a fast IPv6 network, because there is not a direct relationship between good IPv6 connectivity and the DNS server of a user's ISP. Even with the best of intentions and network design, there will still be instances where an IPv6 path or IPv4 path is working when the other path is broken. The result will be excessive delays for IPv4-only clients or dual-stack clients, depending on what sort of breakage occurs.

This situation contributes to the user perception that the Internet, or the particular website being accessed, is "down." The user will visit a different site instead, possibly never returning to the site that was "down."

Happy Eyeballs

A different approach solves these problems. In this approach, rather than an application slowly trying to make a connection on IPv6 and then on IPv4, the application makes its connection attempts more aggressively over both IPv6 and IPv4. Initially, the connection attempts are made *simultaneously* (rather than serialized), in order to provide a fast user experience.

The simultaneous connection attempts consume a little extra network bandwidth and twice the connection attempts on the server. To reduce that chatter, a cache is also maintained to store the success or failure of connecting using IPv6 or IPv4. We nickname this approach "Happy Eyeballs"[1], because the "eyeballs" (users) are happier—their computer provides them immediate content, even if the network is suffering slow performance on IPv6 or IPv4 (Figure 2).

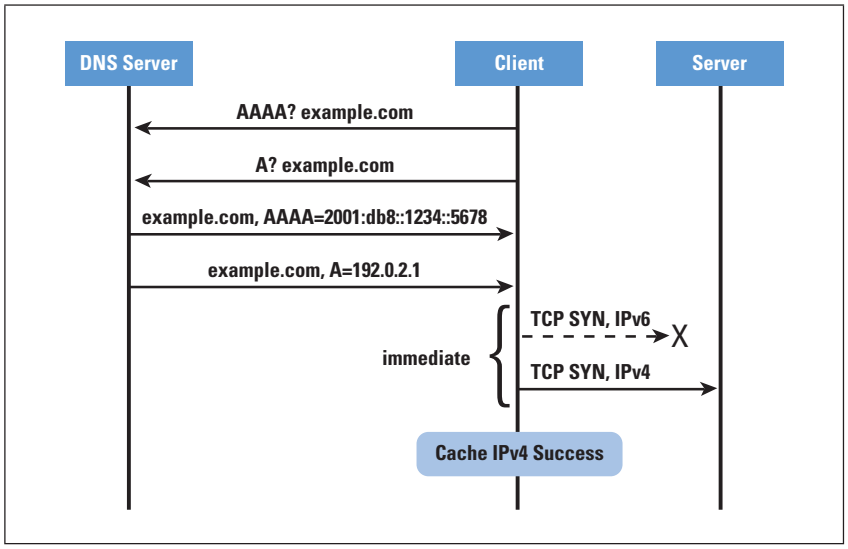


Figure 2: Dual-Stack Web Browser Implementing Happy Eyeballs

Obviously, sending a TCP SYN on both IPv6 and IPv4 doubles the number of connection attempts sent by the client. As discussed in [1], this chatter can be reduced by the application remembering if IPv6 (or IPv4) was successful in the previous connection attempt, and using that information for subsequent connection attempts. The sophistication of this cache is dependent on the memory (or disk) available, but even simple caching can be quite effective. When connecting to a new network (*third generation* [3G], different Wi-Fi network, or physical Ethernet), the connectivity of that new network can be determined and the cache of success or failure entirely or partially flushed, as necessary.

Thus, the doubling of connection attempts occurs only when connecting to a new network. Thereafter, initial connection attempts are delayed so that IPv6 (or IPv4) is tried first. But in all cases, significant user-noticeable delays are avoided when the IPv6 (or IPv4) is broken. The goal of Happy Eyeballs is to keep IPv6 enabled; that is, to make users unaware of IPv6 outages, so the user still visits IPv6-enabled websites without suffering any delay.

In this way, the user experiences a smooth migration from IPv4 to IPv6, and when necessary the fallback to IPv4 is almost immediate. This solution represents a significant improvement over today's web browsers. A drawback of this idea, however, is that it needs to be implemented in the application itself. Although it is a burden to upgrade those web browsers, there are only five major browsers[9], and the browsers receive the immediate benefit of the aggressive probing. Browsers are also commonly upgraded already for faster *JavaScript* engines and other new features.

Another idea to determine if IPv6 is working is to *ping* or send another simple request to an IPv6 resource on the Internet, and disable IPv6 on the host if that IPv6 request fails. This approach interferes with IPv6 traffic within the enterprise (which may be working fine, whereas IPv6 to the Internet is broken), and disabling IPv6 would break IPv6 features deployed in OSs (for example, *DirectAccess* in Windows or *Back to My Mac* in Mac OS X). An advantage of this approach is that if IPv6 is disabled, no application suffers the IPv6 outage and associated delay to fall back to IPv4.

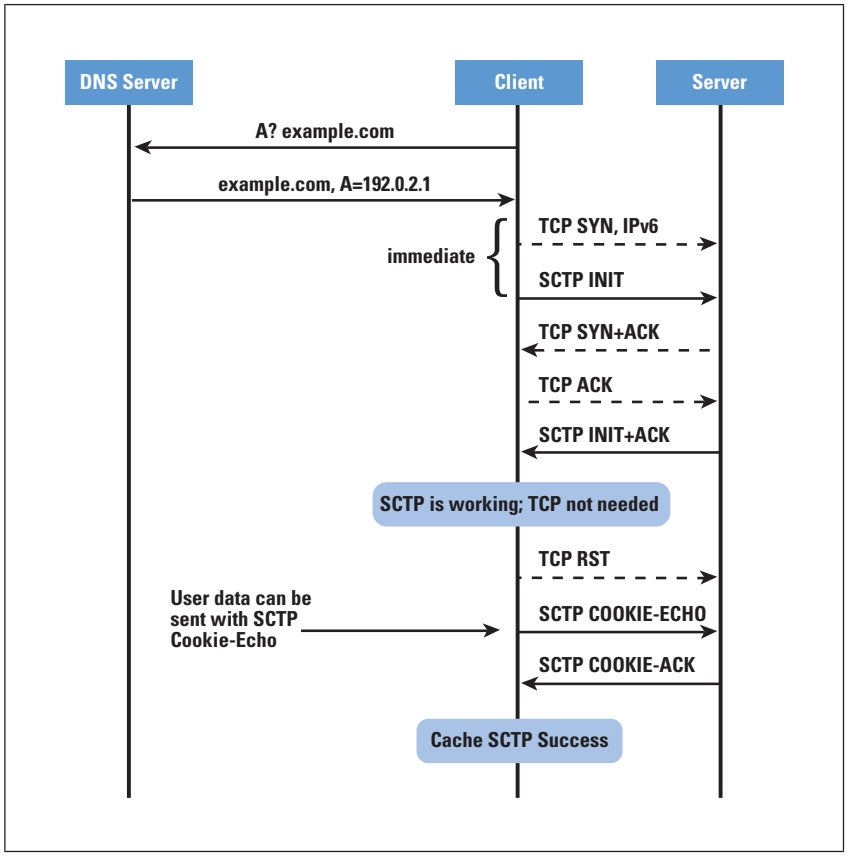
New Transport: SCTP

Besides the problem of network layer protocol selection, a similar task can be performed at the transport layer. Maybe surprisingly, one more transport protocol exists besides TCP, namely *Stream Control Transmission Protocol* (SCTP). SCTP provides significant advantages over TCP, and it was designed with some of the lessons learned by TCP implementations and deployment[4] in mind.

Unlike IPv6 and IPv4, which have different DNS resource records (*AAAA* and *A*), we don't have a resource record to indicate that an application could, or should, use a different transport protocol. But even if we could indicate support for SCTP in DNS, the path might block it, reducing the usefulness of a DNS resource record. The path could be blocked by a NAT or firewall that expects only TCP or *User Datagram Protocol* (UDP).

Happy Eyeballs also describes a technique where a client can simultaneously try connecting using both TCP and SCTP. By necessity, this attempt is done entirely in the application, and the application would prefer the transport that responded faster and cache that information to reduce network chatter for subsequent connections to that server. This scenario is shown in Figure 3.

Figure 3: Client Implementing Happy Eyeballs for TCP/SCTP Selection



By combining the IPv6/IPv4 technique with the SCTP/TCP technique, a web browser running on a computer connected to a new dual-stack network sends four packets—an IPv4 TCP SYN, an IPv6 TCP SYN, an IPv4 SCTP INIT, and an IPv6 SCTP INIT. Based on the responses, it decides which transport protocol and which address family (IPv6 or IPv4) it prefers, and abandons the other connections. As described previously, connection information is cached for subsequent use to avoid consuming network bandwidth and server resources for subsequent network connections.

Conclusion

New technology aimed at improving user experience will be successful only if it meets expectations—an improved user experience. Because many companies are deriving all of their revenue from the Internet, any reduction in service means a loss of revenue. Thus, deploying new technology must not negatively affect the user experience. This article described one of the mechanisms that implementers can use to avoid negative effects on the user experience.

Letter to the Editor

In response to "NAT++: Address Sharing in IPv4," in *The Internet Protocol Journal,* Volume 13, No. 2, June 2010:

Excellent article Geoff, so good I read it twice. While reading your article I was reminded of a recent experience that falls in the category of "unintended consequences." Since one of your situation descriptions was similar to the one I'm in, I thought I would relay my circumstance and experience and see if I can make my point.

A couple of months ago I signed up for an IPTV trial with my provider, and it was installed with a minimum of effort. The service is based on Cisco *Dial-on-Demand Routing* (DDR) and, of course, DSL service.

It worked fine for a couple of days; video feeds were good and all my computers and server worked just as before on a wireless network within my home. Then one day it appeared that I had lost *Domain Name System* (DNS) service, because I couldn't get name resolution to work but could route using the raw IPv4 addresses. So, I placed a trouble ticket and, of course, the provider's first request was to cold boot the DDR device and everything in the house, which I did. Sure enough, upon bringing all components back up (except one), everything was fine.

A day or two later I had to print something and powered on my HP 6510 wireless printer, printed what I needed to print, and then discovered I had lost DNS service again. I placed a trouble call and my provider came out and replaced the DDR device I went through the cold boot process (except one device) and everything was OK until I brought the printer online and the trouble returned. By now I had this nagging memory that wouldn't surface; something about that printer... With the printer powered off I rebooted the DDR, fired up SharkWire, and everything looked and worked OK.

Then I powered up the HP printer and saw another nagging memory; it immediately performed an *Address Resolution Protocol* (ARP) broadcast of the v4 address `169.254.65.206`—the famous black-hole address from RFC 3927[1]. Immediately after the ARP broadcast, the printer put out the normal *Dynamic Host Configuration Protocol* (DHCP) request and was assigned one from the *Network Address Translation* (NAT) pool.

That's when I stepped back from looking at the "trees" and gazed upon the "forest" and realized, with some embarrassment, that the public side (access side) was using a single IPv4 address with *Port Address Translation* (PAT) so the DDR box was blocking all the outbound PAT addresses attached to the single IPv4 address. I wrote down the details and e-mailed them to my provider, and had revised code pushed to the DDR the next day. Problem fixed.

All of this discussion leads me to ponder about other situations of "hard codes" in the network, either RFC-based or circumstance-based, that will falter with a switch to IPv6. Not in the core but in the customer networks. These unintended consequences could be many. Does HP run a dual stack for IPv4 and IPv6? I doubt it.

How can we get customers and vendors thinking about possible long-ago workarounds that they may have hard coded using IPv4? Any other RFCs out there like 3927? (It used to be easy when there were only a few hundred RFCs.) That could be the most expensive portion of the transition, verifying code ...

Keep up the good work; your articles make me think a lot and I really enjoy them. And, yes, I do use them for reference quite often.

Regards,

—Paul Dover
pdover@centeriem.com

[1] S. Cheshire, B. Aboba, and E. Guttman, "Dynamic Configuration of IPv4 Link-Local Addresses," RFC 3927, May 2005.

The author responds:

Thank you Paul for this anecdote and the important lesson behind it. Over some 30 years of intense development we've managed to accumulate a sizeable volume of technical specifications. Indeed, in October 2010 the RFC Editor published RFC 6068, and I'm not sure that any individual could claim a deep familiarity with every one of them, let alone claim to have a good understanding of their potential interaction. So when we look at various transitional technologies to sustain this industry through the next few years of attempting to support a comprehensive dual stack network in the face of the forthcoming hiatus of supply of IPv4 addresses, it should not come as a surprise when some devices or configurations fail in strange and unexpected ways, simply because they adhere to a technical standard that perhaps we've lost sight of in the flurry of generating new transitional technologies.

Dr. Jianping Wu Receives Postel Award

The *Internet Society* (ISOC) recently awarded its prestigious *Jonathan B. Postel Service Award* for 2010 to leading Chinese technologist Dr. Jianping Wu for the pioneering role he has played in advancing Internet technology, deployment, and education in China and Asia Pacific over the last twenty years.

Dr. Wu's best-known contribution is the development of the *China Education and Research Network* (CERNET) which he designed and developed to be the first Internet backbone network in China. Created to establish a nation-wide advanced network infrastructure to support education and research among universities, CERNET has since become the world's largest national academic network. Since 1998, Dr. Wu has also devoted his time to the design and development of a large-scale native IPv6 backbone in China that now serves to connect over 200 universities and millions of users.

The Postel Award was established by the ISOC to honour individuals or organisations that, like Jon Postel, have made outstanding contributions in service to the data communications community. Commenting on its presentation to Dr. Wu, Lynn St. Amour, President and CEO of ISOC said: "Jianping Wu has dedicated his career in China to developing a broadly accessible Internet that brings people together. Twenty years ago, Dr. Wu recognized the importance and future impact of the Internet and the pivotal role it would play in terms of its impact on social reform, technology advancement and economic growth for China. He has worked tirelessly to bring his vision to life. As a result, the networks that resulted from his determination and hard work have played an important role in driving Internet development in China and have had a significant impact on the Internet worldwide."

ISOC presented the award, including a US$20,000 honorarium and a crystal engraved globe, during the 78th meeting of the *Internet Engineering Task Force* (IETF) in Maastricht, The Netherlands 25–30 July 2010.

DNSSEC Deployed in the Root Zone

On July 16, 2010 the U.S. Department of Commerce's *National Telecommunications and Information Administration* (NTIA) and the *National Institute of Standards and Technology* (NIST) announced the completion of an initiative with the *Internet Corporation for Assigned Names and Numbers* (ICANN) and VeriSign to enhance the security and stability of the Internet.

The announcement marks full deployment of a security technology—*Domain Name System Security Extensions* (DNSSEC)[1]—at the Internet's authoritative root zone, which will help protect Internet users against cache poisoning and other related cyber attacks.

"The Internet plays an increasingly vital role in daily life, from helping businesses expand to improving education and health care," said Assistant Secretary for Communications and Information and NTIA Administrator Lawrence E. Strickling. "The growth of the Internet is due in part to the trust of its users—trust, for example, that when they type a website address, they will be directed to their intended website. Today's action will help preserve that trust. It is an important milestone in the ongoing effort to increase Internet security and build a safer online environment for users."

"Improving the trustworthiness, robustness and scaling of the Internet's core infrastructure is an activity that lines up strongly with NIST's mission, and we have been contributing to design, standardization and deployment of DNSSEC technology for several years," said NIST Director Patrick Gallagher. "The deployment of DNSSEC at the root zone is the linchpin to facilitating its deployment throughout the world and enabling the current domain-name system to evolve into a significant new trust infrastructure for the Internet."

The *Domain Name System* (DNS) is a critical component of the Internet infrastructure. The DNS associates user-friendly domain names (for example, `www.commerce.gov`) with the numeric network addresses (for example, `170.110.225.168`) required to deliver information on the Internet, making the Internet easier for the public to navigate. The authenticity of the DNS data is essential to Internet use. For example, it is vital that users reach their intended destinations on the Internet and are not unknowingly redirected to bogus and malicious websites.

The DNS was not originally designed with strong security mechanisms, and technological advances have made it easier to exploit vulnerabilities in the DNS protocol that put the integrity of DNS data at risk. Many of these vulnerabilities are mitigated by the deployment of DNSSEC, which is a suite of *Internet Engineering Task Force* (IETF) specifications for securing information provided by the DNS.

A main goal of this action—DNSSEC deployment at the root zone—is to facilitate greater DNSSEC deployment throughout the rest of the global DNS hierarchy. While deployment of DNSSEC will protect Internet users from certain DNS-related cyber attacks, users must continue to exercise vigilance in protecting their information online.

ISOC Embraces DNSSEC

The *Internet Society* (ISOC) recently announced that it has deployed DNSSEC, a set of extensions to the DNS that provides a level of assurance, for its `isoc.org` domain. The announcement builds on an announcement by the *Public Interest Registry* (PIR) that they have implemented DNSSEC for the entire `.org` top-level domain.

"We are pleased to be among the first organisations in the `.org` top level domain to deploy DNSSEC, as DNSSEC provides an important building block for increasing user confidence in the Internet," said Lynn St.Amour, President and CEO of the Internet Society. "Implementing DNSSEC for the `.org` top-level domain is an important step in ensuring the global Internet serves as a trusted channel for communication and collaboration and we applaud the PIR's efforts in this area."

"DNSSEC acts like tamper-proof packaging to make sure that when you type in the website name of your bank you actually get the server IP address your bank wants you to use," said Leslie Daigle, Chief Internet Technology Officer of ISOC. "In this way, DNSSEC allows us to have more confidence in the online activities that are increasingly becoming a part of our lives at work, home, and school."

DNSSEC technology used today is the result of careful protocol engineering and standardization within the IETF; implementation by various DNS vendors; and operational trials by DNS operators. In addition to `.org`, DNSSEC is currently implemented by several country-specific top-level domains: Brazil (`.br`), Bulgaria (`.bg`), The Czech Republic (`.cz`), Puerto Rico (`.pr`), and Sweden (`.se`).

ISOC is a non-profit organisation founded in 1992 to provide leadership in Internet related standards, education, and policy. ISOC is the organisational home of the IETF. With offices in Washington, D.C., and Geneva, Switzerland, it is dedicated to ensuring the open development, evolution, and use of the Internet for the benefit of people throughout the world. For more information see: `http://isoc.org`

DNSSEC Fund Announced

In order to speed up the process of introduction a more secure global DNS infrastructure, the Netherlands-based charity *NLnet Foundation* has announced the creation of a global fund where open source projects can apply for grants to work on *Domain Name System Security Extensions* (DNSSEC) in their Internet applications.

DNSSEC is one of the key technologies for a safer Internet, as it allows the Internet user to know for sure that he or she is being sent to the right computer or service on the Internet. "If you type the name of your bank into a browser, you want to be sure that you are actually directed to a computer of that bank," said Michiel Leenaars, Director of Strategy at NLnet foundation. "Domain names are vital to the way we use the Internet, and without DNSSEC users are open to serious abuse."

DNSSEC provides a cryptographic seal of authenticity that gives real proof of the validity of the domain name you use when you visit a website, chat or send an e-mail. With DNSSEC you get a *chain of trust* from the root of the Internet to the service you want to connect to—opening the way for many new exciting opportunities for humans and computers to exchange information safely. DNSSEC is being gradually introduced worldwide.

The new fund will provide grants for reengineering important software to reliably work with DNSSEC. "The signing of the root through DNSSEC is a historical moment, but in a way it is only the beginning," said Leslie Daigle, Chief Internet Technology Office at the Internet Society. "Actual users will not fully benefit from protection in the more challenging situations as long as DNSSEC does not reach them." A great deal of work has already been done at the infrastructure level—most DNS servers such as *BIND, NSD* and *Unbound* now support the new technology. However, it will take a lot of work at the user level as well: operating systems, web browsers, e-mail servers, VoIP clients, and many other pieces of software need to be able to reliably work with DNSSEC.

"Every Internet user deserves to be protected by DNSSEC, yet currently almost no end user software is ready to take full advantage of the availability of DNSSEC," said Leenaars. "The IT community has a big responsibility in making sure that DNSSEC gets deployed across the board swiftly. We aim to accelerate the process significantly by putting some money on the table, and we invite other stakeholders to join us."

Since there are many applications and platforms that will require work, the NLnet Foundation is very open to cooperation with others as well as to targeted donations from interested stakeholders such as governments, registries and corporations.

The NLnet Foundation is a registered Netherlands charity with a long history of supporting Internet standardization. The foundation gained its capital from selling the first Dutch Internet Service Provider.

Potential applicants and collaborators can find more information at: **http://nlnet.nl/dnssec**

Call for Papers: Internet Privacy Workshop

The *Internet Architecture Board* (IAB), *World Wide Web Consortium* (W3C), *Internet Society* (ISOC) and the *Massachusetts Institute of Technology* (MIT) will hold a joint *Internet Privacy Workshop* on December 8 and 9, 2010 at MIT, Cambridge, Massachusetts on the question:

"How Can Technology Help to Improve Privacy on the Internet?"

Information about who we are, what we own, what we have experienced, how we behave, where we are located, and how we can be reached are among the most personal pieces of information about us. This information is increasingly being made more easily available electronically via the Internet, often without the consent of the subject. The question for the workshop therefore is: How can we ensure that architectures and technologies for the Internet, including the World Wide Web, are developed in ways that respects users' intentions about their privacy?

This workshop aims to explore the experience and approaches taken by developers of Internet including Web technology, when designing privacy into these protocols and architectures. Engineers know that many design considerations need to be taken into account when developing solutions. Balancing between the conflicting goals of openness, privacy, economics, and security is often difficult, as illustrated by Clark, et al. in "Tussle in Cyberspace: Defining Tomorrow's Internet," see:

http://groups.csail.mit.edu/ana/Publications/PubPDFs/Tussle2002.pdf

As a member of the technical community, we invite you to share your experiences by participating in this important workshop. Workshop participants will focus on the core privacy challenges, the approaches taken to deal with them, and the status of the work in the field. The objective is to draw a relationship with other application areas and other privacy work in an effort to discuss how specific approaches can be generalized.

Interested parties must submit a brief contribution describing their work or approach as it relates to the workshop theme. We welcome visionary ideas for how to tackle Internet privacy problems, as well as write-ups of existing concepts, deployed technologies, and lessons-learned from successful or failed attempts at deploying privacy technologies. Contributions are not required to be original in content.

Submitters of accepted position papers will be invited to the workshop. The workshop will be structured as a series of working sessions, punctuated by invited speakers, who will present relevant background information or controversial ideas that will motivate participants to reach a deeper understanding of the subject.

The organizing committee may ask submitters of particularly topical papers to present their ideas and experiences to the workshop. We will publish submitted position papers and slides together with a summary report of the workshop. There are no plans for any remote participation in this workshop.

To be invited to the workshop, please submit position papers to **privacy@iab.org** by November 5, 2010. More detailed information about the workshop, including further details about the position paper requirements, is available at:

http://www.iab.org/about/workshops/privacy/

We look forward to your input,

Bernard Aboba (IAB)
Daniel Appelquist (W3C)
Jon Peterson (IAB)
Karen Sollins (MIT)
Trent Adams (ISOC)
Karen O'Donoghue (ISOC)
Thomas Roessler (W3C)
Hannes Tschofenig (IAB)

Organizations Urged to Stop Delaying IPv6 Deployment

The *Number Resource Organization* (NRO), the official representative of the five *Regional Internet Registries* (RIRs) that oversee the allocation of all Internet number resources, recently unveiled the findings of a global, independent survey into organizations' IPv6 readiness. Funded by the European Commission and conducted by GNKS Consult and TNO, the study reveals that the majority of organizations are taking steps toward IPv6 deployment, as the IPv4 address pool continues to deplete rapidly.

IP addresses are critical for the operation of the Internet. Every Internet-enabled device needs an IP address to connect to the rest of the network. The biggest threat facing the Internet today is that less than 6% of the current form of IP addresses, IPv4, remains and the pool is likely to be completely depleted next year. This means that organizations need to adopt IPv6, the next-generation addressing protocol. There is a far larger pool of IPv6 addresses, allowing for more devices to connect to the Internet and helping to safeguard the sustainable growth of the Internet.

The survey, which polled over 1,500 organizations from 140 countries, highlights that organizations are increasingly aware of the need to deploy IPv6: approximately 84% already have IPv6 addresses or have considered requesting them from the RIRs. Only 16% of respondents have no plans to deploy IPv6 addresses.

The study also demonstrates that there are some misconceptions around the cost of adopting IPv6. Over half of all respondents noted that the cost of deployment was a major barrier for IPv6 adoption. While organizations might delay investing in IPv6, this may ultimately result in greater costs, with last-minute deployment and poor planning likely to increase the investment required.

Of the 84% of respondents that have requested IPv6 addresses or have considered doing so, three-quarters reported the need to stay ahead of competition as the main reason for IPv6 adoption. Half of these respondents also noted that a lack of available IPv4 space was a major driver for deployment. When asked about issues they had encountered when deploying IPv6:

- 60% cited the lack of vendor support as a major barrier for deployment. However, most of the latest hardware and software support IPv6. The RIRs are strongly urging organizations to check with their suppliers to ensure that the technologies they use are IPv6 compatible.
- 45% reported a struggle to find knowledgeable technical staff to support deployment. However, all five RIRs arrange technical training to facilitate an efficient IPv6 deployment, details of which can be accessed via the NRO website.

Fifty-eight percent of all organizations polled were ISPs. It is likely that respondents to this survey are further ahead in IPv6 deployment than ISPs overall, but all organizations should ensure that their ISP offers or plans to offer services over IPv6. Out of the polled ISPs:

- Approximately 60% already offer, or plan to offer within the next year, IPv6 to consumers.
- 70% already offer, or plan to offer within the next year, IPv6 to businesses.
- Only about 10% of polled ISPs have no plans to offer IPv6 to consumers or businesses.

Axel Pawlik, Chairman of the NRO, commented: "It's great to see that as we move toward complete IPv4 exhaustion, more organizations worldwide are waking up to the need to adopt IPv6 and are sourcing IPv6 addresses from the RIRs."

"Yet there is still a distinct lack of Internet traffic over the next addressing protocol, with not enough ISPs offering IPv6 services and 30% of ISPs saying the proportion of this traffic is less than 0.5%. It's critical that ISPs now take the next step in the global adoption effort by offering IPv6 services to their customers to help boost traffic over IPv6."

Per Blixt, Head of Unit in the Information Society and Medias at the European Commission, said:

"It's encouraging to see that so many organizations have made IPv6 adoption their priority. Still, as the Internet becomes increasingly important for global socio-economic development, it's critical that those who are still sitting on the fence act now on IPv6. Only by ensuring that all organizations adopt IPv6 can we ensure the sustainable growth of the digital economy worldwide."

This survey is a follow-up to a study conducted in 2009 amongst organizations in Europe, Middle East and parts of Central Asia, as well as Asia Pacific; however this year's survey polled organizations worldwide. The full research report is available at:

http://www.nro.net/documents/GlobalIPv6SurveySummaryv2.pdf

The NRO exists to protect the pool of unallocated Internet numbers (IP addresses and AS numbers) and serves as a coordinating mechanism for the five RIRs to act collectively on matters relating to the interests of RIRs. For further information, visit **http://www.nro.net**

The RIRs are independent, not-for-profit membership organizations that support the infrastructure of the Internet through technical coordination. There are five RIRs in the world today. Currently, the *Internet Assigned Numbers Association* (IANA) allocates blocks of IP addresses and ASNs, known collectively as *Internet Number Resources,* to the RIRs, who then distribute them to their members within their own specific service regions. RIR members include *Internet Service Providers* (ISPs), telecommunications organizations, large corporations, governments, academic institutions, and industry stakeholders, including end users

The RIR model of open, transparent participation has proven successful at responding to the rapidly changing Internet environment. Each RIR holds one to two open meetings per year, as well as facilitating online discussion by the community, to allow the open exchange of ideas from the technical community, the business sector, civil society, and government regulators. Each RIR performs a range of critical functions including: The reliable and stable allocation of Internet number resources (IPv4, IPv6 and *Autonymous System Number* resources); The responsible storage and maintenance of this registration data; The provision of an open, publicly accessible database where this data can be accessed. RIRs also provide a range of technical and coordination services for the Internet community. The five RIRs are:

From The Editor

I have recently started using both a smartphone and a tablet device for Internet access. Like millions of other Internet users, I have discovered the wonders of mobile applications that provide everything from the traditional Internet services (e-mail and web browsing) to specialized software that can pinpoint my location on a map, provide live currency-exchange calculations, give weather forecasts, and my favorite: play radio stations from all over the world. I am old enough to remember the orange glow from pre-transistor vacuum-tube radios, so having a customizable "world radio" in the form of an "app" on a smartphone seems almost like science fiction.

But radio is not the only traditional service that is now available over the Internet. Another prominent example is telephony or *Voice over IP* (VoIP). Not only is VoIP replacing traditional land lines in many places, the original circuit-switched telephone network is itself increasingly using VoIP technology in place of an infrastructure of land lines and dedicated switching equipment. An important aspect of traditional phone service is the notion of special numbers for *emergency services*. Such systems rely on a database of phone numbers and addresses that allow emergency personnel to dispatch responders to the correct location. This location identification becomes a lot more complicated if the caller is using an Internet-based calling service rather than a hard-wired telephone. The IETF has been tackling this problem in the *Emergency Context Resolution with Internet Technology* (ECRIT) working group. Our first article, by Hannes Tschofenig and Henning Schulzrinne, is an overview of the architecture this working group is developing.

According to the ITU-T, a *Next Generation Network* (NGN) is "...a packet-based network which can provide services including Telecommunication Services and is able to make use of multiple broadband, Quality of Service-enabled transport technologies in which service-related functions are independent from underlying transport-related technologies." Paul Veitch, Paul Hitchen, and Martin Mitchell describe the integration of a standalone core BGP/MPLS VPN network into an NGN architecture.

Emergency Services for Internet Multimedia

by Hannes Tschofenig, Nokia Siemens Networks and Henning Schulzrinne, Columbia University

Summoning the police, the fire department, or an ambulance in emergencies is one of the most important functions the telephone enables. As telephone functions move from circuit-switched to Internet telephony, telephone users rightfully expect that this core feature will continue to be available and work as well as it has in the past. Users also expect to be able to reach emergency assistance using new communication devices and applications, such as instant messaging or *Short Message Service* (SMS), and new media, such as video. In all cases, the basic objective is the same: The person seeking help needs to be connected with the most appropriate *Public Safety Answering Point* (PSAP), where call takers dispatch assistance to the caller's location. PSAPs are responsible for a particular geographic region, which can be as small as a single university campus or as large as a country.

The transition to Internet-based emergency services introduces two major structural challenges. First, whereas traditional emergency calling imposed no requirements on end systems and was regulated at the national level, Internet-based emergency calling needs global standards, particularly for end systems. In the old *Public Switched Telephone Network* (PSTN), each caller used a single entity, the landline or mobile carrier, to obtain services. For Internet multimedia services, network-level transport and applications can be separated, with the *Internet Service Provider* (ISP) providing IP connectivity service, and a *Voice Service Provider* (VSP) adding call routing and PSTN termination services. We ignore the potential separation between the Internet access provider, that is, a carrier that provides physical and data link layer network connectivity to its customers, and the ISP that provides network layer services. We use the term VSP for simplicity, instead of the more generic term *Application Server Provider* (ASP).

The documents that the IETF *Emergency Context Resolution with Internet Technology* (ECRIT) working group is developing support multimedia-based emergency services, and not just voice. As is explained in more detail later in this article, emergency calls need to be identified for special call routing and handling services, and they need to carry the location of the caller for routing and dispatch. Only the calling device can reliably recognize emergency calls, while only the ISP typically has access to the current geographical location of the calling device based on its point of attachment to the network. The reliable handling of emergency calls is further complicated by the wide variety of access technologies in use, such as *Virtual Private Networks* (VPNs), other forms of tunneling, firewalls, and *Network Address Translators* (NATs).

This article describes the architecture of emergency services as defined by the IETF and some of the intermediate steps as end systems and the call-handling infrastructure transition from the current circuit-switched and emergency-calling-unaware *Voice-over-IP* (VoIP) systems to a true any-media, any-device emergency calling system.

IETF Emergency Services Architecture

The emergency services architecture developed by the IETF ECRIT working group is described in [1] and can be summarized as follows: *Emergency calls are generally handled like regular multimedia calls, except for call routing*. The ECRIT architecture assumes that PSAPs are connected to an IP network and support the *Session Initiation Protocol* (SIP)[2] for call setup and messaging. However, the calling user agent may use any call signaling or instant messaging protocol, which the VSP then translates into SIP.

Nonemergency calls are routed by a VSP, either to another subscriber of the VSP, typically through some SIP session border controller or proxy, or to a PSTN gateway. For emergency calls, the VSP keeps its call routing role, routing calls to the emergency service system to reach a PSAP instead. However, we also want to allow callers that do not subscribe to a VSP to reach a PSAP, using nothing but a standard SIP[2] user agent (see [3] and [4] for a discussion about this topic); the same mechanisms described here apply. Because the Internet is global, it is possible that a caller's VSP resides in a regulatory jurisdiction other than where the caller and the PSAP are located. In such circumstances it may be desirable to exclude the VSP and provide a direct signaling path between the caller and the emergency network. This setup has the advantage of ensuring that all parties included in the call delivery process reside in the same regulatory jurisdiction.

As noted in the introduction, the architecture neither forces nor assumes any type of trust or business relationship between the ISP and the VSP carrying the emergency call. In particular, this design assumption affects how location is derived and transported.

Providing emergency services requires three crucial steps, which we describe in the following sections: recognizing an emergency call, determining the caller's location, and routing the call and location information to the appropriate emergency service system operating a PSAP.

Recognizing an Emergency Call

In the early days of PSTN-based emergency calling, callers would dial a local number for the fire or police department. It was recognized in the 1960s that trying to find this number in an emergency caused unacceptable delays; thus, most countries have been introducing single nationwide emergency numbers, such as 911 in North America, 999 in The United Kingdom, and 112 in all European Union countries.

This standardization became even more important as mobile devices started to supplant landline phones. In some countries, different types of emergency services, such as police or mountain rescue, are identified by separate numbers. Unfortunately, more than 60 different emergency numbers are used worldwide, many of which also have nonemergency uses in other countries, so simply storing the list of numbers in all devices is not feasible. In addition, hotels and university campuses often use dial prefixes, so an emergency caller in some European universities may actually have to dial 0112 to reach the fire department.

Because of this diversity, the ECRIT architecture decided to separate the concept of an emergency dial string, which remains the familiar and regionally defined emergency number, and a protocol identifier that is used for identifying emergency calls within the signaling system. The calling end system has to recognize the emergency (service) dial string and translate it into an emergency service identifier, which is an extensible set of *Uniform Resource Names* (URNs) defined in RFC 5031[5]. A common example for such a URN, defined to reach the generic emergency service, is `urn:service.sos`. The emergency service URN is included in the signaling request as the destination and is used to identify the call as an emergency call. If the end system fails to recognize the emergency dial string, the VSP may also perform this service.

Because mobile devices may be sold and used worldwide, we want to avoid manually configuring emergency dial strings. In general, a device should recognize the emergency dial string familiar to the user and the dial strings customarily used in the currently visited country. The *Location-to-Service Translation Protocol* (LoST)[6], described in more detail later, also delivers this information.

Some devices, such as smartphones, can define dedicated user interface elements that dial emergency services. However, such mechanisms must be carefully designed so that they are not accidentally triggered, for example, when the device is in a pocket.

Emergency Call Routing

When an emergency call is recognized, the call needs to be routed to the appropriate PSAP. Each PSAP is responsible for only a limited geographic region, its service region, and some set of emergency services. For example, even in countries with a single general emergency number such as the United States, poison-control services maintain their own set of call centers. Because VSPs and end devices cannot keep a complete up-to-date mapping of all the service regions, a mapping protocol, LoST[6], maps a location and service URN to a specific PSAP *Uniform Resource Identifier* (URI) and a service region.

LoST, illustrated in Figure 1, is a *Hypertext Transfer Protocol* (HTTP)-based query/response protocol where a client sends a request containing the location information and service URN to a server and receives a response containing the service URL, typically a SIP URL, the service region where the same information would be returned, and an indication of how long the information is valid. Both request and response are formatted as *Extensible Markup Language* (XML). For efficiency, responses are cached, because otherwise every small movement would trigger a new LoST request. As long as the client remains in the same service region, it does not need to consult the server again until the response returned reaches its expiration date. The response may also indicate that only a more generic emergency service is offered for this region. For example, a request for `urn:service:sos.marine` in Austria may be replaced by `urn:service:sos`. Finally, the response also indicates the emergency number and dial string for the respective service.

The number of PSAPs serving a country varies significantly. Sweden, for example, has 18 PSAPs, and the United States has approximately 6,200. Therefore, there is roughly one PSAP per 500,000 inhabitants in Sweden and one per 50,000 in the United States. As all-IP infrastructure is rolled out, smaller PSAPs may be consolidated into regional PSAPs. Routing may also take place in multiple stages, with the call being directed to an *Emergency Services Routing Proxy* (ESRP), which in turn routes the call to a PSAP, accounting for factors such as the number of available call takers or the language capabilities of the call takers.

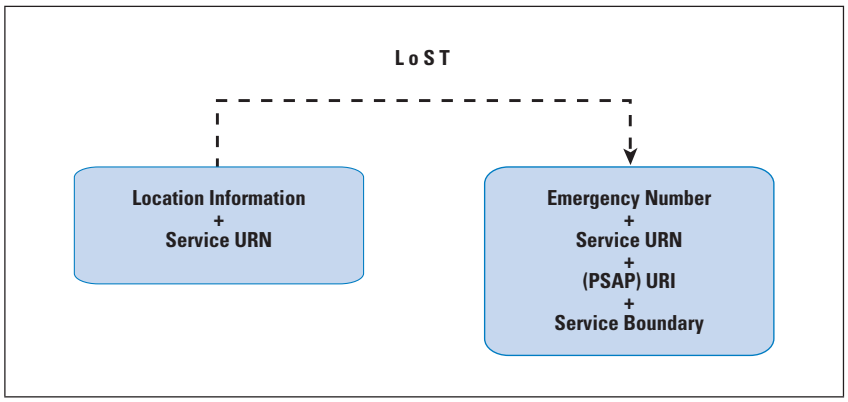

Figure 1: High-Level Functions of Location-to-Service Translation (LoST) Protocol

Location Information

Emergency services need location information for three reasons: routing the call to the right PSAP, dispatching first responders (for example, policemen), and determining the right emergency service dial strings. It is clear that the location must be automatic for the first and third applications, but experience has shown that automated, highly accurate location information is vital to dispatching as well, rather than relying on callers to report their locations to the call taker.

Such information increases accuracy and avoids dispatch delays when callers are unable to provide location information because of language barriers, lack of familiarity with their surroundings, stress, or physical or mental impairment.

Location information for emergency purposes comes in two representations: geo(detic), that is, longitude and latitude, and civic, that is, street addresses similar to postal addresses. Particularly for indoor location, vertical information (floors) is very useful. Civic locations are most useful for fixed Internet access, including wireless hotspots, and are often preferable for specifying indoor locations, whereas geodetic location is frequently used for cell phones. However, with the advent of femto and pico cells, civic location is both possible and probably preferable because accurate geodetic information can be very hard to acquire indoors.

In almost all cases, location values are represented as *Presence Information Data Format Location Object* (PIDF-LO), an XML-based document to encapsulate civic and geodetic location information. The format of PIDF-LO is described in [7], with the civic location format updated in [8] and the geodetic location format profiled in [9]. The latter document uses the *Geography Markup Language* (GML) developed by the *Open Geospatial Consortium* (OGC) for describing commonly used location shapes.

Location can be conveyed either by value ("LbyV") or by reference ("LbyR"). For the former, the XML location object is added as a message body in the SIP message. Location by value is particularly appropriate if the end system has access to the location information; for example, if it contains a *Global Positioning System* (GPS) receiver or uses one of the location configuration mechanisms described later in this section. In environments where the end host location changes frequently, the LbyR mechanism might be more appropriate. In this case, the LbyR is an HTTP/*Secure HTTP* (HTTPS) or SIP/*Secure SIP* (SIPS) URI, which the recipient needs to resolve to obtain the current location. Terminology and requirements for the LbyR mechanism are available in [10].

An LbyV and an LbyR can be obtained through location configuration protocols, such as the *HTTP Enabled Location Delivery* (HELD) protocol[11] or *Dynamic Host Configuration Protocol* (DHCP)[12, 13]. When obtained, location information is required for LoST queries, and that information is added to SIP messages[14].

The requirements for location accuracy differ between routing and dispatch. For call routing, city or even county-level accuracy is often sufficient, depending on how large the PSAP service areas are, whereas first responders benefit greatly when they can pinpoint the caller to a particular building or, better yet, apartment or office for indoor locations, and an outdoor area of at most a few hundred meters. This detailed location information avoids having to search multiple buildings, for example, for medical emergencies.

As mentioned previously, the ISP is the source of the most accurate and dependable location information, except for cases where the calling device has built-in location capabilities, such as GPS, when it may have more accurate location information. For landline Internet connections such as DSL, cable, or fiber-to-the-home, the ISP knows the provisioned location for the network termination, for example. The IETF GEOPRIV working group has developed protocol mechanisms, called *Location Configuration Protocols,* so that the end host can request and receive location information from the ISP. The Best Current Practice document for emergency calling[15] enumerates three options that clients should universally support: DHCP civic[16] and geo[12] (with a revision of RFC 3825 in progress[17]), and HELD[11]. HELD uses XML query and response objects carried in HTTP exchanges. DHCP does not use the PIDF-LO format, but rather more compact binary representations of locations that require the endpoint to construct the PIDF-LO.

Particularly for cases where end systems are not location-capable, a VSP may need to obtain location information on behalf of the end host[18].

Obtaining at least approximate location information at the time of the call is time-critical, because the LoST query can be initiated only after the calling device or VSP has obtained location information. Also, to accelerate response, it is desirable to transmit this location information with the initial call signaling message. In some cases, however, location information at call setup time is imprecise. For example, a mobile device typically needs 15 to 20 seconds to get an accurate GPS location "fix," and the initial location report is based on the cell tower and sector. For such calls, the PSAP should be able to request more accurate location information either from the mobile device directly or the *Location Information Server* (LIS) operated by the ISP. The SIP event notification extension, defined in RFC 3265[19], is one such mechanism that allows a PSAP to obtain the location from an LIS. To ensure that the PSAP is informed only of pertinent location changes and that the number of notifications is kept to a minimum, event filters[20] can be used.

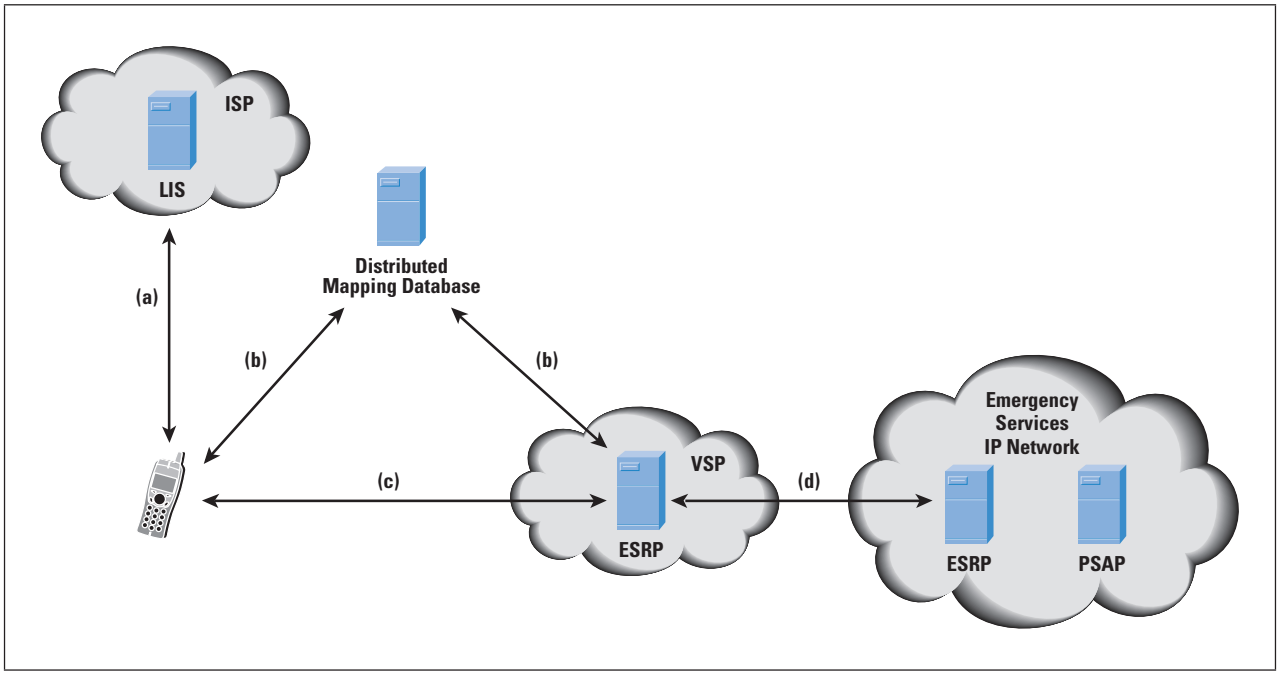
The two-stage location refinement mechanism described previously works best when location is provided by reference (LbyR) in the SIP INVITE call setup request. The PSAP subscribes to the LbyR provided in the SIP exchange and the LbyR refers to the LIS in the ISP's network. In addition to a SIP URI, the LbyR message can also contain an HTTP/HTTPS URI. When such a URI is provided, an HTTP-based protocol can be used to retrieve the current location[21].

Obligations

This section discusses the requirements the different entities need to satisfy, based on Figure 2. A more detailed description can be found in [15].

Note that this narration focuses on the final stage of deployment and does not discuss the transition architecture, in which some implementation responsibilities can be rearranged, with an effect on the overall functions offered by the emergency services architecture. A few variations were introduced to handle the transition from the current system to a fully developed ECRIT architecture.

Figure 2: Main Components Involved in an Emergency Call



With the work on the IETF emergency architecture, we have tried to balance the responsibilities among the participants, as described in the following sections.

End Hosts

An end host, through its VoIP application, has three main responsibilities: it has to attempt to obtain its own location, determine the URI of the appropriate PSAP for that location, and recognize when the user places an emergency call by examining the dial string. The end host operating system may assist in determining the device location.

The protocol interaction for location configuration is indicated as interface (a) in Figure 2; numerous location configuration protocols have been developed to provide this capability.

A VoIP application needs to support the LoST protocol[6] in order to determine the emergency service dial strings and the PSAP URI. Additionally, the device needs to understand the service identifiers, defined in [5].

As currently defined, it is assumed that SIP can reach PSAPs, but PSAPs may support other signaling protocols, either directly or through a protocol translation gateway. The LoST retrieval results indicate whether other signaling protocols are supported. To provide support for multimedia, use of different types of codecs may be required; details are available in [15].

ISP

The ISP has to make location information available to the endpoint through one or more of the location configuration protocols.

In order to route an emergency call correctly to a PSAP, an ISP may initially disclose the approximate location for routing to the endpoint and give more precise location information later, when the PSAP operator dispatches emergency personnel. The functions required by the IETF emergency services architecture are restricted to the disclosure of a relatively small amount of location information, as discussed in [22] and in [23].

The ISP may also operate a (caching) LoST server to improve the robustness and reliability of the architecture. This server lowers the round-trip time for contacting a LoST server, and the caches are most likely to hold the mappings of the area where the emergency caller is currently located.

When ISPs allow Internet traffic to traverse their network, the signaling and media protocols used for emergency calls function without problems. Today, there are no legal requirements to offer prioritization of emergency calls over IP-based networks. Although the standardization community has developed a range of *Quality of Service* (QoS) signaling protocols, they have not experienced widespread deployment.

VSP

SIP does not mandate that call setup requests traverse SIP proxies; that is, SIP messages can be sent directly to the user agent. Thus, even for emergency services it is possible to use SIP without the involvement of a VSP. However, in terms of deployment, it is highly likely that a VSP will be used. If a caller uses a VSP, this VSP often forces all calls, emergency or not, to traverse an outbound proxy or *Session Border Controller* (SBC) operated by the VSP. If some end devices are unable to perform a LoST lookup, VSP can provide the necessary functions as a backup solution.

If the VSP uses a signaling or media protocol that the PSAP does not support, it needs to translate the signaling or media flows.

VSPs can assist the PSAP by providing identity assurance for emergency calls; for example, using [30], thus helping to prosecute prank callers. However, the link between the subscriber information and the real-world person making the call is weak.

In many cases, VSPs have, at best, only the credit card data for their customers, and some of these customers may use gift cards or other anonymous means of payment.

PSAP

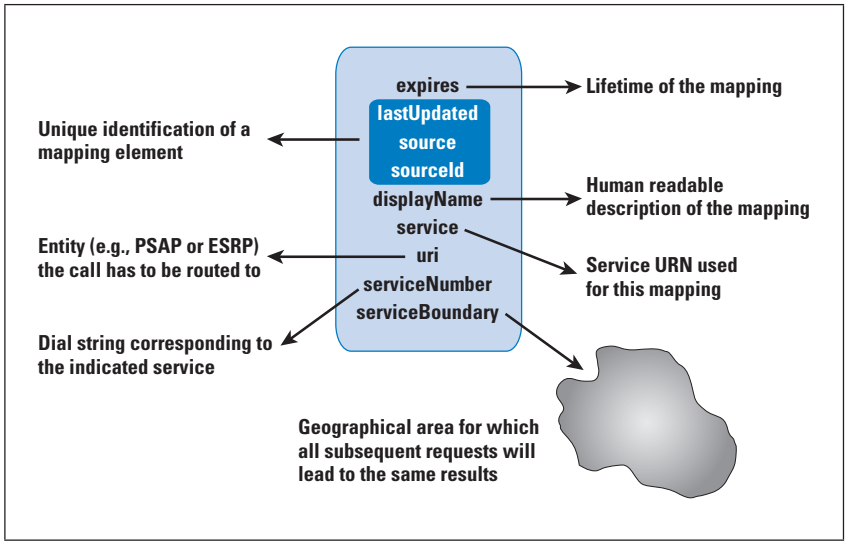
The emergency services Best Current Practice document [15] discusses only the standardization of the interfaces from the VSP and ISP toward PSAPs and some parts of the PSAP-to-PSAP call transfer mechanisms that are necessary for emergency calls to be processed by the PSAP. Many aspects related to the internal communication within a PSAP, between PSAPs as well as between a PSAP and first responders, are beyond the scope of the IETF specification.

When emergency calling has been fully converted to Internet protocols, PSAPs must accept calls from any VSP, as shown in interface (d) of Figure 2. Because calls may come from all sources, PSAPs must develop mechanisms to reduce the number of malicious calls, particularly calls containing intentionally false location information. Assuring the reliability of location information remains challenging, particularly as more and more devices are equipped with *Global Navigation Satellite Systems* (GNSS) receivers, including GPS and Galileo, allowing them to determine their own location[24]. However, it may be possible in some cases to check the veracity of the location information an endpoint provides by comparing it against infrastructure-provided location information; for example, a LIS-determined location.

Mapping Architecture

So far we have described LoST as a client-server protocol. Similar to the *Domain Name System* (DNS), a single LoST server does not store the mapping elements for all PSAPs worldwide, for both technical and administrative reasons. Thus, there is a need to let LoST servers interact with other LoST servers, each covering a specific geographical region. Working together, LoST servers form a distributed mapping database, with each server carrying mapping elements, as shown in Figure 3. LoST servers may be operated by different entities, including the ISP, the VSP, or another independent entity, such as a governmental agency. Typically, individual LoST servers offer the necessary mapping elements for their geographic regions to others. However, LoST servers may also cache mapping elements of other LoST servers either through data synchronization mechanisms (for example, FTP or exports from a *Geographical Information System* [GIS] or through a specialized protocol[25]) or by regular usage of LoST. This caching improves performance and increases the robustness of the system.

Figure 3: Mapping Element



A detailed description of the mapping architecture with examples is available in [29].

Steps Toward an IETF Emergency Services Architecture

The architecture described so far requires changes both in already-deployed VoIP end systems and in the existing PSAPs. The speed of transition and the path taken vary between different countries, depending on funding and business incentives. Therefore, it is generally difficult to argue whether upgrading endpoints or replacing the emergency service infrastructure will be easier. In any case, the transition approaches being investigated consider both directions. We can distinguish roughly four stages of transition (Note: The following descriptions omit many of the details because of space constraints):

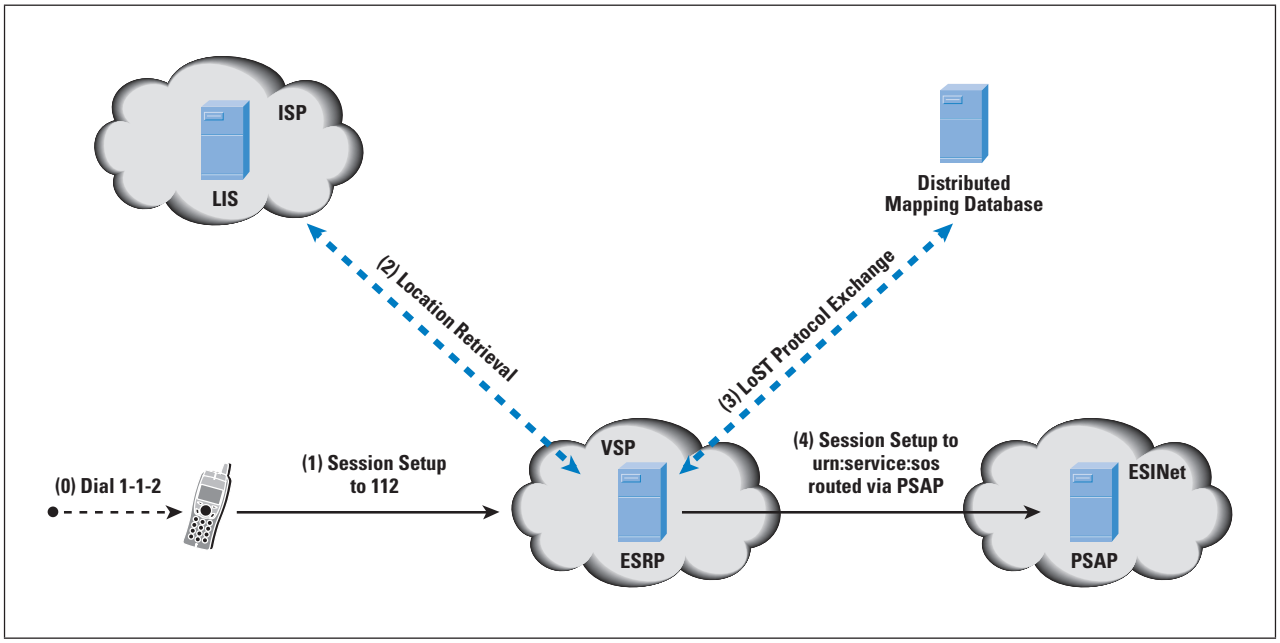
1. Initially, VoIP end systems cannot place emergency calls at all; for example, many software clients, such as *GoogleTalk*, cannot place emergency calls.
2. In a second stage, VoIP callers manually configure their location, and emergency calls are routed to the appropriate PSAP as circuit-switched calls through PSTN gateways using technologies similar to mobile calls. This level of service is now offered in some countries for PSTN-replacement VoIP services; that is, VoIP services that are offered as replacement for the home phone. In the United States, this service is known as the "NENA I2" service.
3. In a third stage, PSAPs maintain two separate infrastructures, one for calls arriving through an IP network and the traditional infrastructure.
4. In the final stage, all calls, including those from traditional cell phones and analog landline phones, reach the PSAP through IP networks, with the traditional calls converted to the ECRIT requirements by the carriers or the emergency service infrastructure.

If devices are used in environments without location services, the VSP's SIP proxy may need to insert location information based on estimates or subscriber data. These cases are described briefly in the following sections.

Traditional Endpoints

Figure 4 shows an emergency services architecture with traditional endpoints. When the emergency caller dials the Europeanwide emergency number 112 (step 0), the device treats it as any other call without recognizing it as an emergency call; that is, the dial string provided by the endpoint that may conform to RFC 4967[26] or RFC 3966[27] is signaled to the VSP (step 1). Recognition of the dial string is then left to the VSP for processing or sorting; the same is true for location retrieval (step 2) and routing to the nearest (or appropriate) PSAP (step 3). Dial-string recognition, location determination, and call routing are simpler to carry out using a fixed device and the voice and application service provided through the ISP than they are when the VSP and the ISP are two separate entities.

Figure 4: Emergency Services Architecture with Traditional Endpoints



There are two main challenges to overcome when dealing with traditional devices: First, the VSP must discover the LIS that knows the location of the IP-based end host. The VSP is likely to know only the IP address of that device, visible in the call signaling that arrives at the VSP. When a LIS is discovered and contacted and some amount of location information is available, then the second challenge arises, namely, how to route the emergency call to the appropriate PSAP. To accomplish the latter task it is necessary to have some information about the PSAP boundaries available.

Reference [15] does not describe a complete and detailed solution but uses building blocks specified in ECRIT. Still, this deployment scenario shows many constraints:

- Only the emergency numbers configured at the VSP are understood. This situation may lead to cases where a dialed emergency number is not recognized.
- Using the IP address to find the ISP is challenging and may, in case of mobility protocols and VPNs, lead to wrong results.
- Security concerns might arise when a potentially large number of VSPs or ASPs are able to retrieve location information from an ISP. It is likely that only authorized VSP and ASPs will be granted access. Hence, it is unlikely that such a solution would work smoothly across national boundaries.
- When the user agent does not recognize the emergency call, functions such as call waiting, call transfer, three-way call, flash hold, and outbound call blocking cannot be disabled.
- The user-agent software may block callbacks from the PSAP.
- Privacy settings may not get considered and identity may get disclosed to unauthorized parties. These identity privacy features exist in some jurisdictions even in emergency situations.
- Certain VoIP call features may not be supported, such as REFER (for conference call and transfer to secondary PSAP) and *Globally Routable UA URI* (GRUU).
- User agents will not convey location information to the VSP (even if available).

Partially Upgraded End Hosts

A giant step forward in simplifying the handling of IP-based emergency calls is to provide the end host with some information about the ISP so that LIS discovery is possible. The end host may, for example, learn the ISP's domain name by using LIS discovery[28], or might even obtain a *Location by Reference* (LbyR) through the DHCP-URI option[13] or through HELD[11]. The VSP can then either resolve the LbyR in order to route the call or use the domain to discover a LIS using DNS.

Additional software upgrades at the end device may allow for recognition of emergency calls based on some preconfigured emergency numbers (for example, 112 and 911) and allow for the implementation of other emergency service-related features, such as disabling silence suppression during emergency calls.

Outlook

In most countries, national and sometimes regional telecommunications regulators, such as the *Federal Communications Commission* (FCC) and individual states, or the European Union, strongly influence how emergency services are provided, who pays for them, and the obligations that the various parties have. Regulation is, however, still at an early stage: in most countries current requirements demand only manual update of location information by the VoIP user. The ability to obtain location information automatically is, however, crucial for reliable emergency service operation, and it is required for nomadic and mobile devices. (Nomadic devices remain in one place during a communication session, but are moved frequently from place to place. Laptops with Wi-Fi interfaces are currently the most common nomadic devices.)

Regulators have traditionally focused on the national or, at most, the European level, and the international nature of the Internet poses new challenges. For example, mobile devices are now routinely used beyond their country of purchase and, unlike traditional cellular phones, need to support emergency calling functions. It appears likely that different countries will deploy IP-based emergency services over different time horizons, so travelers may be surprised to find that they cannot call for emergency assistance outside their home country.

The separation between Internet access and application providers on the Internet is one of the most important differences to existing circuit-switched telephony networks. A side effect of this separation is the increased speed of innovation at the application layer, and the number of new communication mechanisms is steadily increasing. Many emergency service organizations have recognized this trend and advocated for the use of new communication mechanisms, including video, real-time text, and instant messaging, to offer improved emergency calling support for citizens. Again, this situation requires regulators to rethink the distribution of responsibilities, funding, and liability.

Many communication systems used today lack accountability; that is, it is difficult or impossible to trace malicious activities back to the persons who caused them. This problem is not new, because pay phones and prepaid cell phones have long offered mischief makers the opportunity to place hoax calls, but the weak user registration procedures, the lack of deployed end-to-end identity mechanisms, and the ease of providing fake location information increases the attack surface at PSAPs. Attackers also have become more sophisticated over time, and Botnets that generate a large volume of automated emergency calls to exhaust PSAP resources, including call takers and first responders, are not science fiction.

HENNING SCHULZRINNE, Levi Professor of Computer Science at Columbia University, received his Ph.D. from the University of Massachusetts in Amherst, Massachusetts. He was an MTS at AT&T Bell Laboratories and an associate department head at GMD-Fokus (Berlin) before joining the Computer Science and Electrical Engineering departments at Columbia University. He served as chair of Computer Science from 2004 to 2009. Protocols that he co-developed, such as RTP, RTSP, and SIP, are now Internet standards, used by almost all Internet telephony and multimedia applications. His research interests include Internet multimedia systems, ubiquitous computing, and mobile systems. He is a Fellow of the IEEE. E-mail: **hgs@cs.columbia.edu**

HANNES TSCHOFENIG received a Diploma degree from the University of Klagenfurt, Austria. He joined Siemens Corporate Technology, Munich, in 2001 and joined Nokia Siemens Networks in April 2007 to move to Finland in December 2007, where he focuses on standards development. Most of his time is dedicated to the participation in the Internet Engineering Task Force (IETF) where he, among other responsibilities, co-chaired the ECRIT working group from 2005 to early 2010. Additionally, he co-chairs the Next Generation 112 Technical Committee of the European Emergency Number Association (EENA) and contributes to the technical specifications developed within the National Emergency Number Association (NENA), and he co-organized the SDO emergency services workshop series. In March 2010 he joined the Internet Architecture Board (IAB).

Integration of Core BGP/MPLS VPN Networks

by Paul Veitch, Paul Hitchen, and Martin Mitchell, BT Innovate & Design

This article explores the architectural and operational challenges involved in integrating an existing standalone core *Border Gateway Protocol* (BGP)/*Multiprotocol Label Switching* (MPLS) VPN network onto a target *Next-Generation Network* (NGN). The rationale for consolidating and transforming multiple networks is explained, mainly in terms of potential cost savings and operational simplification achieved by the network operator. The article specifically focuses on the MPLS *Carrier-supporting-Carrier* (CsC) architectural framework, which allows the serving nodes of one MPLS VPN network to be interconnected through the serving nodes of another MPLS VPN network. The required architectural building blocks to implement CsC, the manner in which routing protocols must interact, as well as end-to-end packet flow and label encapsulation are all explained. The main design and operational challenges, including maintaining performance levels for customers, network resiliency, fault-handling, and capacity management, are also addressed in this article.

Network operators are under increasing pressure to deliver exceptional levels of customer experience and service while decreasing the capital and operational cost base of their networks. Many operators have traditionally built multiple network platforms, each of which has been uniquely designed to meet the requirements of specific services targeted at specific customer markets, such as voice, broadband IP, *Virtual Private Networks* (VPNs), etc.

In a bid to remain competitive and achieve cost reductions and operational simplifications, many operators have built all IP-based NGNs. The principal transformational benefits of an NGN with a single protocol such as IP at its heart include versatility in catering for multiple traffic requirements (for example, by employing IP *Quality-of-Service* [QoS] techniques), the ability to introduce novel and reusable services and features in a flexible manner, and the potential to maximise vendor interworking due to standards-based technology.

When a network operator builds an NGN, the challenge remains as to how to migrate *existing* networks and customers onto the new platform. The full commercial benefits of an NGN can be properly realised only after legacy networks are either consolidated or phased out completely. Many important factors must be considered, including the cost benefits, the potential effect on end customers, and the operational approach to carrying out migrations. These concerns must be weighed against the commercial and business risks associated with the alternative approach of sustaining and running multiple standalone platforms indefinitely.

This article focuses on a specific scenario: how to integrate an existing BGP/MPLS VPN network that provides VPN services to a corporate customer base with a "target" NGN. Following a brief overview of MPLS VPN services and networks, the rationale for consolidating multiple MPLS VPN networks is explained, mainly in terms of potential cost savings and operational simplification achieved by the network operator. The article then details the MPLS CsC architectural framework that allows the serving nodes or *Points of Presence* (POPs) of one MPLS VPN network to be interconnected to the serving nodes of another MPLS VPN network. The way in which routing protocols must interact and the subsequent effect on end-to-end packet forwarding across a CsC-enabled core network are explained. The principal design and operational challenges introduced by integrating core MPLS networks are then outlined, including maintaining performance levels, network resiliency, fault management, and capacity management.

The Business Case for MPLS VPN Network Consolidation

VPNs are an attractive solution to serve the enterprise networking requirements of a wide range of businesses from *Small-to-Medium Enterprises* (SMEs) to multinational "blue-chip" corporate organisations. Essentially, VPNs provide a transparent network infrastructure that allows multiple customer sites to communicate over a shared backbone network, as though they are using their own private network, regardless of geographical location. Typical applications that run across an organisation's VPN include corporate Intranet, mail services, and *Voice-over-IP* (VoIP) telephony.

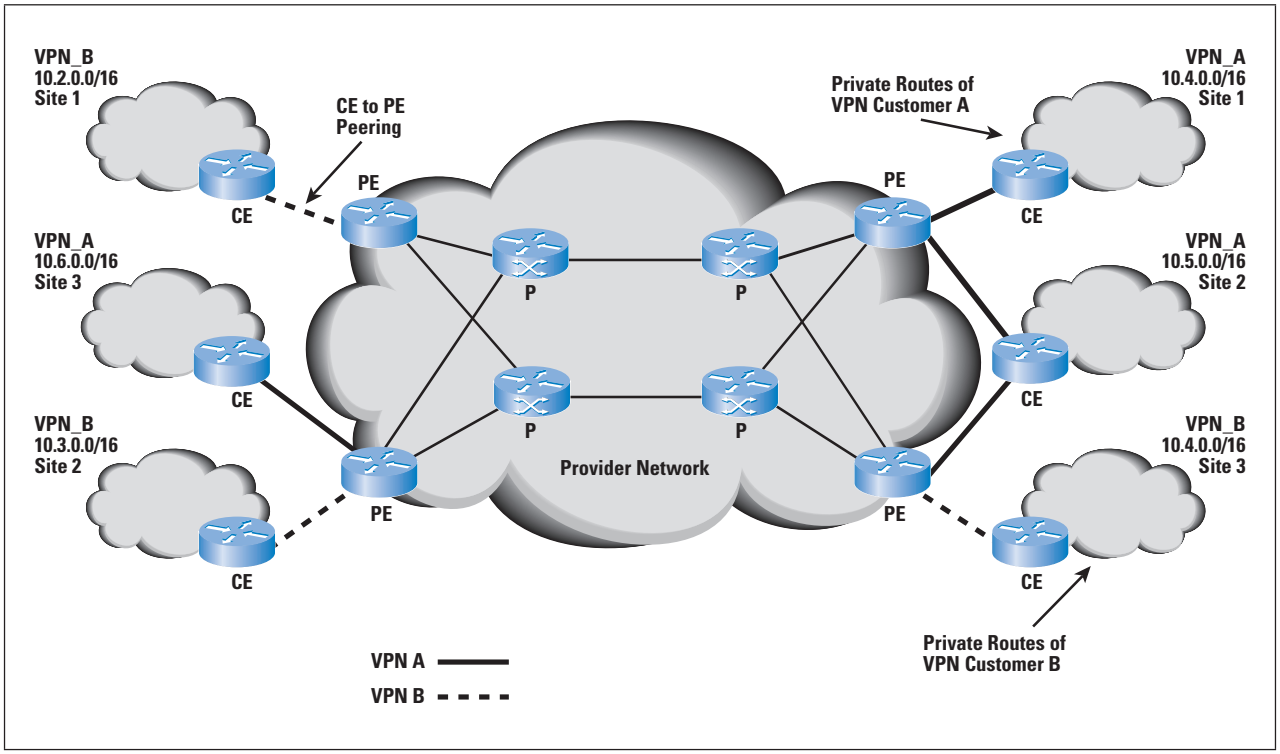
Although distinct categories of VPN networking technology exist[1], this article focuses exclusively on "Layer 3" BGP/MPLS VPNs, as defined in RFC 4364[2] and other related Internet Drafts. Such networks have been deployed for more than 10 years and have seen significant growth during that period.

The critical core network elements of a provider-provisioned BGP/MPLS VPN network are *Provider Edge* (PE) and *Provider Core* (P) routers, as shown in Figure 1.

PE routers terminate customer access circuits, whereas P routers perform packet forwarding and typically do not have directly connected customer access circuits. PE routers perform label encapsulation and de-encapsulation, P routers run label switching, and both operate control-plane protocols that build MPLS *Label Switched Paths* (LSPs) from each PE to each other PE. Many protocols can be used to establish these LSPs; a commonly deployed approach uses the *Label Distribution Protocol* (LDP) in conjunction with an *Interior Gateway Protocol* (IGP), such as *Open Shortest Path First* (OSPF).

When a PE forwards a VPN-addressed packet across the core, it adds an inner MPLS label to identify the VPN of which the packet is a member and then an outer MPLS label to identify the egress PE router. Any intermediate P routers switch the packet to the egress PE using the outer label only. The egress PE uses the inner label to determine which VPN or port to forward the packet to.

Figure 1: Overview of BGP/MPLS VPN Network



The *Customer Edge* (CE) router is not considered part of the provider's core network. It acts as a peer of the PE router, but not a peer of other CE routers. Each PE router supports multiple routing and forwarding tables, called *Virtual Route Forwarding* (VRF) tables. VRF routes are logically separate, and they may contain IP prefixes received from the CE router that overlap with addresses in other VRFs. (For example, in Figure 1, VPN_A, site 1 has the same private routes as VPN_B, site 3.) VPNs are formed by defining individual customer accesses to be members of a specific VRF table, with several sites formed on one PE by defining all sites to use the same VRF table or allocating each site a VRF table and controlling connectivity through selective import and export of the IP routes of each VRF table.

The PE routers use an extended variant of BGP for signaling between themselves and propagating information about the actual routes of each VPN, as well as the inner MPLS label. The extended BGP, referred to as *Multiprotocol BGP*, carries each VPN route together with two new fields, the *Route Distinguisher* (RD) and the *Route Target* (RT), a form of extended BGP Community.

The RD is added to each VPN route to ensure that routes from different customers are unique; BGP treats VPN routes as equal only if both the RD and the IP prefix mask are equal. BGP uses RTs to indicate a group of routes, thus defining VPN membership information for exchange between PEs.

Maintenance Costs of BGP/MPLS VPN Networks

As detailed in the previous section, the main core components of a VPN network based on BGP/MPLS technology are the PE and P routers. Although not shown in detail in Figure 1, another critical element of a core VPN network is the *Wide-Area Network* (WAN) topology that interconnects the P (core) routers residing in specific service nodes, also called POPs. The WAN topology is essentially the way in which transmission links—typically *Synchronous Optical Network* (SONET)/*Packet over SONET/SDH* (PoS), Gigabit Ethernet, or 10 Gigabit Ethernet—are used to interconnect the POPs together.

It follows that maintenance costs associated with a self-contained MPLS VPN network will be incurred for PE and P routers, as well as the interconnecting WAN transmission links. These maintenance costs will split into capital and operational elements.

Capital expenditures are required on an ongoing basis for all IP router infrastructure (PE and P routers), for example, to upgrade hardware to meet increasing capacity demands, replace faulty line cards and processors, or replace end-of-life hardware with newer equipment. Capital expenditures are also needed on WAN links, for example, to replace faulty line cards and optics, as well as to deploy increased capacity transmission links to cater for traffic growth across the core network. Further capital costs accrue from accommodation-related aspects such as power, racking, and air conditioning.

Additional maintenance costs reside in the operational space. For example, if an MPLS VPN network has 40 POP locations, each with a pair of P (core) routers, the 80 core routers will consume a certain amount of operational team resources for critical maintenance, scheduled maintenance activities, and ongoing monitoring and reporting of router status (processors and line cards).

Benefits of Core Integration

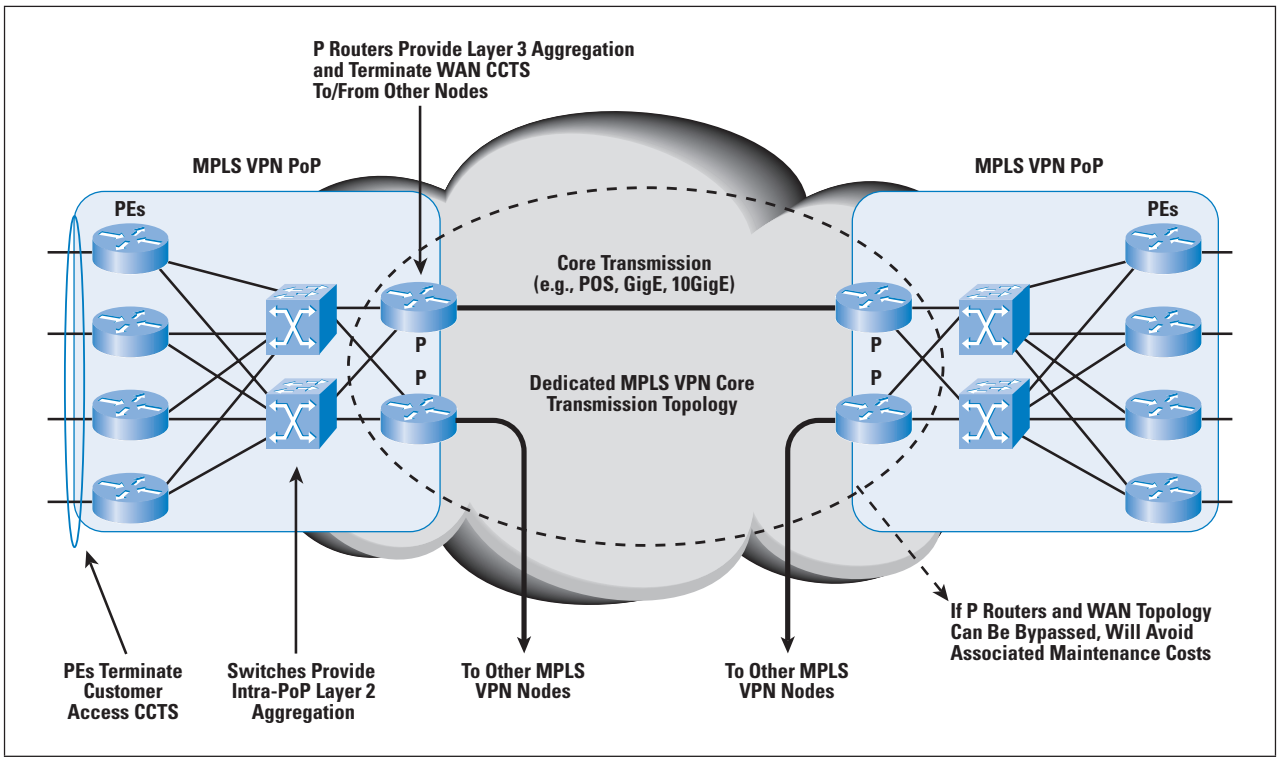
If a network operator has deployed an IP-based NGN alongside an existing MPLS VPN network, the question should be asked: can the existing MPLS VPN network be integrated onto the NGN so as to avoid some or all of the previously stated maintenance costs? One approach would be to target the P (core) routers and WAN transmission links for eventual removal (Figure 2) and replacement by suitable connectivity of the MPLS VPN nodes to the NGN network. The VPN PE routers that often terminate large volumes of customer access circuits and host the rich service-related functions for corporate VPN services can essentially be left *in situ,* minimising the effect on end customers and confining the integration of networks to the inner part of the core infrastructure. The way in which this goal can actually be achieved in practice is detailed in the next section.

The main benefits that can be accrued for the network operator are as follows:

- Substantial cost avoidance for maintaining and upgrading P (core) routers and dedicated WAN links for the existing MPLS VPN network can be achieved (Figure 2). As much as a 35-percent reduction of fixed inner core capital costs is possible.
- If the technical solution for core integration can be made as reusable as possible, then in addition to allowing integration of "same provider" core networks, the network operator could provide the capability on a wholesale basis for other service providers. This capability could be a potentially significant source of new revenue.
- From an operational perspective, integration of core networks should lend itself to a singular and much more streamlined approach to capacity planning, fault management, and network monitoring.

The combination of all these benefits can produce a compelling business case for network operators to consolidate core MPLS-based network platforms.

Figure 2: MPLS VPN Network Showing Inner Core Components Targeted for Replacement



Carrier-supporting-Carrier Framework

Carrier-supporting-Carrier (CsC) is a term used to describe a situation where one network, designated the *customer carrier,* is permitted to use a segment of another network, designated the *backbone carrier*[3]. Although the term "Carrier of Carriers" is also used to describe the same architectural framework, this article uses Carrier-supporting-Carrier for consistency. In principle, the two "carrier" networks could belong to the same organisation, or could belong to two different organisations. Whatever the case, there is no reason why the backbone carrier cannot support multiple customer carrier networks. Furthermore, the customer carrier network itself can be either a BGP/MPLS VPN network providing Layer 3 VPN services or an *Internet Service Provider* (ISP) network[3].

A network operator with an existing BGP/MPLS VPN network infrastructure that has also built an IP-based NGN based on BGP/MPLS technology as per RFC 4364[2] could choose to exploit the CsC architectural framework to merge the two core networks. In such a scenario, the existing BGP/MPLS VPN network that serves the needs of VPN business customers would be viewed as the "customer carrier," whereas the NGN network would be positioned as the "backbone carrier."

Physical Connectivity and CsC VRF Creation

In order to integrate an existing BGP/MPLS VPN network such as that shown in Figure 2, with an NGN core belonging to the same or different organisation, the NGN network must be enabled to act as a backbone carrier. Assuming the NGN network is configured to support BGP/MPLS VPNs as per RFC 4364[2], it comprises PE and P router core infrastructure. The PE routers of the NGN acting as the backbone carrier are denoted "CsC-PEs." The PE routers of the existing BGP/MPLS VPN network, that is, the customer carrier network that is being itself integrated with the NGN core, are denoted "CsC-CEs."

As shown in Figure 3, the NGN backbone carrier network provides MPLS VPN service to the customer carrier network using its own VRF table enabled on the CsC-PE. One important distinction between normal MPLS VPN service and CsC is the fact that traffic passed between the CsC-CE and CsC-PE is labeled rather than native IP[3, 4].

The CsC architecture is designed such that the backbone carrier network—the network provider's NGN network—needs to know only about internal routes within the customer carrier network. This setup allows formation of full "any-to-any" logical connectivity between the customer carrier routers, which in this scenario are the PE routers of the existing BGP/MPLS VPN network providing VPN services to end customers.

Furthermore, the backbone carrier routers themselves do not need to retain route prefix information for the end-customer VPNs connected to the customer carrier network because the end-customer traffic is transported over a second level of VRF tables that bear relevance only to the customer carrier itself, that is, the endpoint CsC-CEs. This *nesting* of MPLS VPN networks emphasises the inherent scalability of the CsC architecture. The CsC backbone carrier is effectively behaving like "proxy" P routers for the customer carrier network.

Figure 3: MPLS VPN "Customer Carrier" Network Connected Across NGN "Backbone Carrier"

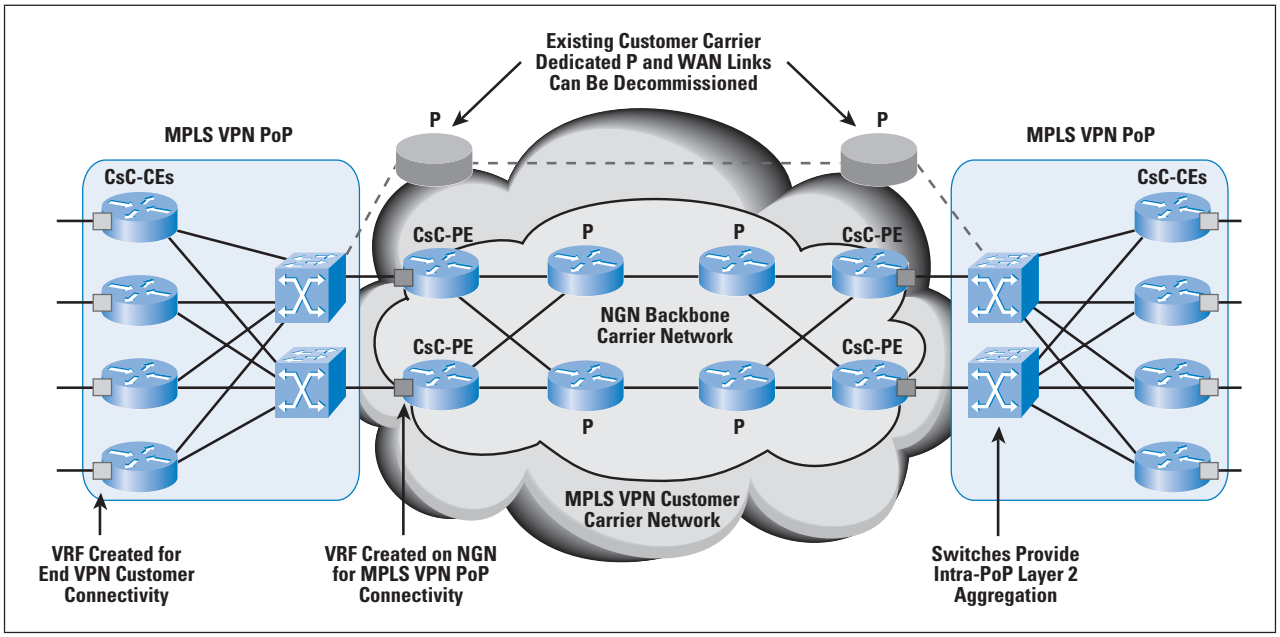


Figure 3 also shows the physical connectivity between the customer carrier network and backbone carrier NGN. Because many large-scale BGP/MPLS network deployments comprise large numbers of PE devices in the same service node or POP, there is often a Layer 2 Ethernet switch acting as an "intra-POP" aggregator. It is convenient to allow physical connectivity between the BGP/MPLS VPN service node and the CsC-PE in the NGN network using this aggregation switch. One or more *Virtual LANs* (VLANs) can be configured across this physical trunk to provide logical Layer 2 connectivity into the CsC-PE on the NGN, and be associated with the CsC VRF on that device. The Layer 2 switch also provides direct intra-POP connectivity between CsC-CEs present on the same VLANs.

Control-Plane Routing Protocols

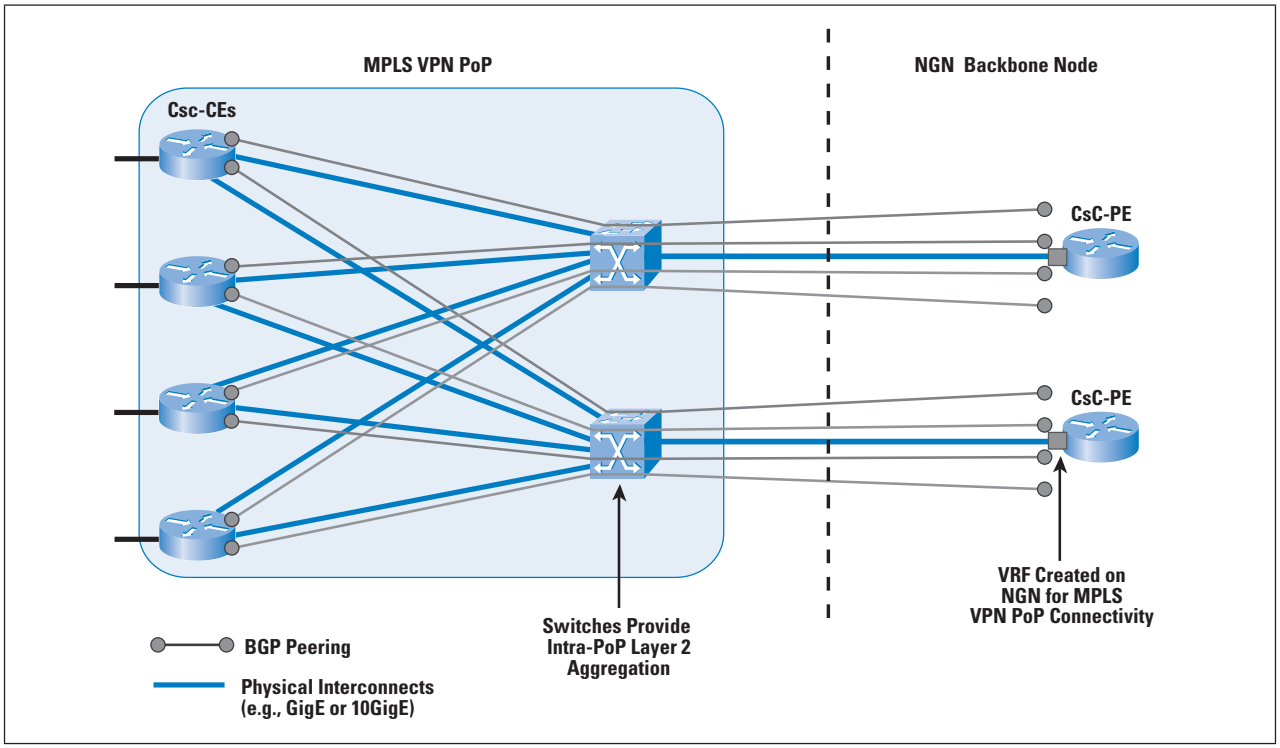
The previous section described the physical connectivity between BGP/MPLS VPN service nodes and the target NGN, with creation of a specific VRF route on the CsC-PEs. This section addresses the way in which the internal routes of the CsC-CEs (that is, the PE routers belonging to the customer carrier BGP/MPLS VPN network) are advertised into this VRF table.

Optional routing protocols include the use of an IGP such as OSPF, or *Exterior Gateway Protocols* (EGPs) such as BGP. With an IGP like OSPF[5], the routing protocol itself is used for route exchange between the CsC-CEs and CsC-PEs, and must be used in conjunction with an LDP[6] for MPLS label exchange between the CsC-CEs and CsC-PEs.

Separating the IP prefix and label allocation protocols between an IGP and LDP can introduce complexities with potential divergence between the two control planes. Such divergence in the extreme case can lead to partial or complete loss in forwarding. Use of an EGP like BGP, however, can be used to implement CsC as a single IP prefix and Label Allocation control-plane protocol between CsC-CE and CsC-PE. Piggybacking MPLS label-mapping information in the BGP update messages helps ensure that an IP prefix and its associated MPLS label are always synchronised in their delivery. The way in which this synchronisation is achieved is documented in RFC 3107[7]. BGP has the benefit of being a mature protocol for use either within the same network organisation or between networks belonging to different operators. Furthermore, BGP employs mechanisms for loop avoidance and control over the number and type of routes advertised and accepted.

Figure 4 shows an example scenario whereby two BGP peerings are established (for resiliency) between each of the four CsC-CEs (which are actually PE routers of the BGP/MPLS VPN customer carrier network) and a pair of target CsC-PE routers (which are the PE routers of the NGN backbone carrier network).

Figure 4: BGP Plus Labels as the Routing Protocol Between CsC-CEs and CsC-PEs

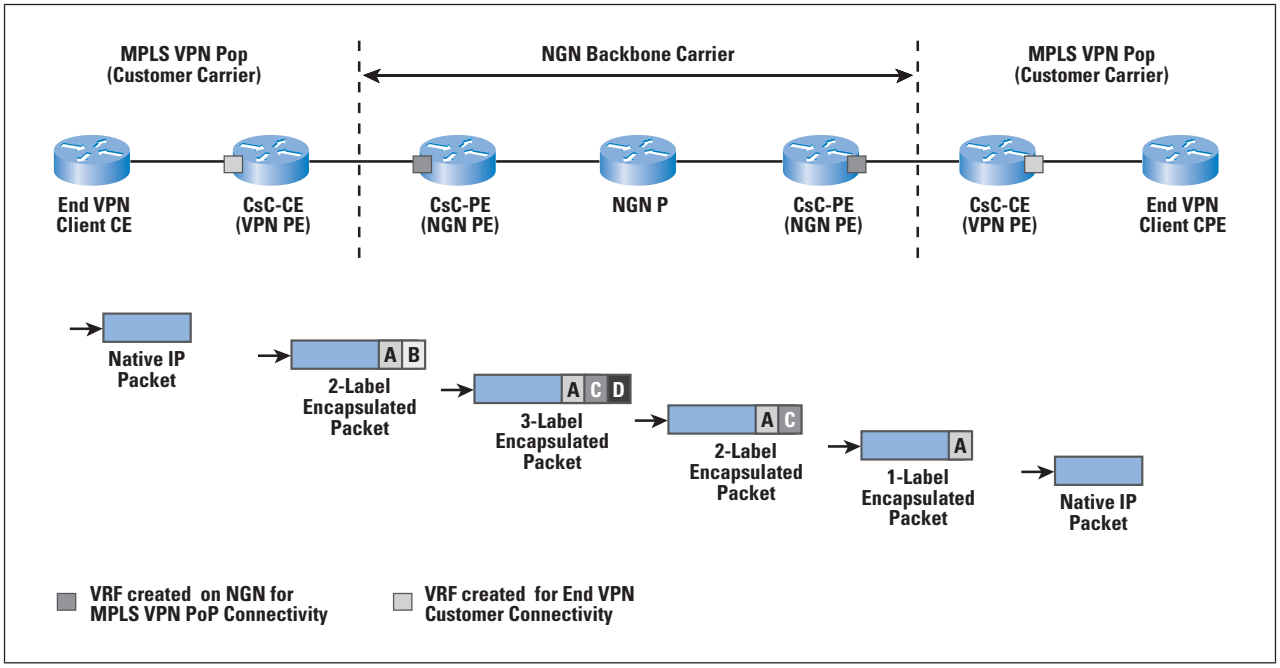


Label Switching of Customer Packets

As shown in Figure 5, viewing packet flow from left to right, a unicast packet originates as a native IP packet when presented from the end client CE router to the MPLS VPN PE router, which is behaving as a CsC-CE in this context. Upon traversal between CsC-CEs in different MPLS VPN POP locations connected by an NGN backbone carrier using CsC, the packet ultimately undergoes three levels of label encapsulation:

- The innermost label corresponds to the *End Customer VRF.* This label is transparent to the NGN backbone carrier (that is, it is not operated upon in lookup and forwarding tables with the NGN). It is label "A" in Figure 5.
- The middle label is the "outer label" as far as the CsC-CE is concerned, swapped at the CsC-PE, and becomes the "inner label" as far as the NGN backbone carrier is concerned. In Figure 5, this label is assigned as label "B" by the CsC-CE as instructed by the CsC-PE through the BGP plus labels (RFC 3107-compliant) peering. At the CsC-PE itself, the label is swapped (to become label "C" in Figure 5) and is used to associate the packet with the CsC VRF. The packet is then identifiable at the destination CsC-PE at the far end of the backbone carrier network; it allows forwarding to the correct interface.
- The outermost label (shown as label "D" in Figure 5) is assigned by the backbone carrier LDP process at the CsC-PE router, and is present only to allow transport across the backbone carrier CsC core. Thus when a packet leaves the CsC-PE for transport across the backbone carrier core it has three levels of labels on each packet.

Figure 5: Label Encapsulation and End-to-End Packet Flow Across a CsC Core Network



As shown in Figure 5, the last P router in the backbone carrier path has "popped" the outermost label (label "D") using penultimate-hop label forwarding. The destination CsC-PE uses and removes the middle label (label "C") to indicate the correct outgoing interface, leaving only the innermost label on presentation to the CsC-CE (label "A"). This CsC-CE, which is the PE router in relation to the end VPN services, uses the last remaining label to determine the VRF route and interface on which to send the native IP packet so that it reaches the required client CE router.

Design and Operational Challenges

The previous section outlined the architectural framework of using CsC to integrate one BGP/MPLS core network with another. This section addresses the important design and operational challenges that such a network transformation brings about.

Maintaining Performance Levels

Many existing operators of "carrier-class" BGP/MPLS networks exploit IP QoS mechanisms to allow different IP-based traffic types to be treated in different ways in terms of how the packets are conveyed across the core network. This treatment relates chiefly to prioritisation of delay, jitter, and/or loss-sensitive traffic, against traffic types that are less sensitive to loss or delay. Customers of VPN services supported on such networks generally demand support of a range of traffic types, including corporate intranet, transactional applications, mail services, data backup, video, and VoIP telephony.

To deal with the range of traffic types, BGP/MPLS VPN service providers have developed the means of supporting IP QoS defining different transport classes with associated service levels. One such example may map, for instance, six service classes based on IETF "Per-Hop Behaviours" as defined by the *Differentiated Services* (DiffServ) working group[8, 9] and the recommended *DiffServ Code Point* (DSCP) values for them. The classes in this example could be broadly described as follows:

- *Expedited Forwarding* (EF), designed and optimised for the delivery of jitter and delay-sensitive applications such as VoIP
- *Assured Forwarding* (AF), intended to support priority data applications; the AF class is split into four equivalent sub-classes (AF1–AF4) used to segregate data or video traffic applications, with priority being maintained over the Default class
- *Default* (DE), to support "best-effort" (that is, unprioritized) data traffic

The DSCP markings dictate the way in which such traffic is placed into queues and conveyed across the core network. At the edge of the MPLS core, the PE maps the incoming DSCP value into the MPLS *Class-of-Service* (CoS) bits (formerly known as EXP bits).

The details of the mapping relate to the specific implementation and policy of the service provider. Under heavy traffic load and congestion situations, such policies dictate how packets are treated in terms of scheduling, queuing, and discard eligibility.

Both the existing BGP/MPLS "customer carrier" and the target NGN "backbone carrier" networks already have their own implementation of QoS classes to allow management and prioritisation of multiple traffic types carried across their respective core infrastructures. A significant design challenge that arises with integrating the networks is that a suitable mapping of the QoS schema present on the PE routers of the customer carrier network (the CsC-CEs in earlier diagrams) to the QoS schema supported on the PE routers of the NGN (the CsC-PEs in earlier diagrams) is necessary.

It is imperative that such a mapping not compromise the existing customer experience for VPN services in terms of packet loss, packet delay, and packet jitter (that is, delay variance). Careful design, mapping of the required service levels, and ultimately end-to-end testing of the QoS mappings is therefore necessary to assure the maintenance of performance levels after the networks are integrated with CsC.

Network Resiliency

As described earlier in the article and shown in Figure 2, an existing standalone BGP/MPLS network platform has interconnected POP locations using underlying core transmission infrastructures such as SONET/SDH/*Dense Wavelength-Division Multiplexing* (DWDM). The actual number of WAN circuits deployed, the use of transmission-layer protection mechanisms, and the overall topological connectivity between POPs determine overall levels of network resiliency. In turn, this aspect of the network architecture significantly affects the overall level of service availability to end customers of VPN services.

When the standalone BGP/MPLS network has its existing core topology replaced with that of the NGN backbone carrier, it is very important to consider the levels of resiliency delivered with the new integrated core architecture, compared with the existing standalone arrangement. Critical considerations include:

- The physical connectivity between the serving nodes of the customer carrier and the backbone carrier should avoid single points of failure where possible.
- If the physical connectivity between the customer carrier and backbone carrier requires the use of WAN transmission links because locations are geographically separate, then suitable levels of circuit protection should be employed
- Because the backbone carrier effectively replaces the existing core topology of the customer carrier, the actual way in which backbone carrier nodes are interconnected and levels of WAN transmission protection etc., should be analysed.

All these aspects should be assessed and incorporated into the actual design process such that there is no detrimental effect on overall levels of service availability to the end customer. Service levels can be verified by reliability modeling of the new network topology, and by comparing the results with the reliability data for the existing topology.

Fault Management

There are many facets of monitoring and managing a core BGP/MPLS network in terms of assurance of service, alarm detection and filtering, customer notification of faults, and so on. In a standalone network environment, it is generally the responsibility of a particular operational team to manage faults on the network and provide service continuity during various types of failure scenarios. As shown in Figure 6, this operational function usually covers all core network elements, including PE and P (core) routers, as well as the WAN topology interconnecting the service nodes or "POPs."

In an integrated core network scenario, however, part of the customer carrier network—the P (core) routers and WAN transmission links, for example—are replaced by the NGN backbone carrier. The NGN backbone carrier has its own operational team with specific processes and systems for carrying out monitoring and management of fault events. A crucial challenge arises in terms of how to realise end-to-end fault management holistically and transparently between customer carrier and backbone carrier networks (Figure 6). Important considerations include:

- The requirement for a clear and unambiguous demarcation between customer carrier and backbone carrier core platforms must be addressed in terms of operational responsibility for specific faults and the hand-over procedures between operational domains.
- The use of existing monitoring tools and systems in both the customer carrier and backbone carrier domains must be assessed to determine whether new interfaces between such systems need to be developed to facilitate the hand-over procedures.

These topics must be factored in to determine the optimal solution for realising smooth and transparent fault-management procedures in an integrated core BGP/MPLS network environment.

Capacity Planning

As shown in Figure 6, in a standalone BGP/MPLS VPN network environment, a particular operational function exists for ongoing core capacity planning to ensure P router and WAN link capacity are suitably dimensioned to cope with current and future traffic demands. When an existing BGP/MPLS VPN network becomes a customer carrier network that is integrated with a target NGN backbone using CsC, there will be a corresponding shift in responsibility for certain aspects of core capacity planning.

VPN service traffic that would have been confined to its own dedicated core network will now be offered onto the NGN backbone carrier core network. As such, the capacity-management function for the NGN backbone carrier must use traffic planning information pertaining to the VPN services in addition to all the other service types supported on the NGN. This aggregated view of traffic demands will accelerate the core capacity dimensioning on the NGN backbone carrier network.

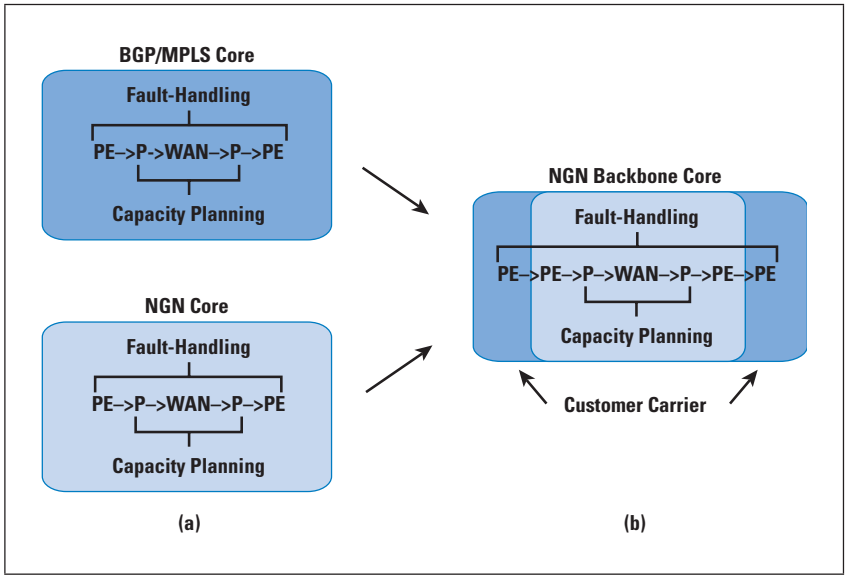


Figure 6: Fault-Management and Capacity-Planning Functions (a) Before Core Integration (b) After Core Integration with CsC

Conclusions

The MPLS-based Carrier-supporting-Carrier (CsC) framework provides network operators with a potential solution for integrating an existing BGP/MPLS VPN network, with a target all-IP based NGN. This solution should enable both capital and operational cost reduction by collapsing multiple core networks into a single NGN core domain. The article emphasised that as well as understanding the critical network architectural building blocks required to implement CsC, there are numerous critical design and operational challenges that an integrated core network presents. These challenges include how to maintain service levels and performance metrics for existing VPN customers, resiliency, fault management, and capacity planning. It is important to note, however, that in addition to the broad topic areas covered in this article, many specific additional challenges will present themselves to network operators who have implemented BGP/MPLS VPN networks, and/or NGN networks in their own specific way.

He joined BT at Martlesham Heath, Ipswich, UK, in September 1996, and worked on various aspects of broadband transmission architectures, multi-service platforms, and 3G network design. In 2000, he joined MCI-WorldCom in Cambridge, UK, and led a number of projects on IP backbone network design. In 2003, he returned to BT to work on IP VPN infrastructure design. He is currently the design authority for BT Retail's Internet networks. He can be reached at: **paul.veitch@bt.com**

PAUL HITCHEN holds a B.Eng. in Electrical and Electronic Engineering from the University of Salford. He joined BT at Martlesham Heath in September 1990 and has worked on numerous aspects of BT's data services. From 1990 to 1997 he led the development of BT's multiprotocol router portfolio, developing routing and QoS functions with BT's equipment suppliers and provided consulting to BT's customers on IP and Ethernet networks. During the same period he worked on the introduction of Frame Relay, ATM, and SMDS WAN services for BT. In 1997 he developed BT's first IP VPN service offering, working on the development and standardisation of MPLS and VPN technology. From 1997 to the end of 2006 he led the design of BT's Global MPLS Network and service, expanding the network to provide service to more than 150 countries across the world. He is currently a principal consultant working on BT's 21CN IP/MPLS network, focusing on the integration of BT's networks onto 21CN and introducing content delivery and IPTV into the network. He can be reached at: **paul.hitchen@bt.com**

MARTIN MITCHELL holds an M.Sci. from the University of Bristol and has worked for BT since 2007. He is currently an IP network designer specializing in service provider core design, Ethernet access, and network migrations. He can be reached at: **martin.3.mitchell@bt.com**

Letter to the Editor

Hi Ole,

I enjoyed the article entitled "PMIPv6: A Network-Based Localized Mobility Management Solution" in the last issue of *The Internet Protocol Journal* (Volume 13, No. 3, September 2010).

I believe that in the "Security Considerations" section it should be mentioned that the CSI (Cga & Send maIntenance) working group in the IETF is also working on updating the *Secure Neighbor Discovery* (SEND) specification (RFC 3971) to include the possibility of authenticating the proxied *Neighbor Discovery* (ND) messages sent between the terminal, the *Mobile Access Gateway* (MAG), and the *Local Mobility Anchor* (LMA). This configuration should work in addition to the proposed *IP Security* (IPsec) tunnel between the MAG and the LMA.

The reference material is available at:

https://datatracker.ietf.org/doc/draft-ietf-csi-proxy-send/

https://datatracker.ietf.org/doc/draft-ietf-csi-send-cert/

Regards,

—*Roque Gagliano, Cisco Systems*
rogaglia@cisco.com

One of the authors responds:

Dear Ole and Roque,

Thanks for reading our article and providing these valuable comments. We agree with your point. We just considered the basic security mechanisms in our article, limiting the scope to the protocols already standardized, which cover only the protection of the MAG-LMA signaling. We agree that the efforts being carried out within the CSI working group are worth mentioning with regard to the security aspects of PMIPv6.

Thanks,

—*Carlos J. Bernardos, Universidad Carlos III de Madrid*

Book Review

A History of the Internet

A History of the Internet and the Digital Future, by Johnny Ryan, Reaktion Books, ISBN 978 1 86189 777 0, September 2010.

Any attempt to document a 50-year history of people and activities that had such a profound and global effect as the Internet faces some challenges. Sequences are complex; written source materials are sketchy; and the many different memories conflict. Added to this reality, of course, are legitimate disagreements about intents and effects. To evaluate such writing effort means first looking for useful criteria. Here are mine: In terms of basic research, was the effort extensive, looking for multiple, appropriate sources and exploring a wide range of probing and constructive questions? Were the sources and questions interesting? This line of thinking leads to a query about the way the author integrates the resulting massive body of data. Is there an effort to develop critical analyses? Are alternative explanations explored?

Johnny Ryan's ambitious *A History of the Internet and the Digital Future* is a rather modest 246 pages, including 28 pages of references. Overall my feeling is that he does quite an interesting job of satisfying the first half of his title, but a somewhat disappointing job with the second half. His research was extensive throughout, but he takes a more critical view of the history than he does of the social aspects of our digital future. In the first half, he integrates information and reports discrepancies and curiosities. In the second half, he indulges in the common, wide-eyed wonderment that technology futurist efforts inherently risk. (Full disclosure: By way of demonstrating the thoroughness of his research, Ryan even included me as one of his many sources.)

Organization

The book is divided into three parts. Broadly, they cover origins, growth, and social effects. Ryan's use of "centrifugal" is contrasted with "centripetal" and is meant to distinguish paradigmatic tensions between approaches that centralize control versus approaches that distribute it. (Oddly, neither of these pivotal terms is in the index.) On page 8 he sets the stage:

"Three characteristics have asserted themselves throughout the Internet's history and will define the digital age to which we must all adjust: The Internet is a centrifugal force, user-driven and open."

By "centrifugal" he means moving outward, away from centralized control. For me, the terminology proved distracting, because I kept hearing my 8th-grade science teacher condescendingly explaining that there is no physics force called centrifugal. Rather it is a perception of the interaction between inertia and centripetal force.

For those with less compulsive (or effective) science teachers, the analogy might prove more helpful, because the design choice really is central to the history of networking. The tension between centralized versus distributed has marked—and continues to mark—much of the development of networking. In fact, I wish Ryan had explored its continuation as much as he explored its effect on origins.

Early History

In general, Ryan presents a narrative with fine-grained detail of the different players who played a critical role in the creation and pursuit of packet switching and then its evolution to link independent networks and technologies[1]. Efforts to take credit for the former have often become quite public and unseemly; Ryan dissects the play of actors, the essence of their technical ideas, and the details of their activities with documentation and diligence, and even uncovers some discrepancies. He develops a narrative that I found intriguing, enlightening, and credible. What I especially liked was that he explored the organizational milieu in which the activities took place. So we hear of the origins of groups such as the *Advanced Research Projects Agency* (ARPA), Lincoln Labs, and The Rand Corporation; the social and political forces that created them; and the roles they played.

Narrative Arcs

The following is really the strength of this book: It develops narrative arcs about social, political, and organizational environments and the steps taken within them that moved along the path of the Internet. It explores who, when, how, and what, both overall and in detail. At its best, the book provides comparative perspective to help the reader understand what was risky and truly innovative and thereby understand what was really challenging to develop and get adopted. As a minor example, Ryan deserves credit for his exploration and debunking of the media distortions surrounding Al Gore's role and statements concerning the Internet. Strictly speaking, debunking media excesses would not normally seem relevant to a review of the history of a technology, but Ryan uses this example for some consideration of the role of politics in the development of the Internet. The U.S. government could have chosen to assume more control over the Internet; it might have quickly turned it into a telecommunications monopoly, rather than letting it develop through independent market forces.

As would be expected for a story this sweeping, Ryan is sometimes redundant and sometimes inconsistent. Overall, the book would have benefited from more careful editing. So it has a quick reference to the "invention" of e-mail messaging at Bolt Beranek and Newman, but later has a more accurate, detailed account of Ray Tomlinson's 1971 effort, there, to add networking to the *existing* e-mail mechanism. (E-mail messaging was present on the first time-sharing systems of the 1960s, but these systems were standalone services. Tomlinson got them to talk each other.)

Another touchstone I use for discussions of Internet history is the role of the *Computer Science Network* (CSNet), because I worked on that. CSNet served as the forerunner of the larger and more obviously pivotal *National Science Foundation Network* (NSFNet). With NSFNet the Internet developed the ability to support multiple backbones—essential for a truly competitive Internet—and the market-priming creation of regional operational services, from which the seeds of the commercial Internet were sown. Ryan notes the role of CSNet as a kind of market research that led to NSFnet, and in this observation his discussion is notable. But his account of CSNet details is somewhat skewed, because CSNet is cast as having full packet-level connectivity, with e-mail-only telephone-based linkages as a secondary service. In reality full connectivity came later; the original years of CSNet were e-mail-only. Why this fact is important to note—besides overly personal fault-finding—is as a reminder that the accounting efforts for this sort of history are always noisy; the story signal is never pure, even with a diligent effort.

A further touchstone topic is the *Domain Name System* (DNS) and the development of the *Internet Corporation for Assigned Names and Numbers* (ICANN). The interesting part of this saga is later-stage Internet history, and Ryan is relatively sloppy with the details. For example, he muddles what *generic Top-Level Domains* (gTLD) already existed and what new ones were proposed, such as `.com` versus `.biz`; he also muddles the distinction between gTLDs and national domains, such as `.uk`. On the other hand, he certainly captures the continuing tone of controversy that surrounded the development and operation of ICANN, the organization now managing assignment of IP addresses and domain names.

But the most obvious, later-stage touchstone for a history like this one must be the development of the World Wide Web. Ryan gets mixed marks here. He misses the long history of open document publishing that existed even in the earlier *Advanced Research Projects Agency Network* (ARPANET), with "anonymous" FTP, and he misses that the use of *Gopher* predated the web by several years. He also misses just how complete and useful a "dynamically linked document" system Doug Englebart's NLS (computer) system provided 20 years before the invention of the web[2]. Hence, he misses the long, historical arc for publishing on the Internet. On the other hand, he does discuss *Gopher* and explores some of the reasons it lost the competition to the web. He focuses on management and intellectual property issues, whereas I tend to consider *Gopher* as having a much poorer cost/benefit mix. *Gopher* was text-only and required going down a potential long lookup tree—quite a few "clicks"—before getting any content. The web is mixed-media and can provide utility to the reader—that is, content—at each step down a lookup path. So the web is more complex to develop than *Gopher,* but it provides enough additional power and better human factors to be worth it.

Ryan's discussion of the commercial explosive growth of the Internet is a good read, including the Dutch tulip market reference and his introduction to some relevant tidbits of economics theory. However, as the book moves into "Web 2.0" and beyond, it provides reasonable descriptions of who did what to create popular new services, but his critical eye largely stops providing serious analysis. Explanations sound more like exuberance than examination. On the other hand, he certainly provides substance to the view that the Internet enables "long-tail" market opportunities to discover and satisfy specialized segments. His discussion of politicians' inventive use of the Internet is nicely concise and integrated. Again, it provides a narrative arc with substance. But his predictions for the future of users as news consumers or as citizens in political processes have too much tone of certitude and positive outcome than is justifiable in my opinion.

Worth Reading

In sum, the book is certainly worth reading. You will likely learn quite a bit, but make sure you read with glasses that have no hint of rose coloring!

References

[1] Debating which milestone marks "the beginning of the Internet" is a favorite pastime, including among those around during the period in question. Various definitions are legitimate, as long as one is clear about the choice. For me, the operational demonstration of packet switching was when the world changed, so I choose 1969 and the first four nodes of the ARPANET; or its public demonstration in 1972. TCP/IP built on this, by refining and minimizing the work to be done within the infrastructure and by linking independent networks.

[2] In the early 1970s, my job at UCLA included technical documentation and supporting online use by the Computer Science Department's secretaries. We did all our editing remotely, on the Engelbart system, because it was so powerful.

Bjoern A. Zeeb Receives Second Itojun Service Award

The second Itojun Service Award was presented at the 79th meeting of the *Internet Engineering Task Force* (IETF) in Beijing, China. Bjoern A. Zeeb received the award for his dedicated work to make significant improvements in open source implementations of IPv6.

First awarded last year, the *Itojun Service Award* honours the memory of Dr. Jun-ichiro "Itojun" Hagino, who passed away in 2007, aged just 37. The award, established by the friends of Itojun and administered by the *Internet Society* (ISOC), recognises and commemorates the extraordinary dedication exercised by itojun over the course of IPv6 development.

"For many years, Bjoern has been a committed champion of, and contributor to, implementing IPv6 in open source operating systems used in servers, desktops, and embedded computer platforms, including those used by some of the busiest websites in the world," said Jun Murai of the Itojun Service Award Committee and Founder of the WIDE Project. "On behalf of the Itojun Service Award Committee, I am extremely pleased to present this award to Bjoern for his outstanding work in support of IPv6 development and deployment."

The Itojun Service Award is focused on pragmatic contributions to developing and deploying IPv6 in the spirit of serving the Internet. The award, expected to be presented annually, includes a presentation crystal, a US$3,000 honorarium, and a travel grant.

"This is a great honour, and I would like to thank the people who recommended me for the award and the committee for believing my work was valuable. I never met Itojun but he was one of the people helping me, and I have the highest respect for his massive foundational work," said Bjoern A. Zeeb. "As the Internet community works to roll out IPv6 to more and more people all around the globe, we also need to help others—developers, businesses, and users—understand and use the new Internet protocols so that the vision Itojun was working so hard for comes true."

Each Internet-connected device uses an IP address and, with the number of Internet-connected devices growing rapidly, the supply of unallocated IPv4 addresses is expected to be exhausted within the next year. To help ensure the continued rapid growth of the Internet, IPv6 provides a huge increase in the number of available addresses. And, while the technical foundations of IPv6 are well established, significant work remains to expand the deployment and use of IPv6.

For more information about the Itojun Service Award see:
`http://www.isoc.org/itojun/`

Remaining IPv4 Address Space Drops Below 5 percent

The *Number Resource Organization* (NRO) recently announced that less than five percent of the world's IPv4 addresses remain unallocated. APNIC, the Regional Internet Registry for the Asia Pacific region, has been assigned two blocks of IPv4 addresses by the *Internet Assigned Numbers Authority* (IANA). This latest allocation means that the IPv4 free pool dipped below 10% in January 2010. Since then, over 200 million IPv4 addresses have been allocated from IANA to the *Regional Internet Registries* (RIRs).

"This is a major milestone in the life of the Internet, and means that allocation of the last blocks of IPv4 to the RIRs is imminent," stated Axel Pawlik, Chairman of the NRO, the official representative of the five RIRs. "It is critical that all Internet stakeholders take definitive action now to ensure the timely adoption of IPv6."

IPv6 is the "next generation" of the Internet Protocol, providing a hugely expanded address space, which will allow the Internet to grow into the future. In 2010, the five RIRs are expected to allocate over 2,000 IPv6 address blocks, representing an increase of over 70% on the number of IPv6 allocations in 2009. In contrast, the number of IPv4 allocations is expected to grow by only 8% in 2010. These statistics indicate an absence of any last minute "rush" on IPv4 addresses, and a strong momentum behind the adoption of IPv6.

"The allocation of Internet number resources by the five RIRs enables every region in the world to benefit from fair and equitable distribution of IPv4 and IPv6 addresses. We are also actively collaborating with stakeholders at the local, regional, and global level to offer training and advice to public and private sector organisations on IPv6 adoption to ensure that everyone is prepared for IPv4 depletion and IPv6 deployment," added Pawlik.

The IANA assigns IPv4 addresses to the RIRs in blocks that equate to 1/256th of the entire IPv4 address space (each block is referred to as a "/8" or "slash-8"). The most recent assignment means that there are now only 12 of these blocks available, which is less than five percent of the entire IPv4 address pool.

The final five blocks of IPv4 addresses will be distributed simultaneously to the five RIRs, leaving only seven blocks to be handed out under the normal distribution method.

According to current depletion rates, the last five IPv4 address blocks will be allocated to the RIRs in early 2011. The pressure to adopt IPv6 is mounting. Many worry that without adequate preparation and action, there will be a chaotic scramble for IPv6, which could increase Internet costs and threaten the stability and security of the global network.

The NRO exists to protect the pool of unallocated Internet numbers (IP addresses and AS numbers) and serves as a coordinating mechanism for the five RIRs to act collectively on matters relating to the interests of RIRs. For further information, visit **http://www.nro.net**

The RIRs are independent, not-for-profit membership organizations that support the infrastructure of the Internet through technical coordination. There are five RIRs in the world today. Currently, the IANA allocates blocks of IP addresses and ASNs, known collectively as *Internet Number Resources,* to the RIRs, who then distribute them to their members within their own specific service regions. RIR members include *Internet Service Providers* (ISPs), telecommunications organizations, large corporations, governments, academic institutions, and industry stakeholders, including end users.

The RIR model of open, transparent participation has proven successful at responding to the rapidly changing Internet environment. Each RIR holds one to two open meetings per year, as well as facilitating online discussion by the community, to allow the open exchange of ideas from the technical community, the business sector, civil society, and government regulators. Each RIR performs a range of critical functions including: The reliable and stable allocation of Internet number resources (IPv4, IPv6 and *Autonymous System Number* resources); The responsible storage and maintenance of this registration data; The provision of an open, publicly accessible database where this data can be accessed. RIRs also provide a range of technical and coordination services for the Internet community. The five RIRs are:

From The Editors

In 2011 we have already seen some important Internet anniversaries and milestones. We have celebrated 25 years of IETF meetings and 40 years of the FTP protocol, but the most significant milestone took place in February when IANA handed out its final blocks of IPv4 addresses to the RIRs (see page 21). It seems like a good time to publish an edition of IPJ devoted entirely to IPv4/IPv6 transition, and to help me with this task I have invited Geoff Huston as co-editor and author for this issue, so let me hand it over to him:

There is a Chinese proverb that states: 寧為太平犬，不做亂世人 "It's better to be a dog in a peaceful time than be a man in a chaotic period." For the Internet, this year is shaping up to be a time that looks more like developing chaos than serenity and peace. The IANA has given out the last /8's, and demand has already depleted the IPv4 address stocks in the Asia Pacific. Meanwhile, the industry has discovered the mass marketing potential of mobile devices, and expects to sell and connect more than 250 million of them in 2011 alone.

The IETF designed IPv6 in the 1990s for this very reason. Its 128-bit address field is easily capable of accommodating the output of a prolific silicon manufacturing industry for many decades to come. But when we look at today's Internet, very little IPv6 can be seen. Estimates of the number of clients with functional IPv6 services hover at around 0.2 to 0.4 percent of the total.

The story about IPv6 transition technologies is complex, and there are many ways to undertake this effort. In this issue we will examine the various approaches and their relative strengths and weaknesses.

In order to send out a broad message about the need to shift online content from exclusively using IPv4 into a dual-stack world of both IPv4 and IPv6, ISOC is supporting *World IPv6 Day* on June 8. Phil Roberts explains this initiative and its role in helping the overall transition effort.

This transition is going to be difficult. It involves all parts of this diverse industry, and means combining some well-understood and widely-deployed technologies in some surprising and challenging ways. There is much to do, and we hope that this issue of IPJ provides an insight into just what the transition to IPv6 will entail.

A Rough Guide to Address Exhaustion

by Geoff Huston, APNIC

The level of interest in IPv4 address exhaustion seems to be increasing, so I thought I would share some answers to the most common questions I have been asked on this topic in recent times.

What is the most significant challenge to the Internet today?

What a wonderfully open-ended question! There are so many challenges that I could identify: improving the level of security on the network, eradicating spam and viruses, improving capacity of the network infrastructure, improving the efficiency of high-speed data transfer, improving the accuracy of search engines, building more efficient and high-capacity data centers, and reducing the unit cost of Internet services, to name but a few.

If there is a common factor in many of these challenges, it is *scaling* the network to meet an ever-expanding agenda of more users, more devices, more traffic, more services, and more policies. And with more users and more forms of use come higher levels of diversity of use and greater need to replace implicit mechanisms of trust with explicit forms of trust negotiation and greater levels of demonstrable integrity of operation.

But these topics are all tactical in nature. They reflect the "how" of making the network work tomorrow by studying how to undertake marginal improvements on the network of today. However, it is not clear that the networks not just of tomorrow or next year, but a decade or more hence should reflect the usage patterns and user population of today. Perhaps a more fundamental challenge is to understand what is missing in today's network that we will need in the future.

This discussion leads to a pretty obvious challenge, at least for me. The basic currency of any network is *identifiers*. Identifiers allow the network to distinguish between clients and ensure that conversations occur between those parties who intended to communicate. In the world of packet-switched networking, such as IP, these endpoint identifiers are synonymous with the concept of an *address*. What is missing in today's network is an abundant supply of new addresses that will allow the network to scale up in size by a further factor of at least 1 million, and hopefully more than a billion-fold.

In fact, the supply of addresses is not just inadequate for future needs for a decade hence. The stock of addresses is facing imminent depletion, and the question of availability of addresses is best phrased in terms of months rather than years.

Perhaps the term "address" is somewhat of a misnomer in this context, but it may well be too late to change that now. The primary role of an IP address is not to uniquely identify the location of an endpoint of a network in relation to some positional or topographical coordinate set, but to simply uniquely identify an endpoint to distinguish it from all other endpoints. Its location is not an intrinsic property of this so-called *address*. But common convention is to call these endpoint identifiers "addresses," so I will stick with the same convention here.

So my candidate "most significant challenge for the Internet today" is that we are running out of further supply of IP addresses.

What is an IP address, and why is it so important?

One of the revolutionary changes introduced by the so-called *packet-switched* network architecture of the Internet—as compared to its telephone predecessor that used *circuit switching*—was that a massive amount of "intelligence" was ripped out of the network and placed into the devices that connect at the edge.

IP networks are incredibly simple, and at their most basic level they do very little. They are built of routers and interconnecting conduits. The function of a router is quite simple. As a packet arrives at the router from the connected circuitry (or from a wireless interface), it is divided into a common IP header and a payload. The IP header of the packet contains, among other components, two fixed-length fields: the address of the intended *destination* of the packet, and, like a postal envelope, the address of the packet creator, or the *source*. The router uses the destination address of the packet to make a routing decision as to how to dispose of the packet. For each incoming packet, the router inspects the destination address in the packet and either passes it to a connected computer if there is an address match or otherwise passes it down the *default* path to the next router. And that is a working description of the entirety of today's Internet. The important aspect here is that every connected device must have a unique address. As long as this condition is satisfied, everything else can be made to work.

In the current version of the Internet Protocol, an "address" is a 32-bit field, which can encompass some 4.4 billion unique values.

Why are we running out of addresses?

Blame silicon. Over the past 50 years, the silicon chip industry has graduated from the humble transistor of the 1950s to an astonishing industry in its own right, and the key to this silicon industry is volume.

Individual processor chips may take hundreds of millions of dollars to design, but if fabricated in sufficient volume, each processor chip may take as little as a few dollars to manufacture and distribute. The larger the production run of the silicon die, the lower the unit price of the resultant chip. We currently produce a huge volume of computers every year. In 2008 alone around 10 billion computer processors were manufactured. Although most of these microprocessors are simple 8-bit processors that are used to open doors or run elevators, a sizable proportion are used in devices that support communications, whether it is in laptop computers, smartphones, or even more basic communication applications. Typically we do not invent a new communications protocol for each new application. We recycle. And these days if we want a communications protocol for a particular application, it is easiest to simply embed the IP protocol engine onto the chip. The protocol is cheap, well tested, and it works across almost any scale we can imagine from a couple of bits per second to a couple of billion bits per second.

So it is not just the entire human population of the planet who may well have a desire to access the Internet in the future, but equally important is the emerging world of "things" that communicate. Whether it is the latest fashion in mobile phones or more mundane consumer electronics devices such as televisions or games consoles, all these devices want to communicate, and to communicate they need to have a unique identification code to present to the network, or, an "address."

We are presently turning on more than 200 million new Internet services every year, and today we have used up most of the 4.4 billion addresses that are encompassed by the IP protocol.

When will we run out?

As of September 2010, some 151 million addresses were left in the general-use pool of unallocated addresses that are managed by the central pool administration, the *Internet Assigned Numbers Authority* (IANA). The world's IP address consumption rate peaked earlier this year at a new all-time high of an equivalent rate of 243 million addresses per year.

By early February 2011 IANA handed out its last address blocks to the RIRs.

The five *Regional Internet Registries* (RIRs)[1] still had pools of addresses available for general use at that time, but from that point, as they further run down their local pools, the IANA is now unable to provide any more addresses to replenish them. The Asia Pacific Regional Registry, APNIC, has been experiencing the highest level of demand in the world, accounting for some two-thirds of all addresses consumed in early 2011. APNIC exhausted its general use IPv4 address pool in April 2011.

Although the current models of address consumption show that the other regions will be able to manage available address pools for a few more months, this prediction does not account for the multi-national nature of many of the largest of the service providers, and at this stage it is not known how much address-consumption pressure will shift outward from APNIC to the other RIRs now that APNIC's available address pool is effectively drained. So it may well be that 2011 will see IPv4 addresses cease to be generally available in many parts of the world, and by early 2012 there will be no further generally available IPv4 addresses in Europe, North America and Asia.

What is the plan?

This news of imminent exhaustion of the supply of addresses is not a surprise. Although the exact date of predicted address exhaustion has varied over time, the prospect of address exhaustion was first raised in technical circles in August 1990, and work has been undertaken since that time to understand what might be possible and how that could be achieved.

The 1990s saw an intense burst of engineering activity that was intended to provide a solution for this forthcoming address problem. The most significant outcome of this effort was the specification of a successor IP protocol to that of IPv4, called IP Version 6 or *IPv6*.

Why IPv6 and not IPv5?

It would be reasonable to expect the successor protocol of IP Version 4 to be called IP Version 5, but as it turned out Version 5 of the Internet Protocol Family was already taken. In the late 1980s the Internet Protocol itself was the topic of a considerable level of research, as researchers experimented with different forms of network behavior. Version 5 of the Internet Protocol was reserved for use with an experimental IP protocol, the *Internet Stream Protocol, Version 2* (ST-II), written up as RFC 1190 in 1990. When it came time to assign a protocol number of the "next generation" of IPv4, the next available version number was 6, hence IPv6.

The outcome of this process was a relatively conservative change to the IP protocol. The major shift was to enlarge the address fields from 32 bits to 128 bits in length. Other changes were made that were thought to be minor improvements at the time, although hindsight has managed to raise some doubts about that!

The design intent of IPv6 is a usable lifetime of more than 50 years, as compared with a "mainstream" deployment lifetime of IPv4 of 15 years, assuming that you are prepared to draw a line at around 1995 and claim that at that time the protocol moved from an interesting academic and research project to a mainstream pillar of the global communications industry.

That 50 years of usable life for IPv6 is admittedly very ambitious, because it is intended to encompass a growth of the ubiquity of silicon from the current industry volumes of hundreds of millions of new connected devices every year to a future level of activity that may encompass in the order of hundreds of billions to possibly some trillions of new connected devices every year.

So the technical plan to address the address-exhaustion problem was to perform an upgrade of the Internet and convert the Internet from IP Version 4 to IP Version 6.

Nothing else needs to be changed. This change is not intended to be radical or revolutionary. The change from circuit switching to packet switching was a revolutionary change for both the communications industry itself and for you and me as enthusiastic communicators. The change from IPv4 to IPv6 is intended to be a polar opposite, and at best it is intended to be a transparent and largely invisible transition. E-mail will still be e-mail. The web should still look just as it always did, and anything that works on IPv4 is expected to work on IPv6. IPv6 is not inherently any faster, nor any cheaper, nor is it even all that much better. The major change in IPv6 is that it supports a much larger address field.

How many addresses are in IPv6?

In theory, there are 2 to the power 128 unique addresses in IPv6—a very large number. If each IPv6 address were a single grain of sand, the entire IPv6 address space would construct 300 million planets, each the size of the earth!

But theory and practice align only in theory. In practice the IPv6 address plan creates a usable span of addresses that encompasses between 2 to the power 50 and 2 to the power 60 devices. Although this number is nowhere near 2 to the power 128, it is still a range of numbers that are between 1 million to 1 billion times the size of the IPv4 address space.

How do we transition to IPv6?

Unfortunately IPv6 is not "backward-compatible" with IPv4. Backward compatibility would allow for a piecemeal transition, where IPv6 could be regarded as a fully functional substitute for IPv4, so that the existing network base would keep using IPv4 forever, while the most recent devices would use IPv6 and all devices could communicate with each other. The lack of such backward compatibility implies that this communication is simply not possible. IPv4 and IPv6 are distinct and different communications protocols, in the same way that English and, say, German are distinct and different languages.

Attempts have been made to design various forms of automated protocol translator units that can take an incoming IPv4 packet and emit a corresponding IPv6 packet in the same manner as a language interpreter. However, this approach also has some major limitations, so it is usable only in very carefully constrained contexts.

The implication of this lack of backward compatibility and inability to perform automated translation within the network is that if we want to preserve comprehensive any-to-any connectivity during the transition, we have to equip each device that is performing a transition with both protocol stacks, or, in effect, allow the device to become "bilingual," and conduct a conversation in either IPv4 or IPv6, as required. This transition has been termed a *dual-stack* transition.

When my computer supports IPv6, can I return my IPv4 address?

Each device needs to maintain its capability to converse using IPv4 while there are still other devices out there that remain IPv4-only. So a device that becomes IPv6-capable cannot immediately give up its IPv4 address. It will need to keep this IPv4 capability and operate in dual-stack mode for as long as there are other devices and services out there that are reachable only using IPv4.

The implication of this constraint is that we will need to add dual-stack devices to the Internet and consume both IPv4 and IPv6 addresses during this transition.

So, no, you will need to keep your IPv4 address for as long as there are folk out there with whom you want to communicate who have not also migrated to be a dual-stack IPv4- and IPv6-capable entity.

What needs to be done to transition the network to IPv6?

What is encompassed in "transition?" Do all *Internet Service Providers* (ISPs) have to decide when and how to reprogram their systems and reconfigure their routers, switches, and middleware? Will they need to replace all their customers' modems with ones that support IPv6? What is the agenda?

This level of uncertainty about the transition to IPv6 is evidently widespread in today's Internet. Most of the actors in the Internet are unsure about what needs to be done, from the largest of the service providers down to individual end users. Yes, it appears to be a simple matter of reprogramming devices from being just IPv4-capable to being capable of supporting both IPv4 and IPv6, but it is not quite so simple. Dual-stack operation is not easy, nor will it just happen without any form of applied impetus. Imagine that this transition is from everyone on the planet speaking Latin to each other to everyone speaking Esperanto. If this situation were a simple matter of everyone stopping using one language and being rebooted to use the other language one by one, then imagine the plight of the first people to undertake this transition—from being connected and being able to communicate with everyone else using Latin, these first users would find themselves speaking exclusively Esperanto to ... nobody! They would in effect have been disconnected from the network.

So the transition is a little trickier than just turning a big switch from IPv4 to IPv6. Because this transition is a piecemeal and fragmentary one, each device, each router, each firewall, each load server, and all those other components of the network service platform need to be programmed with an additional protocol, and become, in effect, bilingual. And in this case there are no magic interpreters that can "translate" between IPv4 and IPv6. So it is only when the entire network is bilingual in a dual-stack mode that we can turn off IPv4 and consider the transition to be complete.

For an extended period of time the Internet is going to have to operate as two Internets. We have never tried that type of operation before, at least not on a grand scale as this one; in fact, it has often been likened to replacing the jet engines of an airplane while the plane is in flight. Somehow we now have to not only sustain a growth rate of at least some 250 million new connections per year, but at the same time retrofit IPv6 to the existing installed base while continuing to support IPv4. The complexity of this operation is significant, and there is considerable confusion about what to do, when to do it, how much it will all cost, and who will pay. So yes, we are all unsure about what needs to be done.

How long do we expect this dual-stack transition to take?

If only we knew! The Internet today encompasses some 1.7 billion users, and hundreds of millions of devices out there are configured to "talk" only IPv4. Some of these devices will surely die in the coming years, and others may be upgraded or reprogrammed, but others will persist in operation for many years to come while continuing to speak only IPv4. Even looking at what is being sold today, although many general-purpose computers (or at least their operating systems) are now configured to operate in dual-stack mode, when you look at embedded devices such as *Digital Subscriber Line* (DSL) or cable modems, or firewalls, or a myriad of other devices that are integral to the operation of today's Internet, many of these devices are still configured in firmware to operate exclusively using IPv4.

Some modeling of the transition process has projected an 80-year transition process. That projection is heading into the realms of the absurd, given that our expectations for the operational lifespan of IPv6 have a lower bound of just 50 years or so. However, given the sheer scope of the conversion task and the current level of penetration of IPv6 to levels of between 2 and 5 percent of today's Internet, and given that a deadline of 2 years from now implies a conversion rate of in excess of 1 million devices every day in that 2-year span. It seems that an expectation that this transition could be substantially completed in as little as 2 years also strikes an unrealistic note.

So a more realistic assumption is that we will probably take around 5 years to complete this transition, and we will need to operate the Internet in dual-stack mode with both IPv4 and IPv6 across this entire period.

But at the current level of Internet growth, the IPv4 address pool cannot sustain a further 5 years of growth—at least not with the current amount of unallocated addresses remaining in the allocation pools. The current address-consumption rate is some 250 million addresses per year. The depleted IPv4 address pool simply cannot withstand the pressures of a 5-year transition without a radical change to the model of the IPv4 network. And if we need to rework the model of the IPv4 network simply to sustain a transition to IPv6, then can't we simply get going with IPv6 a little more quickly instead?

However, "fully depleted" or even "run out" is perhaps not the most appropriate way to describe what will happen to IPv4 addresses in the coming months. It is probably more accurate to say "unobtainable at the current prices." When the current orderly process of allocation of IPv4 addresses comes to an end, that does not mean that IPv4 addresses will be completely unobtainable. In this world many things that are scarce are still obtainable—for a price. It is quite reasonable to anticipate that for as long as there is still a demand for IPv4 addresses there will be some form of "aftermarket" where addresses are traded for money. However, as with many markets, what is not possible to predict is the price for addresses that will be established by such a market-based address-trading regime.

What about "address sharing" in IPv4? Why do we need IPv6, given that we could simply share addresses in IPv4?

Yes, of course address sharing[2] is an option, and we have been doing it for many years already in IPv4. But is it a viable substitute for IPv6?

As part of the engineering effort to develop a successor protocol to IPv4 in the mid 1990s, the IETF published a novel approach of *address sharing,* which we call today *Network Address Translation,* or NAT.[3] These days almost every DSL modem, and other forms of customer connection equipment, comes equipped with NAT functions. Today most Internet Service Providers give their subscribers a single IPv4 address. At home I have a single IPv4 address, and you probably do too. But in my home I have about 20 connected devices of various sorts (I am counting TiVo units, game consoles, televisions, printers, and such, because they are all in essence Internet-connected devices, and I believe that my situation is not unusual). All these devices "share" the single external IP connection, so all of them "share" this single IPv4 address.

But address sharing has its limitations. When a single household shares a single address, nothing unusual happens. But If I were to try to do the same address-sharing trick of using a single IP address to share across, say 2,000 customers, I would cross over into a world of pain. Many applications today gain speed through parallelism, and they support parallelism through consuming port addresses.

Each IP address can support the parallel operation of 65,535 sessions, using a 16-bit *port identifier* as the distinguishing identifier. But when address sharing is used, these ports are shared across the number of devices that are all sharing this common address. When 2,000 customers are sharing a single address and each customer has some 20 or so devices, then the average number of port addresses per device is 1.5. Common applications that exploit parallel operation include such favorites as *Gmail, Google Maps,* and *iTunes*. With a sufficiently constrained number of available ports to use, these applications would cease to work. Indeed, many network applications would fail, and at a level of a single address shared across 2,000 households, I would guess that up to half of these 2,000 customers would not have a working Internet at any single point in time.

Our experience suggests that address sharing works only up to a point, and then it breaks everything badly. We are already address sharing at the level of sharing a single address per household, and households are these days buying more connected devices of various sorts, not *fewer*. So attempting to share that single address across more than one household is at best a temporary solution, and is not a sustainable option that is an alternative to IPv6.

So we need to transition to IPv6, and we need to do so within an impossibly short time.

This discussion all sounds like a terrible problem.
Was this global "experiment" with the Internet all one big mistake?
Should we have looked elsewhere for a networking technology back in the 1990s?

The IP address problem is—for me at any rate—a fascinating one. At the time when researchers were working on the specifications for the Internet Protocol in the 1970s, they decided to use fixed-length 32-bit fields of the interface identifier addresses in the protocol. This decision was a radical one at the time. Contemporary network protocols, such as *DECnet Phase III,* used 16-bit address lengths, and 8-bit addresses were also very common at the time. After all, computers were so big and expensive, who could possibly afford more than 256 unique devices in a single network? Eight bits for addresses was surely enough! Using 32 bits in the address field was not an easy decision to make, because there was constant pressure to reduce the packet headers in order to leave more room for the data payload, so to reserve such a massive amount of space in the address fields of the protocol header to allow two 32-bit address fields was a very bold decision.

However, it was a decision that has proved to be very robust. TCP/IP has sustained the Internet from a mere handful of warehouse-sized computers running at mere kilobits per second to today, where probably more than 3 billion devices connect to the Internet in one way or another, at speeds that range from a few hundred bits per second to a massive 100 Gbps—all talking one single protocol that was invented more than 30 years ago.

IP has demonstrated a scale factor 1 billion! In my mind that achievement demonstrates a level of engineering foresight that is truly phenomenal. So in some sense the underlying observation here is not that IPv4 is running out of addresses today, but that it has been able to get to today at all!

Given that IPv4 has been able to scale by a factor of 1 billion, then if we can make IPv6 scale by a further factor of 1 billion from today we will have done well.

World IPv6 Day

by Phil Roberts, ISOC

On June 8, 2011, websites including *Google, Facebook, Yahoo!,* and *Bing* will make their main webpages reachable over IPv6 for a 24-hour period from 00:00 to 23:59 *Coordinated Universal Time* (UTC). This activity, *World IPv6 Day,* a "test flight" of IPv6, is motivating organizations across the Internet industry to prepare their services for IPv6, the next generation of the Internet Protocol. Internet Service Providers, hardware makers, operation system and application vendors, and other websites are indeed working to make this activity of testing IPv6 on an Internet scale successful.

The Internet is a never-ending exercise in collaboration. Making a successful transition to IPv6 is one of the major challenges facing the Internet today. Although IPv6 is used extensively in many large networks today, the World IPv6 Day activity is acting as a focal point to bring together all parts of the Internet industry to accelerate deployment of IPv6 in all parts of the Internet.

For some time the deployment of IPv6 has faced a "chicken-and-egg problem." Website owners have been reluctant to deploy IPv6 because there were not many end users to view their webpages over IPv6. Network operators have been hesitant to deploy IPv6 for many end users because there were few places for those users to view content over IPv6. That the most popular websites in the world according to Alexa rankings are deploying IPv6 on their main webpages is a clear indication that the Internet industry is moving beyond this long-standing impasse. Although June 8 is a 24-hour test, it is clear that this is a move toward regular operation of IPv6, and network operators can confidently roll out IPv6 to end users knowing that the Internet industry is making a concerted effort to make IPv6 an operational reality.

Today, IPv6 connectivity concerns provide another disincentive for a major website to enable IPv6 for regular operation. Badly configured or poorly behaving implementations may prevent end users from reaching a major website that enables IPv6 on its main page. It is currently estimated that this problem will affect only a minor percentage of end users—at the time of the announcement of World IPv6 Day, the estimate was that only 0.05 percent of end users would experience difficulties.

Although this percentage is small, it is potentially a very large number of end users for a website that has visitors numbering in the tens of millions (or more). It is simply impossible from a business point of view for a website of this magnitude to deploy IPv6 alone when this many users could be affected. The users who would not be able to get to that website will simply go to another website in search of similar services.

However, because several such websites have agreed to do this testing at the same time, and for the same duration, individual end users who experience disruption of their connectivity by IPv6 may be able to determine that the problem they are experiencing is indeed not a problem with a set of major websites but may, in fact, be a problem in their own host or network, and will provide an incentive for them to take steps to determine the source of the problem and repair it.

Website owners, network operators, and hardware and software vendors are collaborating to minimize these effects leading up to World IPv6 Day. All of these organizations are working to provide tools to detect these problems and offer suggested fixes in advance of June 8. The test site **http://test-ipv6.com/** allows end users today to test their connectivity and determine whether their connectivity to websites will be affected when those websites enable IPv6.

Some websites have already performed a similar 24-hour test. Last year, the German online news site Heise (**http://www.heise.de**) conducted a similar experiment. The site enabled IPv6 on its main page for 24 hours, turned it off, examined the effects of the experiment, and then permanently enabled IPv6 on its main page. Two major websites in Norway did a similar test, and they also have enabled IPv6 permanently. An activity like this for many websites is clearly a step toward regular and normal IPv6 operations. Website owners will, of course, determine when it makes sense for their business to make IPv6 operations available permanently.

Since the announcement of World IPv6 Day, many other websites from around the world have indicated that they are deploying IPv6, and many of those have decided to join in the global IPv6 test on June 8. The list of websites includes major websites such as *Google, Facebook,* and *Yahoo!* and very small websites with small numbers of visitors. It is exciting that websites from every inhabited continent plan to participate. Major websites from the Czech Republic, Portugal, Brazil, and Japan, for example, are joining this test, with more websites joining every day.

For further information about World IPv6 Day, please visit:
http://www.isoc.org/wp/worldipv6day

There you will find details about the websites that will be turning on IPv6 on June 8, how to join, and information for networks and individuals, including an FAQ.

Transitional Myths

by Geoff Huston, APNIC

Last October, I attended the *Réseaux IP Européens* (RIPE)[1] meeting in Rome, and—not unexpectedly for a group that has some interest in IP addresses—the topic of IPv4 address exhaustion, and the related topic of the transition of the network to IPv6, captured a lot of attention throughout the meeting. One session I found particularly interesting was on the transition to IPv6, where people related their experiences and perspectives on the forthcoming transition to IPv6.

I found the session interesting, because it exposed some commonly held beliefs about the transition to IPv6, so I will share them here, and discuss a little about why I find them somewhat fanciful.

Myth 1: "We have many years for this transition."

No, I don't think we do!

The Internet is currently growing at a rate that consumes some 200 million IPv4 addresses every year, or 5 percent of the entire address IPv4 pool. This growth rate reflects an underlying growth of service deployment by the same order of magnitude of some hundreds of millions of new services activated per year. Throughout a dual-stack transition, all existing services will continue to require IPv4 addresses, and all new services will also require access to IPv4 addresses. The pool of unallocated addresses was exhausted in February 2011, and the *Regional Internet Registries* (RIRs)[2] will exhaust their local pools commencing early 2011 and through 2012. When those pools exhaust, then all new Internet services will need access to IPv4 addresses as part of the IPv4 part of the dual-stack environment, but at that point there will be no more freely available addresses from the registries. Service providers have some local stocks of IPv4 addresses, but even those stocks will not last for long.

As the network continues to grow, the pressure to find the equivalent of a further 200 million or more IPv4 addresses each year will become acute—and at some point will be unsustainable. Even with the widespread use of *Network Address Translators* (NATs)[3] and further incentives to recover all unused public address space, the inexorable pressure of growth will cause unsustainable pressures on the supply of addresses.

It is unlikely that we can sustain 10 more years of network growth using dual stack, so transition will need to happen faster than that. How about 5 years? Even then, at the higher level of growth forecasts, we will still need to flush out the equivalent of 1.5 billion IPv4 addresses from the existing user base to sustain a 5-year transition, and this number seems to be a stretch target. A more realistic estimate of transition time, in terms of accessible IPv4 addresses from recovery operations, is in the 3–4 year timeframe, and no longer.

So no, we do not have many years for this transition. If we are careful—and a bit lucky—we will have about 4 years.

Myth 2: "It is just a change of a protocol code. Users will not see any difference in the transition."

If only that were true!

In an open market environment, scarcity is invariably reflected in price. For as long as this transition lasts, this industry is going to have to equip new networks and new services with IPv4 addresses, and the greater the scarcity pressure on IPv4 addresses, the greater the scarcity price of IPv4 addresses. Such a price escalation of an essential good is never a desirable outcome, and although numerous possible measures can be taken to mitigate the problem, to some extent or other, the scarcity pressure and the attendant price escalation suggest a reasonable expectation of some level of price pressure on IPv4 addresses.

In addition, an *Internet Service Provider* (ISP) may not be able to rely solely on customer-owned and-operated NATs to locally mask out some of the incremental costs of IPv4 address scarcity. It is likely—and increasingly so the longer the transition takes—that the ISP will also have to operate NATs. The attendant capital and operational costs of such additional network functions will ultimately be borne by the service provider's customer base during the transition.

But it is not just price that is affected by this transition—network performance may also be affected. Today a connection across the Internet is typically made by using the *Domain Name System* (DNS) to translate a name to an equivalent IP address, and then launching a connection-establishment packet (or the entire query in the case of the U*ser Datagram Protocol* [UDP]) to the address in question. But such an operation assumes a uniform single protocol. In a transition world you can no longer simply assume that everything is contactable with a single protocol, and it is necessary to extend the DNS query to two queries, one for IPv4 and one for IPv6. The client then needs to select which protocol to use if the DNS returns addresses in both protocols. Then there is the tricky problem of failover. If the initial packet fails to elicit a response within some parameter of retries and timeouts, then the client will attempt to connect using the other protocol with the same set of retries and timeouts. In a dual-stack transitional world, not only does failure take more time to recognize, but even partial failure may take time.

So users may see some changes in the Internet. They may be exposed to higher prices that reflect the higher costs of operating the service, and they may see some instances where the network simply starts to appear "sluggish" in response.

Myth 3: "NAT upon NAT upon NAT will work."

Maybe. But maybe not all the time, and maybe not in ways that match what happens today.

The Internet has been operating for more than a decade now with a very prevalent model of a single level of address translation in the path. Application designers now assume its existence, and also make some other rather critical assumptions, notably that the NAT is close to the client in a client-server world, and that there is a single NAT in the path, and that its particular form of address translation behavior can be determined with numerous probe tests. There is even a client-to-NAT protocol to assist certain applications to communicate port-binding preferences to the local NAT. In a multilevel NAT world, such assumptions do not directly translate, but it is not necessarily the case that the application is aware of the added NATs in the end-to-end path.

However, it is not just the added complexity of the multipart NAT that presents challenges to applications. The NAT layering is intended to create an environment where a single IP address is dynamically shared across multiple clients, rather than being assigned to a single client at a time. Applications that use parallelism extensively by undertaking concurrent sessions require access to a large pool of available port addresses. Modern web browsers are a classic example of this form of behavior. The multiple NAT model effectively shares a single address across multiple clients by using the port address, effectively placing the pool of port addresses under contention. The higher the density of port contention, the greater the risk that this multiple layering of NATs will have a visible effect on the operation of the application.

There is also a considerable investment in the area of logging and accountability, where individual users of the network are recorded in the various log functions through their public-side address. Sharing these public addresses across multiple clients at the same time—as is the intended outcome of a multilayer NAT environment—implies that the log function is now forced to record operations at the level of port usage and individual transactions. Not only does this reality have implications in terms of the load and volume of logged information, there is also a tangible increase in the level of potential back tracing of individual users' online activities if full port usage logging were to be instituted, with the attendant concerns that this back tracing represents an inappropriate balance between accountability and traceability and personal privacy. It is also unclear whether there will be opportunity to have any public debate on such a topic, given that the pressure to deploy multilevel NAT is already visible.

Myth 4: "Changing the Customer Premises Equipment (CPE) is easy."

No, not necessarily.

I think we have all seen many transition plans, including multilevel Version 4 NATs, NATs that perform protocol translation between IPv4 and IPv6, NATs plus tunneling, as in *Dual-Stack Lite,* the *IVI Bi-direction Mapping Gateway, 6to4, 6RD,* and *Teredo,* to call up but a few of the various transitional technologies that have been proposed in recent times. (See the article "Transitioning Protocols" starting on page 22.)

All approaches to dual-stack transition necessarily make changes to some part of the network fabric, whether it is changes to the end systems to include an IPv6 protocol stack in addition to an IPv4 stack, or the addition of more NATs, or gateways into the network infrastructure. Of course, within a particular transitional model there is a selective choice as to what elements of the infrastructure are susceptible to change and what elements are resistant to change. Some models of transition, such as 6RD and Dual-Stack Lite, assume that changing the CPE is easy and straightforward, or at least that such a broad set of upgrades to customer equipment is logistically and economically feasible. 6RD contains an implicit assumption that the network operator has no economic motivation to alter the network elements, and wishes to retain a single protocol infrastructure that uses IPv4.

Where the CPE is owned, operated, and remotely maintained by the service provider, upgrading the image on the CPE might present fewer obstacles than upgrading other elements of the network infrastructure, such as broadband remote-access servers that operate in a single protocol mode, but sweeping generalizations in this industry are unreliable. Service providers tend to operate customized cost models, and appear to be operating with specialized mixes of vendor equipment and operational support systems. For this reason operators tend to have differing perspectives on what component of their network is more malleable, and correspondingly have differing perspectives on which particular transition technology suits their particular environment.

This industry is volume-based, where an underlying homogeneity of the deployed technology—and economies of scale and precision of process—are critical components of reliable and cost-efficient rollouts. It is somewhat unexpected to see this transition expose a relative high degree of customization and diversity in network service environments.

Myth 5: "My ISP has enough IPv4 addresses to last for years, so it does not have a problem."

Well, not necessarily.

The assumption behind this statement is that everyone else is also able to persist with IPv4, and everyone you wish to reach, and every service point you wish to access, will maintain some form of connectivity in IPv4 indefinitely.

But this assumption is not necessarily valid. At the point in time when a significant number of clients or services cannot be adequately supported on IPv4, then irrespective of how many IPv4 addresses ISPs have, they will need to provide their clients with IPv6 in order to reach these IPv6-only services On a network, the actions of others directly affect your own local actions. So if you believe that you need do nothing, and you can use an IPv4 service for years into the future, then this position will be inadequate at the point in time when a significant number of others encounter critical levels of scarcity such that they are incapable of sustaining the IPv4 side of a dual-stack deployment, and are forced to deploy an IPv6-only service. The greater the level of address hoarding, the greater the level of pressure to deploy IPv6-only services on the part of those service providers who are badly placed in terms of access to IPv4 addresses.

Myth 6: "We will always have to run IPv4 protocols."

Probably not.

Or at least not in terms and volumes that are significant to the industry over the forthcoming decades. Protocols do die. DECnet and *Systems Network Architecture* (SNA) no longer exist as widely deployed networking protocols. In particular, networking in the public space is all about any-to-any connectivity, and to support this connectivity we need a common protocol foundation. In terms of the dynamics of transition, this situation is more about tipping points of the mass of the market than it is about sustained coexistence of diverse protocols. When a new technology—or in this case, protocol—achieves a critical level of adoption, the momentum switches from resisting the change to embracing it.

The aftermath of such transitions does not leave a legacy of enduring demand for the superseded technology. As difficult as it is to foresee today, when the industry acknowledges that the new technology achieves this critical mass of adoption, the dynamics of the networking effect propels the industry into a tipping point where the remainder of the transition is likely to be both inevitable and comprehensive. The likely outcome of this situation is that there is no residual significant level of demand for IPv4.

Myth 7: "There is a technology that will translate between IPv4 to IPv6."

Yes, but...

Such a technology effectively maps between IPv4 and IPv6 addresses. One approach, the *IVI Bi-direction Mapping Gateway,* provides a 1:1 mapping by embedding fields of one address in the other. Another approach, originally termed *Network Address Translator – Protocol Translator* (NAT-PT), uses a mapping table in a fashion similar to a conventional NAT unit. The common constraint here is that if there are no IPv4 addresses, then such a bidirectional mapping cannot be sustained in each approach. Ultimately, if every packet that traverses the public Internet requires public address values in the source and destination fields, and the ISP must provide a protocol bridge between IPv4 and IPv6, then public IPv4 addresses are required.

But it is not just the requirement for continued access to addresses that is the critical concern here. A reading of RFC 4966[4], "Reasons to Move the Network Address Translator – Protocol Translator (NAT-PT) to Historic Status" should curb any untoward enthusiasm that this approach is capable of sustaining the entire load of this dual-stack transition without any further implications or problems.

Myth 8: "We do not necessarily have to transition to IPv6. There are substitutes."

Nothing is visible from here!

If we want to continue to operate a network at the price, performance, and functional flexibility that is offered by packet-switched networks, then the search for alternatives to IPv6 is necessarily constrained to a set of technologies that offer approaches that are—at a suitably abstract level—isomorphic to IP. But going from abstract observations to a specific protocol design is never a fast or easy process, and the lessons from the genesis of both IPv4 and IPv6 point to a period of many years of design and progressive refinement to develop a viable approach. In our current context any such redesign is not a viable alternative to IPv6, given the timeframe of IPv4 address exhaustion. It is unlikely that such an effort would elicit a substitute to IPv6, and it is more likely that such an effort may lead toward an inevitable successor to IPv6, if we dare to contemplate networking technologies further into the future.

Other approaches exist, based on application-level gateways and similar forms of mapping of services from one network domain. We have been there before in the chaotic jumble of networks and services that defined much of the 1980s, and it is a past that I for one find easier to forget! Such an outcome is of considerably higher complexity, considerably less secure, harder to use, more expensive to operate, and more resistant to scaling.

Like it or not, the pragmatic observation of today's situation is that we do not have a viable choice here. No viable substitutes exist.

Myth 9: "We know what is happening."

I am not sure that is universally true! The comments I have heard about the current situation lead me to the observation that there are many different perspectives on the situation. Individuals perceive the transition in terms that relate to their own circumstances and their own limitations, and a more encompassing perspective of the entire Internet and this transition is harder to assemble. So, from the perspective of the Internet as a whole, no, we are not really aware of what is happening.

Myth 10: "We know what we are doing."

Individually this statement is, hopefully, true. But at the level of the entirety of the Internet, no, we do not really have a clear perspective of this transition.

Myth 11: "We have a plan!"

See the comment for myth 10.

Myth 12: "The Internet will be fine!"

I am unsure about this one.

The worrying observation is that the Internet has so far thrived on diversity and competition. We have seen constant innovation and evolution on the Internet, and the entrance of new services and new service providers.

But if we rely solely on IPv4 for the future Internet, then this level of competition and diversity will be extremely challenging to sustain. If we lose that impetus of competitive pressure from innovation and creativity, then the Internet will likely stagnate under the oppression of brutal volume economics. The risks of monopoly formation under such conditions are relatively high.

I hope one observation I heard at the RIPE session will be a myth as this transition gets underway:

> *"The incumbents will have all the IPv4 space.*
> *Thanks for playing!"*

If that is *not* a myth, then we are going to be in serious trouble!

Pool of Unallocated IPv4 Addresses Now Completely Emptied

On February 3, 2011 a critical point in the history of the Internet was reached with the allocation of the last remaining IPv4 Internet addresses from a central pool. It means the future expansion of the Internet is now dependant on the successful global deployment of the next generation of Internet protocol, called IPv6.

The announcement was made by four international non-profit groups, which work collaboratively to coordinate the world's Internet addressing system and its technical standards. At a news conference in Miami, Florida, the *Internet Corporation for Assigned Names and Numbers* (ICANN) joined the *Number Resources Organization* (NRO), the *Internet Architecture Board* (IAB) and the *Internet Society* (ISOC) in announcing that the pool of first generation Internet addresses has now been completely emptied. The final allocation of Internet addresses was administered by the *Internet Assigned Numbers Authority* (IANA), which is a function of ICANN.

"This is a major turning point in the on-going development of the Internet," said Rod Beckstrom, ICANN's President and Chief Executive Officer. "No one was caught off guard by this. The Internet technical community has been planning for IPv4 depletion for some time. But it means the adoption of IPv6 is now of paramount importance, since it will allow the Internet to continue its amazing growth and foster the global innovation we've all come to expect."

Two "blocks" of the dwindling number of IPv4 addresses—about 33 million of them—were allocated in late January to APNIC, the *Regional Internet Registry* (RIR) for the Asia Pacific region. When that happened, it meant the pool of IPv4 addresses had been depleted to a point where a global policy was triggered to immediately allocate the remaining small pool of addresses *equally* among the five global RIRs.

"It's only a matter of time before the RIRs and *Internet Service Providers* (ISPs) must start denying requests for IPv4 address space," said Raúl Echeberría, Chairman of the NRO, the umbrella organization of the five RIRs. "Deploying IPv6 is now a requirement, not an option."

Transitioning Protocols

by Geoff Huston, APNIC

In the previous article, I looked at some common myths associated with the transition to IPv6. In this article I would like to look behind the various opinions and perspectives about this transition, and examine in a little more detail the nature of the technologies being proposed to support the transition to IPv6.

After some time of hearing dire warnings about the imminent exhaustion of the stocks of available IPv4 address space, we have now achieved the first milestone of address exhaustion, the depletion of the central pool of *Internet Assigned Numbers Authority* (IANA)-managed address space. The last five /8s were handed out from IANA to the *Regional Internet Registries* (RIRs) on February 3, 2011. After some years of industrywide general inattention and inaction with IPv6, perhaps it is not unexpected to now see a panicked response along the lines of "Maybe we should do something now!"

But what exactly should be done? It is one thing to decide to "support" IPv6 in a network, but quite another to develop a specific plan, complete with specific technologies, timelines, costs, vendors, and a realistic assessment of the incremental risks and opportunities. Although working through some of this detail has the normal levels of uncertainty that you would expect to see in any environment that is undergoing constant change and evolution, an additional level of uncertainty here is a by-product of the technology itself.

There is not just *one* approach to adding support for IPv6 in your network, but *many.* And it is not just one major objective you need to address—incremental deployment of IPv6 as a second protocol into your operational network without causing undue disruption to existing services—but two, because the second challenging objective is how to fuel continued growth in your network service platform when the current supply lines of readily available IPv4 addresses are effectively exhausted.

When?

The most common question I have heard recently is: "How long do we have?"

The remaining pools of IPv4 address space continue to be drawn down. At the start of February 2011, the IANA pool was fully depleted, with the final allocation to the RIRs[1] of IPv4 addresses.

Using a model based on monthly address demands now predicts that the next 18 months or so will see the first three RIRs depleted of IPv4 addresses.

The *Asia Pacific Network Information Centre* (APNIC) was the first RIR to exhaust its available pool of IPv4 addresses in April 2011, with the *RIPE Network Coordination Centre* (RIPE NCC) predicted to follow in late 2011 and the *American Registry for Internet Numbers* (ARIN) in early 2012. The *Latin American and Caribbean Internet Addresses Registry* (LACNIC) is predicted to follow in 2014, and the *African Network Information Centre* (AFRINIC) in 2016.

The good news is that many people have been busy thinking about these intertwined objectives of extending the useful lifetime of IPv4 in the Internet and simultaneously undertaking the IPv6 transition, and there is a wealth of possible measures you can take, and a broad collection of technologies you can use. Fortunately, we are indeed spoiled with choices here!

The not-so-good news is that there is no simple single path to follow. Each individual network needs to carefully consider the transition and select an approach that matches their particular circumstances. For an industry used to playing "follow the leader" for many years, a variety of choice is not always appreciated. And, unfortunately, we are spoiled for choices here.

Let's look at each of the major transitional technologies that are currently in vogue, and examine their respective strengths and weaknesses and their intended area of applicability. We will look at these technologies first from the perspective of the end user and then from the other side, examining options for *Internet Service Providers* (ISPs).

The Dual-Stack ISP Client

If your service provider provides a dual-stack service with both IPv6 and IPv4, then your task should be relatively straightforward. If you configure your modem or router with IPv6 in addition to IPv4, you are finished, assuming of course that your local modem or router unit actually supports IPv6—an assumption that may not be valid in many of the older and, unfortunately, many of the currently available devices.

The conventional approach in this form of environment is to use *IPv6 Prefix Delegation,* where the ISP provides the client with an IPv6 prefix, usually a /48 or a /56 IPv6 address prefix, which is then passed into the client network through an *IPv6 Router Advertisement*. Local hosts should be constructed to configure their IPv6 stack automatically, and your system should be connected as a dual-protocol system.

You probably do, however, need to be aware of some caveats, of which the most important is likely to relate to the probable absence of a *Network Address Translation* (NAT)[2] function in IPv6. Currently most commercial IPv4 Internet services assign a single IP address to each client.

To allow this address to be shared within the client's network, most IPv4 "edge" devices autoconfigure themselves as NAT devices, permitting outgoing connections using the *Transmission Control Protocol* (TCP) or *User Datagram Protocol* (UDP), and allowing some *Internet Control Message Protocol* (ICMP) message types to traverse the NAT, but not much else. For many clients this NAT configuration becomes the default local security framework, because it permits outbound connections through TCP and UDP to be made, but not much else, and permits initiation of no sessions as incoming sessions. With IPv6 the local network is generally configured with an entire subnet, and instead of a NAT, this subnet is directly connected to the Internet.

The local network is then in a mixed situation of being behind a NAT in IPv4, but directly connected to the Internet using IPv6. This asymmetric configuration with respect to IPv4 and IPv6 raises some questions about the effect on the security of your local network. You need to think about adding appropriate filter rules to the gateway IPv6 configuration that performs the same level of access control to your local site that you have already set up with IPv4 and the NAT. The best advice here is to configure some filter rules for IPv6 that limit the extent of exposure of your internal network to the broader Internet to be directly comparable to the configuration you are using with IPv4.

The IPv4-Only ISP Client

Even today, when the IPv4 pools are rapidly depleting, it is really not very common to have an ISP offering dual-stack IPv4 and IPv6 services. Let's look at the more common situation, when your ISP is still offering only IPv4. As an end user, can you still set up some form of IPv6 access?

The answer is "Yes," but you must use tunnels, and the story can get somewhat ugly.

6to4 Tunnels

If you have public IPv4 addresses on your local network, you may elect to configure your local system to use the *6to4 Tunneling Protocol*.

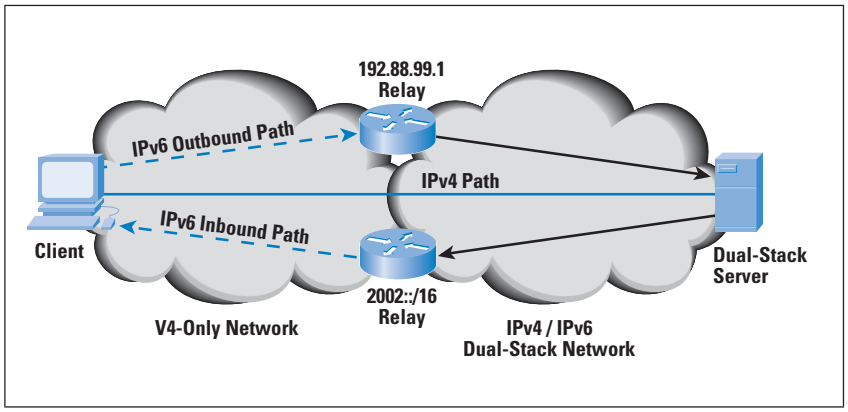
6to4 is an autotunneling protocol coupled with an addressing structure. The IPv6 address of a 6to4-reachable host begins with the IPv6 prefix `2002::/16`. The address architecture embeds a 32-bit IPv4 address of the end host into the next 32 bits. That way the IPv6 address carries the "equivalent" IPv4 address within the IPv6 address.

To send an IPv6 packet, the local host must first tunnel through the local IPv4 network. To perform this tunneling, the local host encapsulates the IPv6 packet in an outer IPv4 packet header. The IP protocol used is neither TCP nor UDP, but protocol 41, an IP protocol number reserved for tunneling IPv6 packets (RFC 2473)[3].

The IPv4 packet is addressed to an IPv4-to-IPv6 relay. To avoid manual configuration of each client, all these relays share the same *anycast* address, `192.88.99.1`. These relays strip the outer IPv4 packet header off the packet and forward the IPv6 packet into the IPv6 network. The IPv6 destination treats the packet normally, and generates a packet in response without any special processing.

The reverse path to a 6to4 host uses an IPv6-to-IPv4 relay. The IPv6 address of the 6to4 local host started with the IPv6 address prefix `2002::/16`, so the IPv6 packet that is being sent back to this host has a destination address that uses the `2002::/16` 6to4 prefix. This prefix is interpreted as an anycast relay address. A route to the IPv6 `2002::/16` prefix is advertised by IPv6-to-IPv4 relays. When a relay receives a packet destined to a `2002::/16` address, it lifts the IPv4 address from inside the IPv6 address. It then wraps the IPv6 packet in an IPv4 packet header, using as a destination address this extracted IPv4 address, and using protocol 41 as the IP protocol. The resultant IPv4 packet is then passed to the 6to4 host in the IPv4 network (Figure 1).

Figure 1: 6to4 Tunneling Architecture



If the local network has public IPv4 addresses on the local network, then individual hosts on the local network may use 6to4 directly. Of course then the local gateway needs to be configured to accept incoming IP packets that use protocol 41.

An alternative is to configure the gateway device of the local network as a 6to4 gateway, and use the IPv4 address on the ISP side of the gateway as a common 6to4 address for the local network. The gateway then advertises this synthetic 48-bit IPv6 prefix to the interior network with a conventional IPv6 Router Advertisement. The gateway can couple this advertisement with a NAT function and provide native IPv6 to interior hosts that are configured on RFC 1918[4] local IPv4 addresses.

In general, 6to4 is a relatively poor approach to provisioning IPv6, and you really should avoid it if at all possible. Indeed, your experience will probably be better overall if you continue running IPv4 and avoid accessing IPv6 with 6to4!

The major concern here is that a successful connection relies on the assistance of both an outbound and an inbound 6to4 third-party relay. On the IPv4 side a 6to4 connection relies on the presence of a usable route to a IPv4-to-IPv6 relay, and preferably one that is as close as possible to the IPv4 endpoint. On the IPv6 side a 6to4 connection relies on a usable relay advertising a route to `2002::/16`. Again, to avoid extended path overheads, this relay should be as close as possible to the IPv6 endpoint. This path asymmetry can cause connection "black holes," where one party can deliver packets to the other but not the reverse.

Also, such configurations have problems if the IPv4 host is configured with stateful filters that insist that the IPv4 source address in incoming packets match the destination address of outgoing packets, not necessarily true in a 6to4 connection.

Finally, it seems that many sites operate with firewall filters that disallow incoming packets other than TCP and UDP (and possibly some forms of ICMP). The 6to4 packets use protocol 41, and there appears to be widespread use of filter rules that block such packets.

Tunneling also adds an additional packet header to a packet, inflating the size of the packet. Such an expansion of the packet on certain path elements of the network may cause path packet size problems, increasing the risk of encountering Path *Maximum Transmission Unit* (MTU) "black holes" due to the increase of the packet size by 20 bytes when the IPv4 packet header is attached to the packet.

Teredo Tunnels

If the local network is behind an IPv4 NAT and the NAT gateway does not support 6to4, then all is not lost, because another form of tunneling could possibly be an answer. *Teredo* is described in RFC 4380[5].

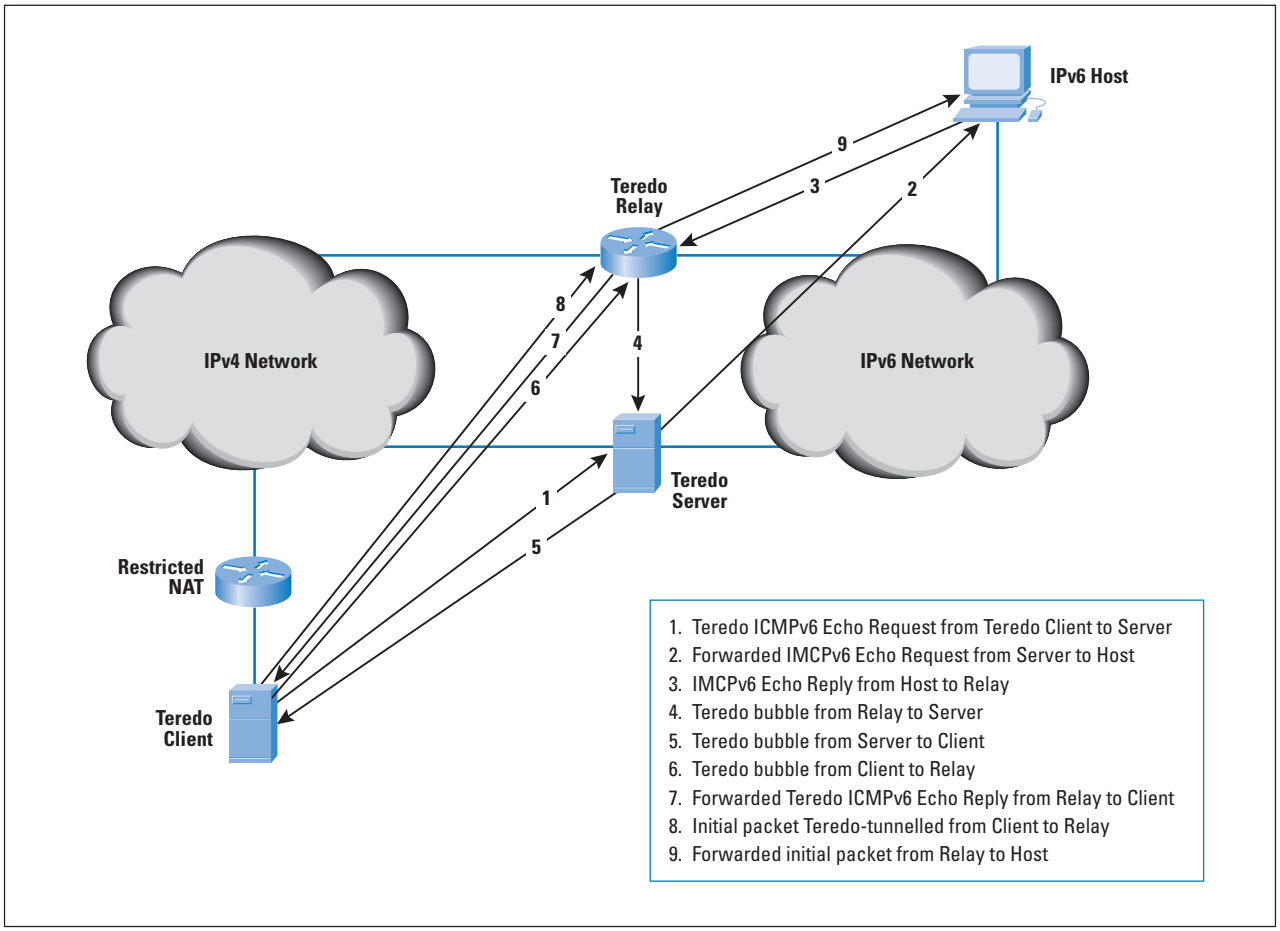
Teredo, like 6to4, is an autotunneling protocol coupled with an addressing structure. Like 6to4, Teredo uses its own address prefix, and all Teredo addresses share a common IPv6 /32 address prefix, namely `2001:0000::/32`. The next 32 bits are the IPv4 address of the Teredo server. The IPv6 interface identifier field is used to support NAT traversal, and it is encoded with the triplet of a field describing the NAT type, the view of the relay of the UDP port number used to reach the client (the external UDP port number used by the NAT binding for the client), and the view of the relay of the IPv4 address used to reach the client (the external IPv4 address used by the NAT binding for the client).

Teredo uses what has become a relatively conventional approach to NAT traversal, using a simplified version of the *Session Traversal Utilities for NAT* (STUN)[6] active probing approach to determine the type of NAT; it uses concepts of "clients," "servers," and "relays."

A Teredo *client* is a dual-stack host that is located in the IPv4 world, assumed to be located behind a NAT. A Teredo *server* is an address and reachability broker that is located in the public IPv4 Internet, and a Teredo *relay* is a Teredo tunnel endpoint that connects Teredo clients to the IPv6 network. The tunneling protocol used by Teredo is not the simple IPv6-in-IPv4 protocol 41 used by 6to4. NAT devices are sensitive to the transport protocol and generally pass only TCP and UDP transport protocols. In the Teredo case the tunneling is UDP, so all IPv6 Teredo packets are composed of an IPv4 packet header and a UDP transport header, followed by the IPv6 packet as the UDP payload. Teredo uses a combination of ICMPv6[7] message exchanges to set up a connection and tunneled packets encapsulated using an outer IPv4 header and a UDP header, and it contains the IPv6 packet as a UDP payload.

It should be noted that this reliance on ICMPv6 to complete an initial protocol exchange and confirm that the appropriate NAT bindings have been set up is not a conventional feature of IPv4 or even IPv6, and IPv6 firewalls that routinely discard ICMP messages will disrupt communications with Teredo clients.

Figure 2: Teredo Tunneling



The exact nature of the packet exchange in setting up a Teredo connection depends on the nature of the NAT device that sits in front of the Teredo client. Figure 2 shows an example packet exchange that Teredo uses when the client is behind a Restricted NAT.

Teredo represents a different set of design trade-offs as compared to 6to4. In its desire to be useful in an environment that includes NAT functions in the IPv4 path, Teredo is a per-host connectivity approach, as compared to the 6to4 approach, which can support both individual hosts and entire end sites within the same technology. Also, Teredo is a host-centric multiparty rendezvous application, and Teredo clients require the existence of dual-stack Teredo servers and relays that exist in both the public IPv4 and IPv6 networks. Teredo is more of a connectivity tool than a service solution, and one that is prone to many forms of operational failure.

On the other hand, if you are an isolated IPv6 host behind an IPv4 NAT and you want to access the IPv6 network, then 6to4 is not an option, and you either have to set up static tunnels across the NAT to make it all work or turn on Teredo in your dual-stack host; if everything goes according to theory, you should be able to establish IPv6 connectivity. It is highly likely that the IPv6 Teredo connection will fail in strange ways, and, like 6to4, this is a technology best avoided!

Tunnel Brokers

In contrast to these autotunnel approaches, the simplest form of tunneling IPv6 packets over an IPv4 network is the manually configured IPv6-in-IPv4 tunnel.

Here an IPv6 packet is simply prefixed by a 20-octet IPv4 packet header. In the outer IPv4 packet header, the source address is the IPv4 address of the tunnel ingress, the destination address is the IPv4 address of the tunnel egress, and the IP protocol field uses value 41, indicating that the payload is an IPv6 packet. The packet is passed across the IPv4 network from tunnel ingress to egress using conventional IPv4 packet forwarding, and at the egress point the IPv4 IP packet header is removed and the inner IPv6 packet is routed in an IPv6 network as before. From the IPv6 perspective the transit across the IPv4 network is a single logical hop.

Alternatively, like *Virtual Private Network* (VPN) tunnels, the tunnel can be configured using UDP or TCP, and with some care, the tunnel can be configured through NAT functions in the same way as VPN tunnels can be configured through NAT functions.

The advantage of this approach is that the need to manually configure the tunnel endpoints ensures that the tunnel relay function is not provided, intentionally or unintentionally, by third parties through some well-intentioned, but ultimately random, act of goodwill. The need to perform a manual configuration also reduces the chances that the tunnel will be broken through local firewall filters.

Of course the need to perform a manual configuration does not lend itself to a "plug-and-play" environment, nor is this approach a viable one for a larger mass market of consumer devices and services.

Client Conclusions

None of these approaches to offer IPv6 connectivity to end hosts behind an IPv4-only service provider offers the same level of robustness and performance as native IPv4 services. All of these approaches require a significant degree of local expertise to set up and maintain, and they often require a solid understanding of other aspects of the local environment, such as firewall and filter conditions and Path MTU behavior to maintain. With the exception of the tunnel broker approach, they also require third-party assistance to support the connection, further adding to the set of potential performance and reliability concerns.

It appears that the most robust and reliable way to provision IPv6 to end hosts is for the service provider to provision IPv6 as an integral part of its service offering, and offer clients a dual-stack service in both IPv4 and IPv6.

IPv6 for Internet Service Providers

Although the "self-help" autotunneling approaches for clients outlined earlier in this article are a possible answer, their utility is appropriately restricted to a very small number of end clients who have the necessary technical expertise and who are willing to debug some rather strange resultant potential problems relating to asymmetric paths, third-party relays, potential MTU mismatches, and interactions with filters. This approach is not a reasonable one for the larger Internet.

From the perspective of the mass market for Internet Services, we cannot assume that clients have the motivation, expertise, and means to bypass their ISP and set up IPv6 access on their own, either through autotunneling or manually configured tunnels. The inference from this observation is that for as long as the mass-market ISPs do not commit to IPv6 services, and for as long as they continue to stall in deploying services supporting dual access for their clients, the entire IPv6 transition story remains effectively stalled.

How can ISPs support IPv6 access for their clients?

The Dual-Stack Service Network

Perhaps it is obvious, but the most direct response here is for the ISP to operate a *Dual-Stack Network*.

And the most direct way to achieve this operation is for the ISP's infrastructure to also support IPv6 wherever there is IPv4, so that the delivery of services to the ISP's clients in IPv6 faithfully replicates the service offered in IPv4.

This solution implies that the network needs to support IPv6 in the ISP's routing infrastructure, in the network data plane, in the load-management systems, in the operational support infrastructure, in access and accounting, and in peering and in transit. In short, wherever there is IPv4 there needs to be IPv6.

The infrastructure elements that require dual-stack service at the next level include the routing and switching elements, including the internal and external routing protocols. The task includes negotiating peering and transit services in IPv6 to complement those in IPv4. Network infrastructure also includes VPN support and other forms of tunnels, as well as data center front-end units, including load balancers, filters and firewalls, and various virtualized forms of service provision. The task also includes integration of IPv6 in the network management subsystem and the related network measurement and reporting system. Even a comprehensive audit of the supported *Management Information Bases* (MIBs) in the active elements of the network to ensure that the relevant IPv6 MIBs are supported is an essential task. A similar task is associated with equipping the server infrastructure with IPv6 support, and at the higher levels of the protocol stack are the various applications, including web services, mail, *Domain Name System* (DNS), authentication and accounting, *Voice over IP* (VoIP) servers, Load Balancers, Cloud Servers, and similar applications.

And those are just the common elements of most ISPs' infrastructures. Every ISP also has more specialized elements in its service portfolio, and each one of these elements also requires a comprehensive audit to ensure that there is an IPv6 solution for each of these elements that leads to a comprehensive dual-stack outcome.

As obvious as this approach might appear, it has two significant problems. First, it requires a comprehensive overhaul of every element in the ISP's service network. Even for small-scale ISPs this overhaul is not trivial, and for larger service provider platforms it is an exercise that may take months if not years and make considerable inroads into the operating budgets of the ISPs. Secondly, it still does not account for the inevitable fact that in the coming months the current supply lines of IPv4 addresses will end and any continued expansion of the service platform will require some different approaches to the way in which IPv4 addresses are deployed in the service platform.

Although the approach of simply provisioning IPv6 alongside IPv4 in a simple dual-protocol service infrastructure may appear to be the most obvious response to the need to transition to IPv6, it may not necessarily be the most appropriate response for many ISPs to the dual factors of IPv6 transition and IPv4 address exhaustion.

Are there alternative approaches for ISPs? Of course.

Hybrid Approaches

Saying that an ISP must deploy IPv6 across all of its infrastructure and actually doing it are often quite different. The cost of converting all parts of an ISP's operation to run in dual-stack mode can be quite high, and the benefit of running every aspect of an ISP's service offering in dual-stack mode is dubious at best.

Are there middle positions here? Is it possible for an ISP to deliver robust IPv6 services to clients while still operating an IPv4-only internal network? One way to look at an ISP's network is as a transit conduit (Figure 3).

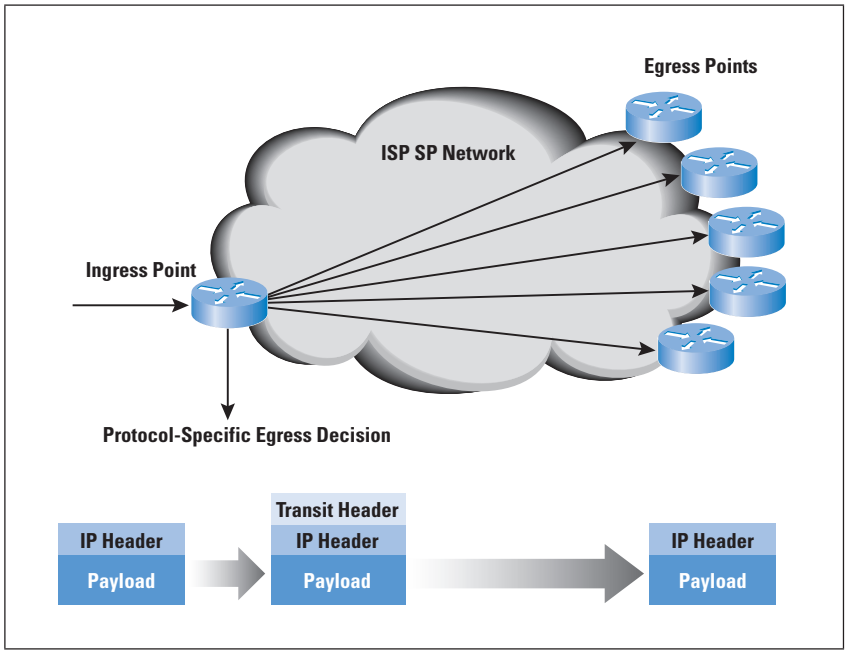


Figure 3: Generic ISP Packet Transit Architecture

The ISP needs to be able to accept packets from an external interface, determine the appropriate egress point for the packet within the context of the local network, and then ensure that the packet is passed out this egress interface. The internal network need not operate in the same protocol context as the protocol of the packets the network is handling. Viewed at a level of the minimal essentials, the network needs to be able to have some protocol-specific capability at its ingress points in order to determine the appropriate egress point of each incoming packet, and thereafter during the transit of the service provider's network, the minimum necessary association to maintain the identity of this preselected egress point with the packet. Now if the network uniformly supports the same protocol as the packet, then the same egress decision can be made at each forwarding point within the network.

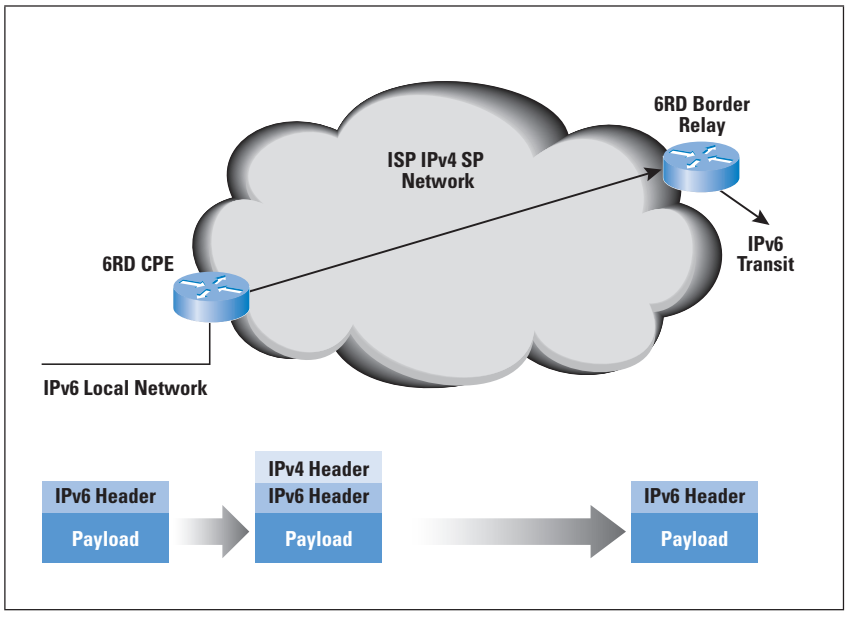
Alternatively, the packet can be encapsulated with an outer wrapper that identifies the egress point using the same protocol context as that used by the service provider's internal switching elements, and the packet can be passed through the service provider's transit network using only this temporary wrapper to determine the sequence of forwarding decisions. *Multiprotocol Label Switching* (MPLS) networks are an excellent example of this form of approach, as are other forms of IP-in-IP encapsulation. The advantage of this approach is that the internal infrastructure of the service provider network need not be altered to support additional carriage protocols: the changes to specifically support IPv6 are required only at the network ingress elements, and a basic encapsulation stripping function is used at all egress points.

With this information in mind, let's look at some of these hybrid approaches to supporting IPv6 in a service provider network.

6RD

6RD, described in RFC 5969[8], is an interesting refinement of the 6to4 approach. It shares the same basic encapsulation protocol and the same address structure of embedding of the IPv4 tunnel endpoint into the IPv6 address. However, it has removed the concept of third-party relays and the use of the common `2002::/16` IPv6 prefix, and instead uses the provider's IPv6 prefix. The effect of these changes is to limit the scope of the tunneling mechanism to that of tunneling across the network infrastructure of a single provider, and the intended function is to tunnel from the *Customer Premises Equipment* (CPE) to IPv6 *Border Relays* operated by the customer's ISP (Figure 4).

Figure 4: 6RD Tunneling



If 6to4 is not recommended for use because of high failure rates of connections and suboptimal performance, then why would 6RD be any better?

The most compelling reason to believe that 6RD will perform more reliably than 6to4 is that 6RD removes the wild-card third-party relay element from the picture. For outbound traffic the CPE provides the tunnel encapsulation, which is, hopefully, under the ISP's operational control. The IPv6-in-IPv4 tunnel is directed to the ISP's own 6RD Border Relay rather than the 6to4 relay anycast address. Because this process is also under the ISP's direct operational control, it eliminates the outbound third-party relay function. For the reverse path, the use of the provider's own IPv6 prefix in 6RD, instead of the generic `2002::/16` prefix, ensures that the inbound packets are sent through IPv6 directly to the ISP, and the IPv6-in-IPv4 tunnel is again limited to a hop across the ISP's own internal infrastructure.

As long as the ISP effectively manages all CPE devices, and as long as the CPE itself is capable of supporting the configuration of additional functional modules that can deliver unicast IPv6 to the client and 6RD tunnels inward to the ISP, then 6RD is a viable option for the ISP. At the cost of upgrading the CPE set to include 6RD support, and the cost of deployment of 6RD Border Relays that terminate these CPE tunnels, together with IPv6 transit from these Border Relays, the ISP is in a position to provide dual-stack support to its client base from an internal network platform that remains an IPv4 service platform, thereby deferring the process of conversion of its entire network infrastructure base to support IPv6.

For ISPs seeking to defray the internal infrastructure IPv6 conversion costs over a number of years, or for ISPs seeking an incremental path to IPv6 support that allows the existing infrastructure to remain in place temporarily, 6RD can be an interesting and cost-effective alternative to a comprehensive dual-stack deployment, as long as the ISP has some mechanism to load the CPE with IPv6 support and 6RD relay functions.

MPLS and 6PE

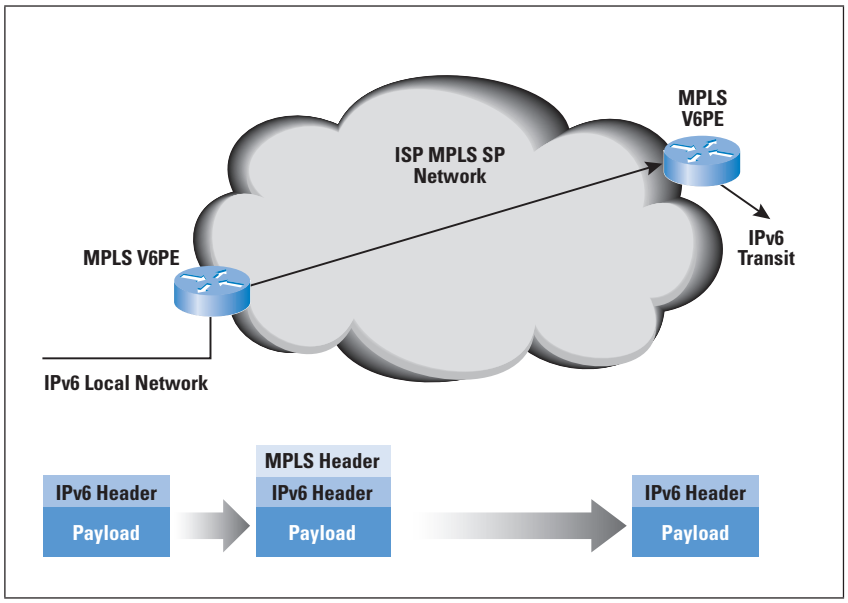
The 6RD approach has many similarities to MPLS, in that an additional header is added to incoming packets at the network boundary, and the encapsulation effectively directs the packet to the appropriate network egress point (as identified by ingress), where the encapsulation is stripped and the original packet is passed out.

Rather than using an IPv4 header to direct a packet from ingress to egress, if the network is already using MPLS, why not simply support IPv6 on an existing MPLS network as a PE-to-PE MPLS path set and bypass the IPv4 step?

Why not, indeed, and RFC 4659[9] describes how this bypass can be achieved.

If you are running an MPLS network, then the role of the interior routing protocol and label distribution function is to maintain viable paths between all network ingress and egress points. The protocol-specific function in such networks is not the interior network topology management function, but the maintenance of the mapping of egress to protocol-specific destination addresses (Figure 5).

Figure 5: MPLS and 6PE



As with 6RD, if the local problem is some form of prohibitive barrier to the immediate deployment of IPv6 in a dual-stack configuration across the network infrastructure, then this approach allows an IPv4 MPLS network to set up paths across the network IPv4 MPLS infrastructure from provider edge to provider edge. These paths may be used to tunnel IPv6 packets across the network by associating the IPv6 destination address of the incoming packet with the IPv4 address of the egress router, using the *interior Border Gateway Protocol* (iBGP) *Next-Hop* address, for example.

The incremental changes to support IPv6 are constrained to adding IPv6 to the service provider's iBGP routing infrastructure, and to the provider-edge devices in the MPLS network, while all other parts of the service provider's service platform can continue to operate as an MPLS IPv4 network for now.

IPv4 Address Compression

It is not just the challenge of adding a new protocol to the existing IPv4 network infrastructure that confronts ISPs. The entire reason for this activity is the prospect of exhaustion of supply of IPv4 addresses. When this prospect was first aired, in 1990, it was assumed that the Internet would be supported by industry players that acted rationally in terms of common interests.

One of the more critical assumptions made in the development of transitional tools was that transition activity would be undertaken well in advance of IPv4 address exhaustion. Competitive interest would see each actor making the necessary investments in new technologies to mitigate the risks of attempting to operate a network in an environment of acute general scarcity of addresses. As much fun as the debate as to whom the "last" IPv4 address should be given might be, it was assumed that this event was, in fact, never going to happen. The assumption was that industry actors would anticipate this situation and take the necessary steps to avoid it. The transition to IPv6 would be effectively complete well before the stocks of IPv4 addresses had been exhausted, and IPv4 addresses would be an historical artefact well before we needed to use the last one!

Obviously, this scenario has not happened.

This industry is going to exhaust the available supplies of IPv4 addresses well before the transition to IPv6 is complete—and in some cases well before the transition process has even commenced! This situation creates an additional challenge for ISPs and the Internet, and raises a further question as well. The challenge is to fold into this dual-stack transition the additional factor of having to work with fewer and fewer IPv4 addresses as the transition process continues. This situation implies that the necessary steps that the ISP must take include ones that increase the intensity of use of each IPv4 address, and wherever possible substitute a private-use IPv4 address for public IPv4 addresses.

The question that this scenario raises is one of guessing how long this hybrid model of an Internet where a significant proportion of network services and network clients remains entrenched in an IPv4-only world will persist. For as long as such IPv4-only network domains persist, and for as long as these IPv4-only network domains encompass significant service and customer populations, all the other parts of the Internet are forced to maintain residual IPv4 capability and cannot transition their customers and services to an IPv6-only environment. Students of economic game theory may see some rich areas of study in this developing situation.

More practically, for an ISP the question becomes one of attempting to understand how long this hybrid period of attempting to operate a dual-stack network with continuing postexhaustion demand for further IPv4 addresses will last. Will an after-market for the redistribution of addresses emerge? How will the increasing scarcity pressure affect pricing in such a market? How long will demand persist for IPv4 addresses in the face of escalating prices? Will the industry turn to IPv6 in a rapid surge in response to cost escalation for additional IPv4 addresses, or will a dual-stack transition lumber on for many years? In such a large, diverse, heterogeneous environment of today's Internet, the one constant factor is that the immediate future of the Internet is clouded with extremely high levels of uncertainty.

The cumulative effect of the individual decisions made by service providers, enterprises, carriers, vendors, policy makers, and consumers has created a somewhat chaotic environment that adds a significant level of uncertainty and associated investment risk into the current planning process for ISPs.

Carrier-Grade NATs

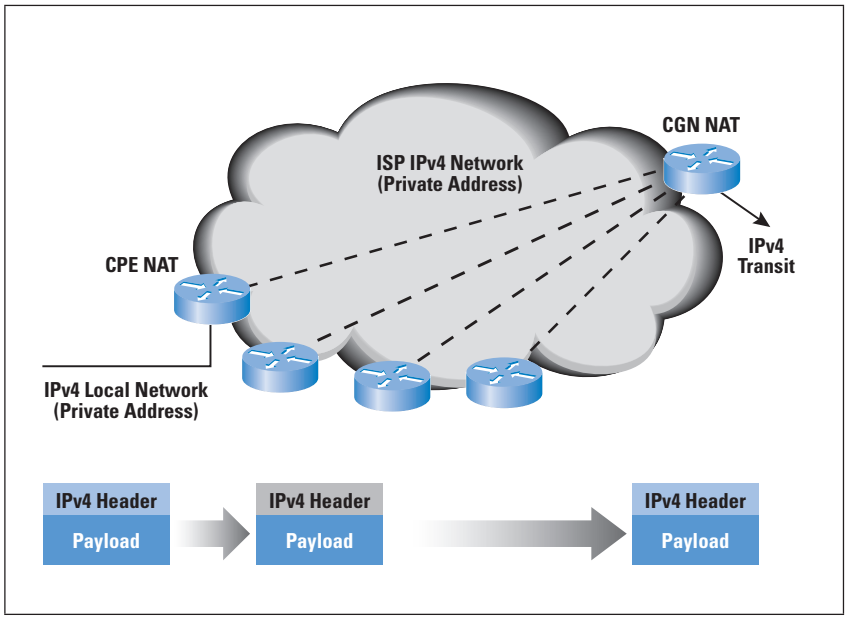
I have often heard it said that address scarcity in IPv4 is nothing new, and it first occurred when the first NAT device that supported port mapping was deployed. At this point the concept of *address sharing* was introduced to the Internet, and, from the perspective of the NAT industry, we have not looked back since.

In today's world NATs are extremely commonplace. Most clients are provisioned with a single address from their ISP, which they then share across their local network using a NAT. Whether it is well advised or not, NATs typically form part of a client's network security framework, and they often are an integral part of a customer's multihoming configuration if the client uses multiple providers.

But in this model of NATs as the CPE, the ISP uses one IPv4 address for each client. If the ISP wants to achieve greater levels of address compression, then it is necessary to share a single IPv4 address across multiple customers.

The most direct way to achieve this scenario is for ISPs to operate their own NAT, variously termed a *Carrier-Grade NAT* (CGN) or a *Large-Scale NAT* (LSN), or *NAT444*. This approach is the simplest, and, in essence, is a case of "more of the same" (Figure 6).

Figure 6: Carrier-Grade NATs



The Carrier-Grade NAT allows a single public address to be shared across multiple clients, who, in turn, further share this address across the end systems in their local networks.

From behind the CPE in the client edge network not much has changed with the addition of the CGN in terms of application behavior. It still requires an outbound packet to trigger a binding that would allow a return packet through to the internal destination, so nothing has changed there. Other aspects of NAT behavior, notably the NAT binding lifetime and the form of NAT "cone behavior" for UDP, take on the more restrictive of the two NAT functions in sequence. The binding times are potentially problematic in that the two NATs are not synchronized in terms of binding behavior. If the CGN has a shorter binding time, it is possible for the CGN to misdirect packets and cause application-level problems. However, this situation is not overly different from a single-level NAT environment where aggressively short NAT binding times also run the risk of causing application-level problems when the NAT drops the binding for an active session that has been quiet for an extended period of time.

However, one major assumption is broken in this structure, namely that an IP address is associated with a single customer. In the CGN model a single public IP address may be used simultaneously by many customers at once, albeit on different port numbers. This scenario has obvious implications in terms of some current practices in filters, firewalls, "black" and "white" lists, and some forms of application-level security and credentials where the application makes an inference about the identity and associated level of trust in the remote party based on the remote party's IP address.

This approach is not without its potential operational problems as well. For the service provider, service resiliency becomes a critical concern in so far as moving traffic from one NAT-connected external service to another will cause all the current sessions to be dropped. Another concern is one of resource management in the face of potentially hostile applications. For example, an end host infected with a virus may generate a large amount of probe packets to a large range of addresses. In the case of a single edge NAT, the large volumes of bindings generated by this behavior become a local resource-management problem because the customer's network is the only affected site. In the case where a CGN is deployed, the same behavior will consume port-binding space on the CGN and, potentially, can starve the CGN of external address port bindings. If this problem is seen to be significant, the CGN would need to have some form of external address rationing per internal client in order to ensure that the entire external address pool is not consumed by a single errant customer application.

The other concern here is one of *scalability*. Whereas the most effective use of the CGN in terms of efficiency of usage of external addresses occurs when the greatest numbers of internal edge NATed clients are connected, there are some real limitations in terms of NAT performance and address availability when a service provider wants to apply this approach to networks where the customer population is in the millions or larger. In this case the service provider must use an IPv4 private address pool to number every client. But if network 10 is already used by each customer as its "internal" network, then what address pool can be used for the service provider's private address space? One of the few answers that come to mind is to deliberately partition the network into numerous discrete networks, each of which can be privately numbered from `172.16.0.0/12`, allowing for some 600,000 or so customers per network partition, and then use a transit network to "glue" together the partitioned elements.

The advantage of the CGN approach is that nothing changes for the customer. There is no need for any customers to upgrade their NAT equipment or change it in any way, and for many service providers this motivation is probably sufficient to choose this path. The disadvantages of this approach lie in the scaling properties when looking at very large deployments, and the concerns of application-level translation, where the NAT attempts to be "helpful" by performing *Deep Packet Inspection* and rewriting what it thinks are IP addresses found in packet payloads. Having one NAT do this process is bad enough, but loading them up in sequence is a recipe for trouble.

Are there alternatives?

The Address-plus-Port Approach

One NAT in the path is certainly worse than none from the perspective of application agility and functions. And two NAT functions do not make it any better! Inevitably, that second NAT device adds some additional levels of complexity and fragility into the process.

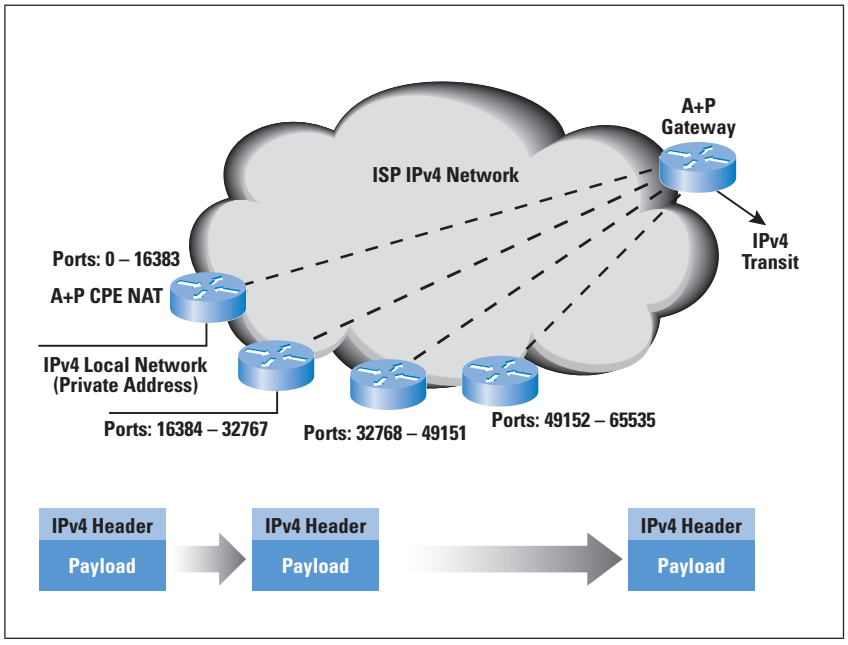
The question is, can these two NAT functions be collapsed back into a single NAT, yet still allow sharing of public IPv4 addresses across multiple end clients? CPE NAT devices currently map connections into the 16-bit *port* field of the single external address. If the CPE NAT could be coerced into performing this mapping into, say, 15 bits of the port field, then the external address could be shared between two edge CPEs, with the leading bit of the port field denoting which CPE. Obviously, moving the bit marker further across the port field will allow more CPE devices to share the one address, but it will reduce the number of available ports for each CPE in the process.

The theory is again quite simple. The CPE NAT is dynamically configured with an external address, as happens today, and a port range, which is the additional constraint. The CPE NAT performs the same function as before, but it is now limited in terms of the range of external port values it can use in its NAT bindings to those that lie within the provided port range. Other CPE devices are concurrently using the same external IP address, but with a different port range.

For outgoing packets this scenario implies only a minor change to the network architecture, in that the RADIUS exchange to configure the CPE now must also provide a port range to the CPE device. The CPE is then constrained such that as it maps private addresses and TCP or UDP port values to the external address and port values, the mapped port value must fall within the configured range.

The handling of incoming packets is more challenging. Here the service provider must forward the packet based not only on the destination IP address, but also on the port value in the TCP or UDP header, because there are now multiple CPE egress points that share the same IP address. A convenient way to perform forwarding is to take the Dual-Stack Lite approach and use an IPv4-in-IPv6 tunnel between the CPE and the external address-plus-port (A+P) gateway. This address-plus-port gateway needs to be able to associate each address and port range with the IPv6 address of a CPE (which it can learn dynamically as it decapsulates outgoing packets that are similarly tunneled from the CPE to the address-plus-port gateway). Incoming packets are encapsulated in IPv6 using the IPv6 destination address that it has learned previously. In this manner the NAT function is performed just once, at the edge, much as it is today, and the interior device is a more conventional form of tunnel server (Figure 7).

Figure 7: Address-plus-Port-Approach



This approach relies on every CPE device being able to operate using a restricted port range, to perform IPv4-in-IPv6 tunnel ingress and egress functions, and act as an IPv6 provisioned endpoint for the service provider network. This set of constraints is perhaps unrealistic for many service provider networks. Further modifications to this model propose the use of an accompanying CGN operated by the service provider to handle those CPE devices that cannot support this address-plus-port function.

This approach has some positive aspects. Pushing the NAT function back to the network edge has some considerable advantage over the approach of moving the NAT to the interior of the network. The packet rates are lower at the edge, allowing for commodity computing to process the NAT functions across the offered packet load without undue stress. The ability to control the NAT behavior with the *Internet Gateway Device* protocol as part of the *Universal Plug and Play* (uPnP) framework will still function in an environment of restricted port ranges. Aside from the initial provisioning process to equip the CPE NAT with a port range, the CPE and the edge environment are largely the same as that of today's CPE NAT model.

That is not to say that this approach is without its negative aspects, and it is unclear as to whether the perceived benefits of a "local" NAT function outweigh the problems in this particular model of address sharing. The concept of port "rationing" is a very suboptimal means of address sharing, given that when a CPE is assigned a port range, those port addresses are unusable by any other CPE. The prudent service provider would assign to each CPE a port address pool equal to some estimate of peak demand, so that, for example, each CPE would be assigned some 1024 ports, allowing a single external IP address to be shared across only some 60 such CPE clients. The Carrier-Grade NAT and Dual-Stack Lite approaches do not attempt this form of rationed allocation, allowing the port address pool to be treated as a common resource, with far higher levels of usage efficiency. The leverage obtained in terms of efficiently using these additional 16 bits of address space is reduced by the imposition of a fixed boundary between customer and service provider use. The central NAT model effectively pools the port address range and would result in more efficient sharing of this common pool across a larger client base.

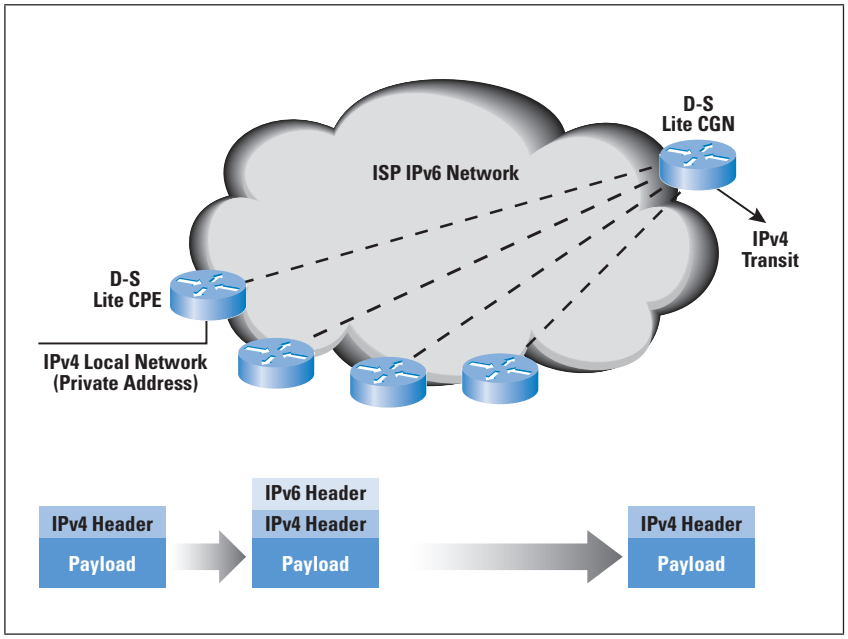
The other consideration here is that this approach means a higher overhead for the service provider, in that the service provider would have to support both "conventional" CPE equipment and address-plus-port equipment. In other words, the service provider will have to deploy a CGN and support customer CPE using a two-level NAT environment in addition to operating the address-plus-port infrastructure. Unless customers would be willing to pay a significant price premium for such address-plus-port service, it is unlikely that this option would be attractive for the service provider as an additional cost above the CGN cost.

Dual-Stack Lite

The concept behind the *Dual-Stack Lite* approach is that the service provider's network infrastructure will need to support IPv6 running in native mode in any case, so is there a way in which the service provider can continue to support IPv4 customers without running IPv4 internally?

Here the customer NAT is effectively replaced by a tunnel ingress-egress function in the Dual-Stack Lite home gateway. Outgoing IPv4 packets are not translated, but are encapsulated in an IPv6 packet header, which contains a source address of the carrier side of the home gateway unit, and a destination address of the ISP's gateway unit. From the service provider's perspective, each customer is no longer uniquely addressed with an IPv4 address, but instead is addressed with a unique IPv6 address, and provided with the IPv6 address of the provider's combined IPv6 tunnel egress point and IPv4 NAT unit (Figure 8).

Figure 8: Dual-Stack Lite



The service provider's Dual-Stack Lite gateway unit will perform the IPv6 tunnel termination and a NAT translation using an extended local binding table. The NAT "interior" address is now a 4-tuple of the IPv4 source address, protocol ID, and port, plus the IPv6 address of the home gateway unit, while the external address remains the triplet of the public IPv4 address, protocol ID, and port. In this way the NAT binding table contains a mapping between interior "addresses" that consist of IPv4 address and port plus a tunnel identifier, and public IPv4 exterior addresses. This way the NAT can handle a multitude of net 10 addresses, because they can be distinguished by different tunnel identifiers.

The resultant output packet following the stripping of the IPv6 encapsulation and the application of the NAT function is an IPv4 packet with public source and destination addresses. Incoming IPv4 packets are similarly transformed, where the IPv4 packet header is used to perform a lookup in the Dual-Stack Lite gateway unit, and the resultant 4-tuple is used to create the NAT-translated IPv4 packet header plus the destination address of the IPv6 encapsulation header.

The advantage of this approach is that there now needs to be only a single NAT in the end-to-end path, because the functions of the customer NAT are now subsumed by the carrier NAT. This scenario has some advantages in terms of those messy "value-added" NAT functions that attempt to perform deep packet inspection and rewrite IP addresses found in data payloads. There is also no need to provide each customer with a unique IPv4 address, public or private, so the scaling limitations of the dual-NAT approach are also eliminated. The disadvantages of this approach lie in the need to use a different CPE device—or at least one that is reprogrammed. The device now requires an external IPv6 interface and at the minimum an IPv4/IPv6 tunnel gateway function. The device can also include a NAT if so desired, but it is not required in terms of the basic Dual-Stack Lite architecture.

This approach pushes the translation into the interior of the network, where the greatest benefit can be derived from port multiplexing, but it also creates a critical hotspot for the service itself. If the Dual-Stack Lite NAT fails in any way, the entire customer base is disrupted. It seems somewhat counterintuitive to create a resilient end-to-end network with stateless switching environments and then place a critical stateful unit right in the middle!

Protocol Translation

So far we have looked at two general forms of approach to hybrid networks that are intended to support both IPv6 transition and greater levels of address usage in IPv4, namely address mapping and tunneling. A third approach lies in the area of protocol translation.

RFC 2765[10] contains the details of a relatively simple protocol-translation mechanism. The approach relies on the basic observation that IPv6 did not make any radical changes to the basic IP architecture of IPv4, and that it was therefore possible to define a stateless mapping algorithm that could translate between certain IPv4 and IPv6 packets. Of course the one major problem here is that there are far more addresses in IPv6 than in IPv4, so the approach used was to map IPv4 addresses into the trailing 32 bits of the IPv6 address prefix `::FFFF:0:0/96`. The approach assumed that to the IPv6-only end host the entire IPv4 network was visible in this mapped IPv6 prefix, and that when the IPv6-only end host wished to communicate with a remote host who was addressed using this IPv4-mapped prefix it would use a source address also drawn from the same IPv4-mapped prefix. In other words, it assumed that all IPv6-only hosts were also assigned a unique IPv4 address.

The *NAT-Protocol Translation* (NAT-PT) approach attempted to relax this constraint, allowing IPv6-only hosts to use a dynamic mapping to a public IPv4 address through the NAT-PT function, in the same way as NAT functions work in an all-IPv4 domain (Figure 9). The proposed approach assumed that the local host was located behind a modified DNS environment where the IPv4 "A" record of an IPv4-only remote service is translated by the DNS gateway into a local IPv6 address where the initial 96 bits of the IPv6 address identify the internal address of the NAT-PT gateway and the trailing 32 bits are the IPv4 address of the remote service. When the local host then uses this address as an IPv6 destination address, the packet is directed by the local routing environment to the NAT-PT device. This device can construct an "equivalent" IPv4 packet by using the local IPv4 address as the source address and the last 32 bits of the IPv6 address as the destination address, and bind the IPv6 source port to a free local port value. These sets of transforms can be locally stored as an active NAT binding. Return IPv4 packets can be mapped back into their "equivalent" IPv6 form by using the values in the binding to perform a reverse set of transforms on the IP address and port fields of the packet.

This approach was published as RFC 2766[11] in February 2000. Some 7 years later in July 2007, the IETF published RFC 4966[12], deprecating NAT-PT to "historic," with an associated list of applications that would not operate correctly through such a device. This negative judgement of NAT-PT seems rather curious to me, given that conventional CPE NAT functions in IPv4 appear to share most, if not all, of the same shortfalls that are listed in RFC 4966. Given the extensive set of compromises that are required in the environment that is partially crippled by IPv4 address exhaustion, it seems rather contradictory to insist upon extremely high levels of functions and robustness from these hybrid translation approaches.

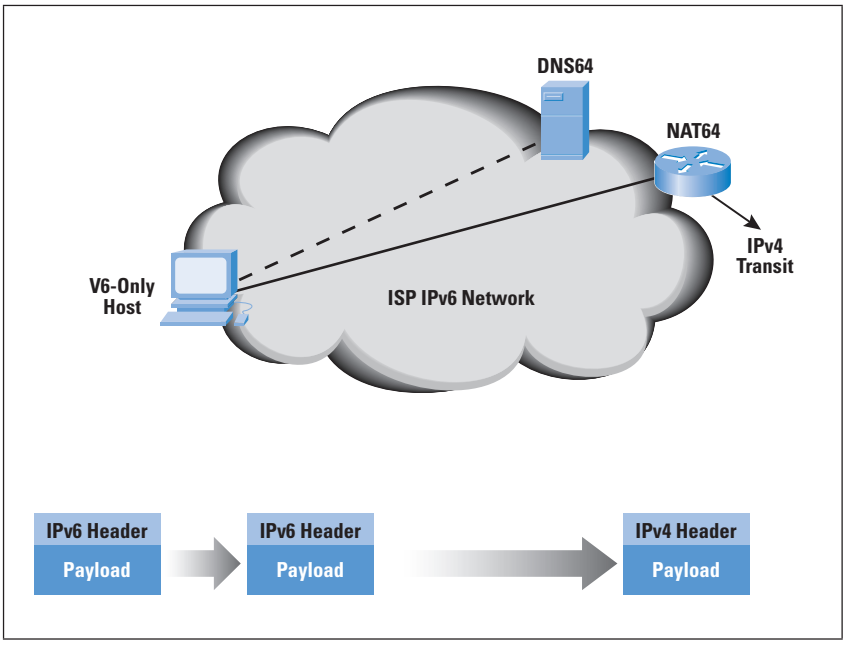


Figure 9: NAT Protocol Translation – NAT64

Not unsurprisingly, NAT-PT is undergoing a revival, this time under the name "NAT64." Not much has changed from the basic approach outlined in NAT-PT. The IPv6-only client performs a DNS lookup through a modified DNS server that is configured with DNS64. If the queried name contains only an IPv4 address, the DNS64 server synthesises an IPv6 response by merging the prefix address of the NAT64 gateway with the IPv4 address. When the client uses this address, the IPv6 packet is directed to the NAT64 gateway, and the same transform as described previously for NAT-PT takes place.

This setup is similar to the CGN model, in so far as the service provider operates a common NAT that shares an IPv4 address pool across a set of end clients.

ISP Conclusions

There really is no single clear path forward from this point. Different ISPs will see some advantages in pursuing different approaches to this dual problem of introducing IPv6 into their service portfolio and at the same time introducing additional measures that allow more efficient use of IPv4 addresses.

However, one common theme is becoming clear. So far ISPs have been able to "externalize" many of these problems by pushing much of the complexity and fragility of NAT functions out to the customer and loading up the CPE with these functions. This approach of externalizing much of the complexity of address compression in NAT functions over to the customer's network cannot be sustained with the IPv6 transition, and no matter which approach is used, whether it is a CGN, NAT64, Dual-Stack Lite, 6RD, or MPLS with 6PE, the ISP now has to actively participate in the delivery of IPv6 and in increasing the efficiency of the use of IPv4.

So for the ISP it is time to start making some technical choices as to how to address the combination of these two rather unique challenges of transition and exhaustion.

Further Reading

The IETF has been working on the issues related to the transition to IPv6 for the past 18 years, and in the intervening period has generated many hundreds of documents. In selecting the following documents as a helpful reading list, I have tried to select only from the more recent documents and those that are overviews of transition technologies rather than reference specifications for individual technologies.

[1] Jari Arkko and Fred Baker, "Guidelines for Using IPv6 Transition Mechanisms during IPv6 Deployment," Internet Draft, Work in Progress, December 2010.

The document discusses the IPv6 deployment models and migration tools, and considers what appears to be effective in networks to date. This Internet Draft, **`draft-arkko-ipv6-transition-guidelines-14.txt`***, is about to be published as an Informational RFC.*

[2] Brian Carpenter and Sheng Jian, "Emerging Service Provider Scenarios for IPv6 Deployment," RFC 6036, October 2010.

This document describes practices and plans that are emerging among Internet Service Providers for the deployment of IPv6 services, using data collected in a survey of numerous ISPs carried out in early 2010.

[3] Reinaldo Penno, Tarun Saxena, Mohamed Boucadair, and Senthil Sivakumar, "Analysis of 64 Translation," Internet Draft, Work in Progress, **draft-ietf-behave-64-analysis-01**, January 2011.

This paper is a working document of the IETF's BEHAVE Working Group. The document notes that because of specific problems, NAT-PT was deprecated by the IETF as a mechanism to perform IPv6-IPv4 translation. Since then, new efforts have been undertaken within IETF to standardize alternative mechanisms to perform IPv6-IPv4 translation. This document evaluates how the new translation mechanisms avoid the problems that caused the IETF to deprecate NAT-PT.

[4] Fred Baker, Xing Li, and Kevin Yin, "Framework for IPv4/IPv6 Translation," Internet Draft, Work in Progress, August 2010.

It is common in the IETF these days to generate a "framework" document as part of the process of developing technical specifications. This draft is a framework document for the general IPv4/IPv6 translation technology. This Internet Draft, **draft-ietf-behave-v6v4-framework-10.txt***, will soon be published as an Informational RFC.*

[5] Elwyn Davies, Suresh Krishnan, and Pekka Savola, "IPv6 Transition/Coexistence Security Considerations," RFC 4942, September 2007.

The transition into a dual-stack environment, while attempting to preserve the integrity of a single service regime, presents numerous security concerns. This document is a good overview of such concerns.

[6] Dan Wing and Andrew Yourtchenko, "Improving User Experience with IPv6 and SCTP," *The Internet Protocol Journal,* Volume 13, No. 3, September 2010.

Building efficient applications in a dual-stack world can be very challenging. It is often the case that poor management of a dual-stack system can make the user experience far slower than just continuing in the IPv4 world. One way to redress this problem is to exchange sequential testing of IPv6 and IPv4 connectivity into a parallel operation—both protocols at once. This article explains the concept.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ contains standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

From The Editor

The process of adding security to various components of Internet architecture reminds me a little bit of the extensive seismic retrofitting that has been going on in California for decades. The process is slow, expensive, and occasionally intensified by a strong earthquake after which new lessons are learned. Over the past 13 years this journal has carried many articles about network security enhancements: *IP Security* (IPSec), *Secure Sockets Layer* (SSL), *Domain Name System Security Extensions* (DNSSEC), Wireless Network Security, and E-mail Security, to name but a few. In this issue we look at routing security again, specifically the efforts underway in the *Secure Inter-Domain Routing* (SIDR) Working Group of the IETF to provide a secure mechanism for route propagation in the *Border Gateway Protocol* (BGP). The article is by Geoff Huston and Randy Bush.

Our second article discusses *Site Multihoming* in IPv6. Multihoming is a fairly common technique in the IPv4 world, but as part of the development and deployment of IPv6, several new and improved solutions have been proposed. Fred Baker gives an overview of these solutions and discusses the implications of each proposal.

By all accounts, *World IPv6 Day* was a successful demonstration and an important step toward deployment of IPv6 in the global Internet. Several major sites left IPv6 connectivity in place after the event, an encouraging sign. Discussions are already underway for another similar event, this time perhaps lasting for as long as a week. Phil Roberts gives an overview of what happened on June 8 and provides pointers to some of the important lessons learned from this experiment.

I want to take a moment to mention the IPJ subscription renewal campaign. As you know, each subscriber is issued a unique subscription ID that, coupled with an e-mail address, gives access to the subscription database by means of a "magic URL." Unfortunately, sometimes the e-mail containing this URL may not arrive in the subscriber's mailbox, perhaps because of spam filtering. Additionally, readers change e-mail addresses as well as postal addresses. If your subscription has expired or you have changed e-mail, postal mail, or delivery preference, send an e-mail to **ipj@cisco.com** with the updated information and we will make sure your subscription is re-instated. The purpose of the renewal campaign is to ensure that we are sending copies of IPJ to the correct addresses and only to those who prefer paper copies. IPJ is always available via our website at **http://cisco.com/ipj**

Securing BGP with BGPsec

by Geoff Huston, APNIC and Randy Bush, IIJ

For many years the fundamental elements of the Internet: *names* and *addresses*, were the source of basic structural vulnerabilities in the network. With the increasing momentum behind the deployment of *Domain Name System Security Extensions* (DNSSEC)[0], there is some cause for optimism that we have the elements of securing the name space now in hand, but what about addresses and routing? In this article we will look at current efforts within the *Internet Engineering Task Force* (IETF) to secure the use of addresses within the routing infrastructure of the Internet, and the status of current work of the *Secure Inter-Domain Routing* (SIDR) Working Group.

We will look at the approach the SIDR Working Group has taken, and examine the architecture and mechanisms that it has adopted as part of this study. This work was undertaken in three stages: the first concentrated on the mechanisms to support attestations relating to addresses and their use; the second looked at how to secure origination of routing announcements; and the third looked at how to secure the transitive part of *Border Gateway Protocol* (BGP) route propagation.

Supporting Attestations About Addresses Through the RPKI

Prior work in the area of securing the Internet routing system has focused on the operation of BGP in an effort to secure the operation of the protocol and validate, as far as is possible, the contents of *BGP Update* messages. Some notable contributions in more than a decade of study include *Secure-BGP* (S-BGP)[1, 16], *Secure Origin BGP* (soBGP)[2], *Pretty Secure BGP* (psBGP)[3], IRR[4], and the use of an *Autonomous System* (AS) *Resource Record* (RR) in the *Domain Name System* (DNS), signed by DNSSEC[5].

The common factor in this prior work was that they all required, as a primary input, a means of validating basic assertions relating to origination of a route into the interdomain routing system: that the IP address block and the AS numbers being used are valid and that the parties using these IP addresses and AS numbers in the context of routing advertisement are properly authorized to so do.

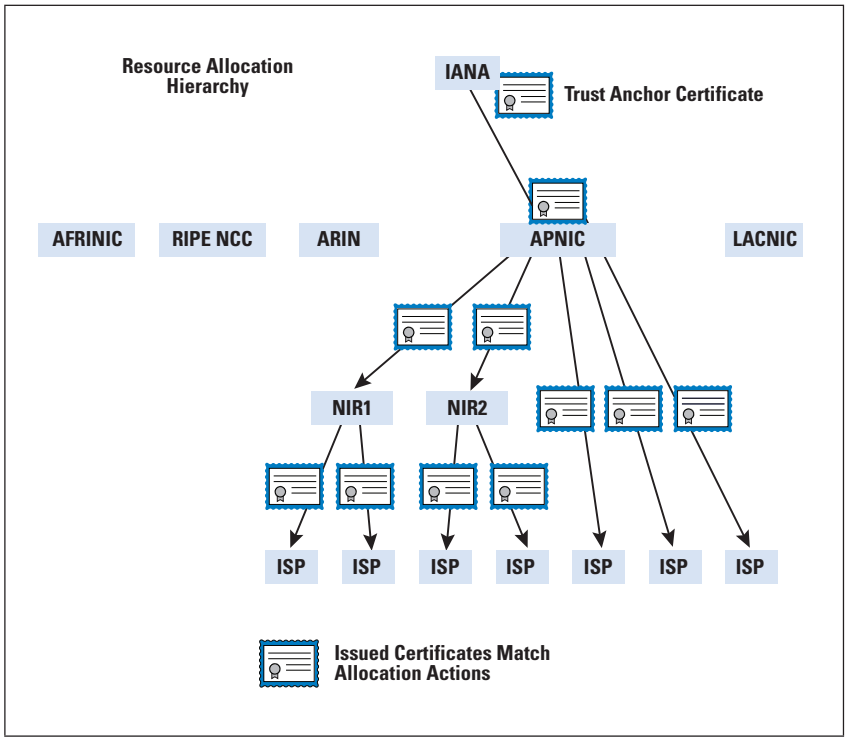
The approach adopted by SIDR for the way in which trust is formalized in the routing environment is through the use of *Resource Certificates*. These certificates are X.509 certificates that conform to the *Public-Key Infrastructure X.509* (PKIX) profile[6]. They also contain an extension field that lists a collection of IP resources (IPv4 addresses, IPv6 addresses, and AS Numbers)[7]. These certificates attest that the certificate issuer has granted to the certificate subject a unique "right-of-use" for the associated set of IP resources, by virtue of a resource allocation action.

This concept mirrors the resource allocation framework of the Internet *Assigned Numbers Authority* (IANA), the *Regional Internet Registries* (RIRs), operators, and others, and the certificate provides a means for a third party (relying party) to formally validate assertions related to resource allocations[8].

The hierarchy of the *Resource Public Key Infrastructure* (RPKI) is based on the administrative resource allocation hierarchy, where resources are distributed from the IANA to the RIRs, *Local Internet Registries* (LIRs), *National Internet Registries* (NIRs), and end users. The RPKI mirrors this allocation hierarchy with certificates that match current resource allocations (Figure 1).

The *Certification Authorities* (CAs) in this RPKI correspond to entities that have been allocated resources. Those entities are able to sign authorities and attestations, and to do so they use specific-purpose *End Entity* (EE) certificates. This additional level of indirection allows the entity to customize each issued authority for specific subsets of number resources that are administered by this entity. Through the use of single-use EE certificates, the issuer can control the validity of the signed authority through the ability to revoke the EE certificate used to sign the authority. As is often the case, a level of indirection comes in handy.

Figure 1: Hierarchy of the RPKI



Signed attestations relating to addresses and their use in routing are generated by selecting a subset of resources that will be the subject of the attestation, by generating an EE certificate that lists these resources, and by specifying validity dates in the EE certificate that correspond to the validity dates of the authority. The authority is published in the RPKI repository publication point of the entity. The RPKI makes conventional use of *Certificate Revocation Lists* (CRLs) to revoke certificates that have not expired but are no longer valid. Every Certification Authority in the RPKI regularly issues a CRL according to the declared CRL update cycle of the Certification Authority. A Certification Authority certificate may be revoked by an issuing authority for numerous reasons, including key rollover, the reduction in the resource set associated with the certificate subject, or termination of the resource allocation. To invalidate an object that can be verified by a given EE certificate, the Certification Authority that issued the EE certificate can revoke the corresponding EE certificate.

The RPKI uses a distributed publication framework, wherein each Certification Authority publishes its products (including EE certificates, CRLs, and signed objects) at a location of its choosing. The set of all such repositories forms a complete information space, and it is fundamental to the model of securing BGP in the public Internet that the entire RPKI information space be available to every *Relying Party* (RP). It is the role of each RP to maintain a local cache of the entire distributed repository collection by regularly synchronizing each element in the local cache against the original repository publication point. To assist RPs in the synchronization task, each RPKI publication point uses a *manifest,* a signed object that lists the names (and hash values) of all the objects published at that publication point. It is used to assist RPs to ensure that they have managed to synchronize against a complete copy of the material published at the Certification Authority publication point.

The utility of the RPKI lies in its ability to validate digitally signed information and, therefore, give relying parties some confidence in the validity of signed attestations about addresses and their use. The particular utility of the RPKI is not as a means of validation of attestations of an individual's identity or that individual's role, but as a means of validating that person's authority to use IP address resources. Although it is possible to digitally sign any digital object, it has been suggested that the RPKI system uses a very small number of standard signed objects that have particular meaning in the context of routing security.

Securing Route Origination

The approach adopted by SIDR to secure origination of routing information is one that uses a particular signed authority, a *Route Origination Authorization* (ROA)[10]. An ROA is an authority created by a prefix holder that authorizes an AS to originate one or more specific route advertisements into the interdomain routing system.

An ROA is a digital object formatted according to the *Cryptographic Message Syntax Specification* (CMS)[11] that contains a list of address prefixes and one AS number. The AS is the specific AS being authorized to originate route advertisements for one or more of the address prefixes in the ROA. The CMS object also includes the EE resource certificate for the key used to verify the ROA. The IP Address extension in this EE certificate must encompass the IP address prefixes listed in the ROA contents.

The ROA conveys a simple authority. It does not convey any further routing policy information, nor does it convey whether or not the AS holder has even consented to actually announce the prefix(es) into the routing system. The associated EE certificate is used to control the validity of the ROA, and the CMS wrapper is used to securely bind the ROA and the EE certificate within a single signed structure.

There is one special ROA, one that authorizes AS 0 to originate a route. Because AS 0 is a reserved AS that should never be used by a BGP speaker, this ROA is a "negative" authority, used to indicate that no AS has authority to originate a route for the address prefix(es) listed in the ROA.

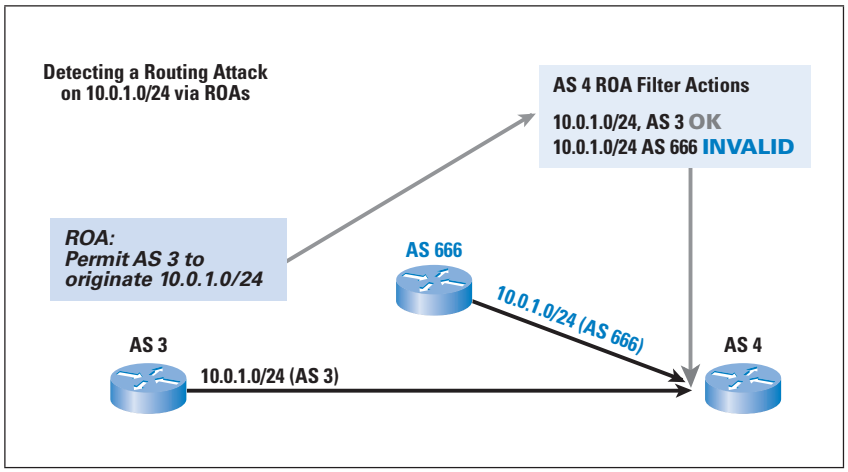
If the entire routing system were to be populated with ROAs, then identification of an invalid route advertisement would be directly related to detection of an invalid ROA or a missing ROA. However, in a more likely scenario of partial use of ROAs (such as when only some legitimate route originations are authorized in a ROA), the absence of an ROA cannot be interpreted simply as an unauthorized use of an address prefix. This scenario leads to the use of a tri-state validation process for routes, as follows.

If a given route matches exactly the information contained in an ROA whose EE certificate can be validated in the RPKI (a "valid" ROA), then the route can be regarded as a "valid" origination. Where the address prefix matches that in a valid ROA but the origination AS does not match the AS number in the ROA, and there are no other valid ROAs that explicitly validate the announcing AS, then the route can be considered to be "invalid." Also, where the address prefix is more specific than that of a valid ROA, and there are no other valid ROAs that match the prefix, then the route can also be considered "invalid." Where the prefix in a route is not described in any ROA and is not a more specific prefix of any ROA, the route has an "unknown" validation outcome.

These three potential outcomes can be considered a set of relative local preferences. Routes whose origins can be considered "valid" are generally proposed to be preferred over routes whose origins are unknown, which, in turn, can generally be preferred over routes whose origins are considered invalid. However, such relative preferences are a matter to be determined by local routing policy. Local policies may choose to adopt a stricter policy and, for example, discard routes with an invalid validation outcome[12].

The way in which ROAs are used to validate the origin of routes in BGP differs from many previous proposals for securing BGP. In this framework the ROAs are published in the RPKI distributed repository framework. Each RP can use the locally cached collection of valid ROAs to create a validation filter collection, with each element of the set containing an address, prefix size constraints, and an originating AS. It is this filter set—rather than the ROAs themselves—that are fed to the local routers[13]. An example of the way in which ROAs can be used to detect prefix hijack attempts is shown in Figure 2.

Figure 2: Use of ROAs to detect Unauthorized Route Origination



The model of injecting validation of origination into the BGP domain is an example of a highly modular and piecemeal deployment. There are no changes to the BGP protocol for this origin validation part of the secure routing framework.

The process of securing origination starts with the address holder, who generates local keys and requests certification of their address space from the entity from whom their addresses were allocated or assigned. With this Certification Authority resource certificate, the address holder is then in a position to generate an EE certificate and a ROA that assigns an authority for a nominated AS to advertise a route for an address prefix drawn from its address holdings. The one condition here is that if an address holder issues a ROA for an address prefix providing an authority for one AS to originate a route for this prefix, then the address holder is required to issue ROAs for all the ASs that have been similarly authorized to originate a route for this address prefix. The address holder publishes this ROA in its publication point in the distributed RPKI repository structure.

Relying parties can configure a locally managed cache of the distributed RPKI repository and collect the set of valid ROAs. They can then, with the dedicated RPKI cache-to-router protocol[13], maintain, on a set of "client" routers, the set of address prefix/originating AS authorities that are described in valid ROAs. The BGP-speaking router can use this information as an input to the local route decision process.

This model of operation supports piecemeal incremental deployment, wherein individual address holders may issue ROAs to authorized routing advertisements independent of the actions of other address holders. Also, ASs may deploy local validation of route origination independently of the actions of other ASs. And given that there are no changes to the operation of BGP, then there are no complex inter-dependencies that hinder piecemeal incremental deployment of this particular aspect of securing routing.

Securing Route Propagation: BGPsec

Origin validation as described earlier does not provide cryptographic assurance that the origin AS in a received BGP route was indeed the originating AS of this route. A malicious BGP speaker can synthesize a route as if it came from the authorized AS. Thus, it is very useful in detecting accidental misannouncements, but origination validation does little to prevent malicious routing attacks from a determined attacker.

In looking at the operation of the BGP protocol, some parts of the protocol interaction are strictly local between two BGP-speaking peers, such as advising a peer of local attributes. Another part of the BGP protocol is a "chained" interaction, in which each AS adds information to the protocol object. This attribute of a BGP update, the *AS Path,* is not only useful to detect and prevent routing loops, it is also used in the BGP best-path-selection algorithm.

A related routing security question concerns the validity of this "chained" information, namely the AS Path information contained in a route. Within the operation of the BGP protocol, each AS that propagates an update to its AS neighbors is required to add its AS number to the AS Path sequence. The inference is that at any stage in the propagation of a route through the interdomain routing system, the AS Path represents a viable AS transit sequence from the local AS to the AS originating the route. This AS Path attribute of a route is used for loop detection. Locally, the AS Path may also be used as input to a local route policy process, using the length of the AS Path as a route metric.

Attacks on the AS Path can be used to subvert the routing environment. A malicious BGP speaker may manipulate the AS Path to prevent an AS from accepting a route by adding its AS number to the AS Path, or it may attempt to make a particular route more likely to be selected by a remote AS by stripping out ASs from the AS Path. Accordingly, it is important to equip a secure BGP framework with the ability to validate the authenticity of the AS Path presented in a BGP update[14].

When attempting to validate an AS path, many potential validation questions must be addressed.

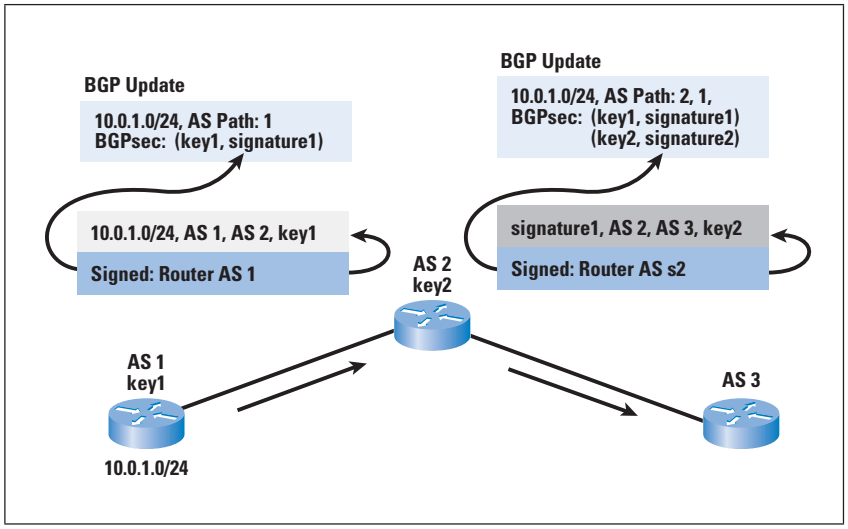
- The first and weakest question is: Are all ASs in the AS Path valid ASs?
- A slightly stronger validation question is: Do all the AS pairs in the AS Path represent valid AS adjacencies (where both ASs in the pair-wise association are willing to attest to their mutual adjacency in BGP)?
- A even stronger question is: Does the sequence of ASs in the AS Path represent the actual propagation path of the BGP route object?

This last question forms the basis for the SIDR activity in defining an AS Path validation framework, BGPsec. This attempt is to assure a BGP speaker that the operation of the BGP protocol is operating correctly and that the content of a BGP update correctly represents the inter-AS propagation path of the update from the point of origination to the receiver of the route. This tool is not the same as a policy validation tool and it does not necessarily assure the receiver of the route that this update conforms to the routing policies of neighboring BGP speakers. This route also does not necessarily reflect the policy intent of the originator of the route. The BGPsec framework proposed for securing the AS Path also uses a local RPKI cache, but it includes an additional element of certification. The additional element of the security credentials used here is an extension to the certification of AS numbers with a set of operational keys and their associated certificates used for signing update messages on *External Border Gateway Protocol* (eBGP) routers in the AS. These "router certificates" can sign BGP update attributes in the routing infrastructure, and the signature can be interpreted as being a signature made "in the name of" an AS number.

In the BGPsec framework, eBGP-speaking routers within the AS have the ability to "sign" a BGP update before sending it. In this case, the added signature "covers" the signature of the received BGP update, the local AS number, the AS number to which the update is being sent, as well as a hash of the public key part of the router key pair used to sign route updates.

The couplet of the public key hash and the signature itself are added to the BGP protocol update as BGPsec update attributes. As the update traverses a sequence of transit ASs, each eBGP speaker at the egress of each AS adds its own public key hash and digital signature to the BGPsec attribute sequence (Figure 3).

Figure 3: BGPsec AS Path Protection



This interlocking of signatures allows a receiver of a BGP update to use the interlocking chain of digital signatures to validate (for each AS in the AS Path) that the corresponding signature was correctly generated "in the name of" that AS in the AS Path, and that the next AS in the path matches the next AS in the signed material. The "forward signing" that includes the AS to which the update is being sent prevents a man-in-the-middle attack of the form of taking a legitimate outbound route announcement destined for one neighbor AS and redirecting it to another AS. But this signing of the AS Path is not quite enough to secure the route update, because the AS Path needs to be coupled to the actual address prefix by the route originator. The route originator needs to sign across not only the local AS and the AS to whom the route update is being sent, but also the address prefix and the expiry time of the route. This action allows the path to be "bound" to the prefix and prevents a man-in-the-middle from splicing a signed path or signed-path fragment against a different prefix.

If the signatures that "span" the AS Path in the BGP update can all be validated, then the receiver of the BGP update can validate, in a cryptographic sense, the currency of the routing update. It can also validate that the route update was propagated across the inter-AS routing space in a manner that is faithfully represented in the AS Path of the route.

The expiry time of the EE certificates used in conjunction with signed route updates introduces a new behavior into BGPsec. In the context of BGP, an announced route remains current until it is explicitly withdrawn or until the peer session that announced the route goes down. This property of BGP introduces the possibility of "ghost-route" attacks in BGP, wherein a BGP speaker fails to propagate a withdrawal in order to divert the consequent misdirected traffic from its peers.

In BGPsec, all route advertisements are given an expiry time by the originator of the route. This expiry time corresponds to the "notAfter" time of the EE certificate used to sign the protocol update, after which time the route is considered invalid. The implication is that a route originator is required to readvertise the route, and refresh the implicit expiry timer of the associated digital signature at regular intervals.

This approach to route-update validation is not quite the "light-touch" of origination validation. In this case the mechanism requires the use of a new BGP attribute and negotiation of a new BGP capability between eBGP peers, in turn meaning that the model of incremental deployment is one that is more "viral" than truly piecemeal. By "viral" we mean that this model is one of incremental deployment in which direct eBGP peers of a BGPsec-speaking AS will be able to speak BGPsec between themselves in a meaningful way. In turn these adjacent ASs can offer to speak BGPsec with their eBGP peers, and so on. This reality does not imply that BGPsec deployment must necessarily start from a single AS, but it does imply that communities of interconnected ASs all speaking BGPsec will be able to provide assurance via BGPsec on those routes originated and propagated within that community of interconnected ASs. It also implies that the greatest level of benefit to adopters of secure BGP will be realized by ASs that adopt BGPsec as a connected community of ASs.

Other changes to the behavior of BGP are implied by this mechanism. BGP conventionally permits "update packing," where numerous address prefixes can be placed in a single update message if they share a common collection of attributes, including the AS Path. At this stage it appears that such update packing would not be supported in secure BGP, and each update in secure BGP would refer to a single prefix. Obviously this situation would have some effect on the level of BGP traffic, but early experiments suggest not at an unreasonable cost.

There are further effects on BGP that have not been fully quantified in studies to date. The addition of a compound attribute of a signature and a public key identifier for every AS in the AS Path has size implications on the amount of local storage a secure BGP speaker will need to store these additional per-prefix per-peer attributes. It also has broader implications if used in conjunction with current proposals for multipath BGP where multiple paths, in addition to the "best" path, are propagated to eBGP peers. Also, the computational load of validation of signatures in secure BGP is significantly higher in terms of the number of cryptographic operations that are required to validate a BGP update.

However, BGPsec is not intended to "tunnel" across those parts of the interdomain routing space that do not support BGPsec capabilities. When an update leaves a BGPsec realm, the BGPsec signature attributes of the route are stripped out, so the storage overheads of BGPsec are not seen by other BGP speakers.

Similarly, the periodic updates that result from the expiry timer should not propagate beyond the BGPsec realm. If the boundary is prepared to perform BGP update packing to non-BGPsec peers, then even the unpacked update overhead is not carried outside of the BGPsec realm.

It is also noted that the "full" load of BGPsec would only necessarily be carried by "transit" ASs; that is, those ASs that propagate routes on behalf of other ASs. Historically we see some 15 percent of ASs are "transit" ASs, while all other ASs behave as "stub" ASs that only originate routes and do not appear to transit routes for others. Such stub ASs can support a "lightweight" simplex version of BGPsec that can either point a default route to its upstream AS provider or trust its upstream ASs to perform BGPsec validation. In this case the stub AS needs to provide BGPsec signed originated routes to its upstream ASs, but no more.

Conclusion

The work on the specification of the RPKI itself and the specification of origin validation is nearing a point of logical completion of the first phase of standardization within the IETF, and the working draft documents are being passed from the working group into the review process leading to their publication as proposed standard RFCs. The RIRs are in the process of launching their RPKI services based on these specifications, and the initial deployment of working code has been made by numerous parties, who are also working on integration of origination validation in BGP implementations.

The work on securing the AS Path is at an earlier phase in the development process, and the SIDR Working Group is considering the initial design material. It is expected to take a similar path of further review and refinement in light of developing experience and study of the proposed approach.

The RPKI has been designed as a robust and simple framework. As far as possible, existing standards, technologies, and processes have been exploited, reflecting the conservatism of the routing community and the difficulty in securing rapid, widespread adoption of novel technologies.

Acknowledgements

The work described here is the outcome of the efforts of many individuals who have contributed to securing BGP over a period that now spans two decades, and certainly too many to ensure that all the contributors are recognized here. Instead, the authors would like to acknowledge their work and trust that the mechanisms described here are a faithful representation of the cumulative sum of their various contributions.

Randy has been in computing for 45 years, and has a few decades of Internet operations experience. He was the engineering founder of Verio, which is now NTT/Verio. He has been heavily involved in transferring Internet technologies to developing economies for more than 20 years. E-mail: **randy@psg.com**

Views of IPv6 Site Multihoming

by Fred Baker, Cisco Systems

In today's Internet, *site multihoming*—an edge network configuration that has more than one service provider but does not provide transit communication between them—is relatively common. Per the statistics at **www.potaroo.net**, almost 40,000 *Autonomous Systems* are in the network, of which about 5,000 seem to offer transit services to one or more customers. The rest are in terminal positions, possibly meaning three things. They could be access networks, broadband providers offering Internet access to small companies and residential customers; they could be multihomed edge networks; or they might be networks that intend to multihome at some point in the future. The vast majority, on the order of 75 percent, are multihomed or intend to multihome. That is but one measure; you do not have to use *Border Gateway Protocol* (BGP) routing to have multiple upstream networks. Current estimates suggest that there is one multihomed entity per 50,000 people worldwide, and one per 18,000 in the United States.

We also expect site multihoming to become more common. A current proposal in Japan suggests that each home might be multihomed; it would have one upstream connection for Internet TV, and one or more other connections provided by *Internet Service Providers* (ISPs), operating over a common *Digital Subscriber Line* (DSL) or fiber-optic infrastructure. That scenario has one multihomed entity for every four people.

Why do edge networks multihome? Reasons vary. In the Japanese case just propounded, it is a fact of life—users have no other option. In many cases, it is a result of a work arrangement, or a strategy for achieving network reliability through redundancy.

For present purposes, this article considers scaling targets derived from a world of 10 billion people (circa 2050), and a ratio of one multihomed entity per thousand people—on the order of 10,000,000 multihomed entities at the edge of the Internet. Those estimates may not be accurate 40 years from now, but given current trends they seem like reasonable guesses.

RFC 1726[1], the technical criteria considered in the selection of what at the time was called *IP Next Generation* (IPng), did not mention multihoming per se. Even so, among the requirements are scalable and flexible routing, of which multihoming is a special case. When IPv6 was selected as the "next generation," multihoming was one of the topics discussed. The Internet community has complained that this particular goal was not fulfilled. Several proposals have been proffered; unfortunately, each has benefits, and each has concerns. No single perfect solution is universally accepted.

In this article, I would like to look at the alternatives proposed and consider the effects they have. In this context, the goals set forth in RFC 3582[2] are important; many people tried to state what they would like from a multihoming architecture, and the result was a set of goals that solutions only asymptotically approach.

The proposals considered in this article include:

- *Provider Independent Addressing,* also known as *BGP Multihoming*
- *Exchange-Based Addressing*
- *Shim6,* also known as *Level 3 Multihoming*
- *Identifier-Locator Network Protocol* (ILNP)
- *Network Prefix Translation,* also known as *NAT66*

BGP Multihoming

BGP Multihoming involves a mechanism relatively common in the IPv4 Internet; the edge network either becomes a member of a *Regional Internet Registry* (RIR) [APNIC, RIPE, LACNIC, AFRINIC, ARIN] and from that source obtains a *Provider-Independent* (PI) prefix, or obtains a *Provider-Allocated* (PA) prefix from one provider and negotiates contracts with others using the same prefix. In any case, it advertises the prefix in BGP, meaning that all ISPs—including in the PA case—the provider that allocated it, must carry it as a separate route in their routing tables.

The benefit to the edge is easily explained, and in the case of large organizations it is substantial. Consider the case of Cisco Systems, whose internal network rivals medium-sized ISPs for size and complexity. With about 30 *Points of Attachment* (PoAs) to the global Internet, and at least as many service providers, Cisco has an IPv6 /32 PI prefix, and hundreds of offices to interconnect using it. One possible way to enumerate the Cisco network would be to use the next five bits of its address (32 /37 prefixes) at its PoAs, and allocate prefixes to its offices by the rule that if their default route is to a given PoA, their addresses are derived from that PoA. By advertising the PoAs /37 and a backup /32 into the Internet core at each PoA, Cisco could obtain effective global routing. It would also obtain relative simplicity for its internal network—only one subnet is needed on any given *Local-Area Network* (LAN) regardless of provider count or addressing, and routing can be optimized independently from the outside world.

The problem that arises with PI addressing, if taken to its logical extreme, is that the size of the routing table explodes. If every edge network obtains a PI prefix—neglecting for the moment both BGP traffic engineering and the kind of de-aggregation suggested in Cisco's case—the logical outcome of enumerating the edge is a routing table with on the order of 107 routes. The memory required to store the routing table, and in the *Secure Interdomain Routing* (SIDR) case the certificates that secure it, is one of the factors in the cost of equipment. The volume of information also affects the time it takes to advertise a full routing table, and in the end the amount of power that a router uses, the heat it produces, and a switching center's air conditioning requirements. Thus both the capital cost of equipment used in transit networks and the cost of operations would be affected. In effect, the Internet becomes the "poster child" for the *Tragedy of the Commons*.

Exchange-Based Addressing

Steve Deering proposed the concept of exchange-based addressing at the IETF meeting in Stockholm in 1995, under the name *Metropolitan Addressing*. In this model, prefixes do not map to companies, but to Internet exchange consortia, likely regional. One organizing principle might be to associate an Internet exchange with each commercial airport worldwide, about 4000 total, resulting in a global routing table on the same order of magnitude in size. Edge networks, including residential networks, within that domain obtain their prefix from the exchange, and they are used by any or all ISPs in the region. Routes advertized to other regions, even within the same ISP, are aggregated to the consortium prefix.

The benefits to the edge network in exchange-based addressing are similar to the benefits of PI addressing for a large corporation. In effect, the edge networks served by an exchange consortium behave like the "departments" of a "user consortium," and they enjoy great independence from their upstream providers. They can multihome or move between providers without changing their addressing, and on a global scale the routing table is contained to a small multiple of the number of such consortia.

However, the benefit to users is in most cases a detriment to their ISPs; the ISPs are forced to maintain routes to each user network served by the consortium—or at least routes for their own customers and a default route to the exchange. Thus, the complexity of routing is moved from the transit core to the access networks serving regional consortia. In addition, if there is no impediment to a user flitting among ISPs, users can be expected to flit, imposing business costs.

The biggest short-term effect on the ISP might well be the reengineering of its transit contracts. In today's Internet, a datagram sent by users to their ISPs is quickly shuttled to the destination's ISPs, which then carry it over the long haul. In an exchange-based network, there is no way to remotely determine which local ISP or ISP instance is serving a given customer.

Hence, the sender's ISP carries the datagram until it reaches the remote consortium, whence it switches to the access network serving the destination. One could argue that a "sender-pays" model might have benefits, but it is very different from the present model.

The edge network has problems, too. If the edge network is sufficiently distributed, it will have services in several exchange consortia, and therefore several prefixes. Although there is nothing inherently bad about that, it may not fit the way a cloud computing environment wants to move virtual hosts around, or miss other requirements.

Level 3 Multihoming: Shim6

The IETF's *shim6* model[9] starts from the premise that edge networks obtain their prefixes from their upstream ISPs—PA Addressing. If a typical residential or small business does so, there is no question of advertising its individual route everywhere; the ISP can route internally as its needs to, but globally, the number of ISPs directs the size of the routing table. If that is, as `potaroo` suggests, on the order of 10,000, the size of the routing table will be on the same order of magnitude.

The benefit to the ISP should be obvious; it does not have to change its transit contracts, and although there will be other concerns, it does not have the routing table ballooning memory costs or route exchange latencies.

However, as exchange-based addressing moves operational complexity from the transit core to the access network, shim6 moves such complexities to the edge network itself and to the host in it. If a network has multiple upstream providers, each LAN in it will carry a subnet from each of those providers—not one subnet per LAN, but as many as the providers of the host's LAN will use. At this point, the ingress filtering of RFC 3704[21] at the provider becomes a problem at the edge; the host must select a reasonable address for any session it opens, and must do so in the absence of specific knowledge of network routing. A wrong guess can have dramatic effects; a session routed to the wrong provider may not work at all, and an unfortunate address choice can change end-to-end latency from tens of milliseconds to hundreds or worse by virtue of backbone routing.

Application layer referrals and other application uses of addresses also have difficulties. Although the address a session is using will work both within and without the network, if a host has more than one address, one of the other addresses may be more appropriate to a given use. Hence, the application that really wants to use addresses is saddled with finding all of the addresses that its own host or a peer host might have.

There is also an opportunity. TCP today associates sessions with their source and destination addresses. The shim6 model, implemented in the *Stream Control Transmission Protocol* (SCTP)[17] and *Multipath TCP* (MPTCP)[16], allows a session to change its addresses, meaning that a session can survive a service provider outage. Doing the same in TCP requires the insertion of a shim protocol between IP and TCP; at the Internet layer, the address might change, but the shim tracks the addresses for TCP.

There are, of course, ways to solve the outstanding problems. For simple cases, RFC 3484[3, 4] describes an address-selection algorithm that has some promise. In the Japanese case, a residential host might use link-local addresses within its own network, addresses appropriate to the television service on its TV and set-top box, and an ISP's prefix for everything else. If there is more than one router in the residential LAN serving more than one ISP, exit routing can be accomplished by having the host send data using an ISP's source address to the router from which it learned the prefix. When the network becomes more complex, though, we are looking at new routing protocols that can route based on a combination of the source and the destination addresses, and we are looking at network management methodologies that make address management simpler than it is today, adding and dropping subnets on LANs—and as a result renumbering networks—without difficulty. It also implies a change to the typical host implementing the shim protocol. Those technologies either do not exist or are not widely implemented today.

Identifier-Locator Network Protocol

The concept of separating a host's identity from its location has been intrinsic to numerous protocol suites, including the *Xerox Network Systems* (XNS), *Internetwork Packet Exchange* (IPX), and *Connectionless Network Service* (CLNS) models. In the IP community, it was first proposed in Saltzer's ruminations on naming and binding, RFC 1498[5], and in Noel Chiappa's NIMROD routing architecture, RFC 1992[6]. In short, a host (or a set of applications running on a host, or a set of sessions it participates in) has an identifier independent of its network topology, and sessions can change network paths by simply changing the topological locations of their endpoints. Mike O'Dell, in Internet Drafts in 1996 and 1997 called *8+8* and *GSE,* suggested an implementation of this scenario using the prefix in the IPv6 address as a locator and the interface identifier as an identifier. One implication of the GSE model is the use of a network prefix translation between an edge network and its upstream provider whatever prefix the edge network uses internally, in the transit backbone, the locator appears to be a PA prefix allocated by the ISP in question. As a result, the routing table, as in shim6, enumerates the ISPs in the network—on the order of 10,000.

The *Identifier-Locator Network Protocol* (ILNP) takes the solution to fruition, operating on that basic model and adding a *Domain Name System* (DNS) Resource Record and a random number nonce to mitigate on-path attacks that result from the fact that the *IPv6 Interface Identifier* (IID) is not globally unique.

As compared to the operational complexities and costs of PI Addressing, Exchange-Based Addressing, and shim6, ILNP has the advantage of being operationally simple. Each LAN has one subnet, when adding or changing providers no edge network renumbering is required, and, as noted, the cost of the global routing table does not increase. Additionally, it is trivial to load-share traffic across points of attachment to multiple ISPs, because the locator is irrelevant above the network layer. And unlike IPv4/IPv4 *Network Address Port Translation* (NAPT), the translation is stateless; as a result, sessions using *IP Security* (IPsec) *Encapsulation Security Protocol* (ESP) encryption can cross it.

In this case, the complexities of the network are transferred to the application itself, and to its transport. The application must, in some sense, know all of its "outside" addresses. It can learn them, of course, by using its domain name in referrals and other uses of the address; in some cases however, the application really wants to know the address itself. If it is communicating those addresses to other applications—the usual usage—the assumption that its view of its address is meaningful to its remote peer is, in the words of RFC 3582[2], *Unilateral Self-Address Fixing* (UNSAF), and the concerns raised in RFC 2993[7] are the result. To mitigate those concerns, ILNP excludes the locator from the TCP and *User Datagram Protocol* (UDP) pseudo-headers (and as a result from the checksum).

The implication of ILNP is, as a result, that TCP and UDP must be either changed or exchanged for other protocols such as *Stream Control Transmission Protocol* (SCTP) or *Multipath TCP* (MPTCP), and that applications must either use DNS names when referring to themselves or other systems in their network—sharply dividing between the application and network layers—or devise a means by which they can determine the full set of their "outside" addresses.

Network Prefix Translation, Also Known as NAT66

Like ILNP, *Network Prefix Translation* (NPTv6) derives from and can be considered a descendant of the GSE model. It differs from ILNP in that it defines no DNS Resource Record, defines no end-to-end nonce, and requires no change to the host, especially its TCP/UDP stacks. To achieve that, the translator updates the TCP/UDP checksum in the source and destination addresses.

If the ISP prefix is a /48 prefix, this prefix allows for load sharing of sessions across translators leading to multiple ISPs; if the ISP prefix is longer, such as a /56 or /60, the checksum update must be done in the IID, and as a result load sharing can be accomplished only across translators between the same two networks. Like ILNP and unlike IPv4/IPv4 NAPT, the translation is stateless; as a result, sessions using IPsec ESP encryption can cross it.

The complexities of the network are again transferred to the application itself, but not to its transport. The application must, in some sense, know all of its "outside" addresses. Using its domain name in referrals and other uses of the address can determine these addresses; in some cases, however, the application really wants to know the address itself. If it is communicating those addresses to other applications—the usual usage—the assumption that its view of its address is meaningful to its remote peer is, again in the words of RFC 3582[2], "UNSAF," and some of the concerns raised in RFC 2993[7] result.

The implication of NPTv6 is that applications must either use DNS names when referring to themselves or other systems in their network—sharply dividing between the application and network layers—or devise a means by which they can determine the full set of their "outside" addresses. However, the IPv6 goal of enabling any system in the network to communicate with any other given administrative support is retained.

Ways Forward

From the perspective of this author, the choice of multihoming technology will in the end be an operational choice. The practice of multihoming is proliferating and will continue to do so. There is a place for provider-independent addressing; it may not in reality make sense for 40,000 companies, but it probably does for the largest edge networks. At the other extreme, shim6-style multihoming makes sense in residential networks with a single LAN; as described earlier, there are simple approaches to making that work through reasonable policy approaches.

For the vast majority of networks in between, policy suggestions that do not substantially benefit the network or users who implement them do not have a good track record. Hence, while Exchange-Based Addressing materially assists in edge network problems, there is no substantive reason to believe that the transit backbone will implement it. Similarly, although shim6 materially helps with the capital and operational expenses of operating the transit backbone, it is not likely that edge networks will implement it.

We also have a poor track record in changing host software. For example, SCTP is in many respects a superior transport protocol to TCP—it allows for multiple streams, it is divorced from network layer addressing, and it allows endpoints to change their addresses midsession.

In a 2009 "Train Wreck" workshop at Stanford University, in which various researchers argued all day in favor of the development of a new transport with requirements much like those of SCTP, the research community acted as if ignorant of it when the protocol was brought up in conversation.

NPTv6 is not a perfect solution, but this author suspects that it will be operationally simple enough to deploy and manage and close enough to the requirements of edge networks and applications that it will, in fact, address the topic of multihoming.

FRED BAKER, a Cisco Fellow, has been active in technology development and Internet standardization since the 1980s. He participated in early development of IEEE 802.1d switching and IP routing. In the IETF, he has written or edited RFCs on a variety of topics, and chaired both working groups and the IETF itself. At this time, he is the IETF's Voting Member on the U.S. NIST Smart Grid Interoperability Panel, a member of the SGIP's Architecture Committee, and co-chair of the IETF IPv6 Operations Working Group. At Cisco, his group supports research at universities; he is looked to for research advice and mentorship both within and outside the company. E-mail: **fred@cisco.com**

Reflecting on World IPv6 Day

by Phil Roberts, ISOC

On June 8, 2011, many websites around the world made their main webpage reachable over IPv6 for 24 hours, and many of those that did this left their sites IPv6-accessible afterward.

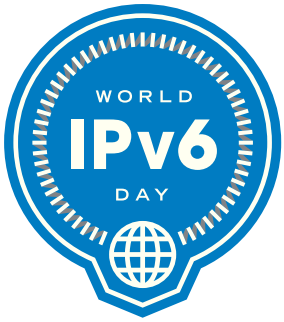
Major worldwide websites enabled IPv6 on their main page. Google enabled not only its main website but also YouTube and Blogger. Facebook and Yahoo! both enabled their main webpages as well. These websites are the five most visited websites in the world according to Alexa rankings. Other major worldwide websites that enabled IPv6 include Yahoo! Japan, Bing, Microsoft, BBC, CNN, and AOL.

Important local websites in countries around the world also joined in. In South Korea both Naver and Daum (the first and fourth most visited sites in South Korea according to Alexa) joined the event. In the Czech Republic four of the top 25 local websites joined. There were also major sites from Brazil, Portugal, and Indonesia.

Purposes

Enabling IPv6 in this way served numerous purposes:

- Network operators clearly saw that content is going to be available on IPv6. Although the major websites may not be quite there yet, it is clear that they are seriously moving in that direction.
- The industry worked to improve problems with IPv6 connectivity. Some immediate improvement resulted, and more fixes are underway to further improve IPv6 connectivity.
- Setting a public date created a deadline that accelerated deployment for many of the organizations that contacted us.
- It was important to be compared with Google, Facebook, and Yahoo!. Participants in this experiment wanted to be seen doing the same thing as the industry giants.
- This event was a clear example of how the Internet industry can work together to deploy technology that is for the good of the Internet, without intervention from outside entities. The multi-stakeholder model of Internet development continues to function well.



More than 1000 organizations contacted the Internet Society. Many of these organizations had already permanently enabled IPv6. Of the 430 or so websites the Internet Society monitored on the day, roughly two-thirds have continued to provide IPv6 access after the day.

In addition, major hosting companies enabled IPv6 for large numbers of domains, including Domain Factory, which, as a result of participating in World IPv6 Day, has made IPv6 "on by default" for all of its more than 800,000 domains. Another hosting company, Stratos, left IPv6 on after June 8 for its more than 4 million domains.

RIPE Labs did extensive measurements of IPv6 leading up to, on, and after the day, and it has published results indicating an increase in IPv6 traffic on the day—and an overall increase in IPv6 traffic also after the day.

Letters to the Editor

Hi Geoff,

Thanks you for your contribution to the March 2011 issue of *The Internet Protocol Journal*. Your description in "A Rough Guide to Address Exhaustion" and the article on "Transitional Myths" were very insightful into the whole issue of IPv4 to IPv6, and the issues concerning migration. Some of your thoughts on the migration hit home, as I am speaking to customers about the planning for the transition and I see a lot of "Got You" that I must now incorporate in my discussions with my customer.

If you do have a means of updating the technical community with activities in the area of IPv6 and how to move customers to this protocol platform, can you please point me in that direction? I like your approach and so would like to stay close to what you are doing in this area. Again, thank you for your contribution!

Ole, thanks for getting this type of information out to the technical community. Great work.

—Joel Smith, Verizon Business, Toronto, Ontario, Canada
joel.smith@one.verison.com

The author responds:

Hi Joel,

Thank you for your comments.

Running IPv6 in a dual-stack configuration certainly presents some issues, some of which are unique to particular networks and configurations, some of which appear to be common to particular roles (such as content delivery platform, Internet Service Provider, Enterprise Provider, and end user), and some of which are common across most, if not all, circumstances.

In assisting to set up some dual-stack services a year ago, I wrote down some of the issues that I found helpful in an article: "Two Simple Hints for Dual Stack Servers" (**http://www.potaroo.net/ispcol/2010-05/v6hints.html**). You may find those hints to be of some value to your work. Some other sites that have a good collection of information are: **http://www.ipv6actnow.org/** and the community site **http://www.getipv6.info/index.php/Main_Page**, which also contains a wealth of information of a technical nature.

The basic guideline is to approach adding IPv6 to a network like any other engineering project: exercise care and attention to detail, and you will find it to be very straightforward!

Kind regards,

—Geoff Huston, APNIC
gih@apnic.net

Geoff and Ole,

Many thanks for your excellent papers in the March 2011 issue of IPJ. You have brought all the issues together in one place. They are clearly explained. Now I'll do my small part by suggesting to one and all that they read it. My IPv6 service comes from a manually configured tunnel from Hurricane Electric.

—Dan Cotts
dcotts@lisco.com

The author responds:

Thanks, Dan, for this feedback. It's certainly the right time for both users and content providers to act now to ensure that we continue to enjoy an Internet that still operates with a coherent end-to-end architecture into the future. The only way we can ensure that this happens is to act now and insist on IPv6—everywhere!

—Geoff Huston, APNIC
gih@apnic.net

Hello,

I enjoyed the recent IPv6 issue (Volume 14, No. 1, March 2011), but was dismayed by the lack of any frank discussion of the IPv6 "any-to-any" mantra versus the benefits of IPv4 *Network Address Translation* (NAT).

Internet purists don't hide their desire to rid the world of NAT and return to an any-to-any Internet where they could use FTP to/from any host. But for the past 15 years, NAT, RFC 1918, and perimeter security have been great for the Internet and for home and enterprise networking. When dealing with billions of endpoints, the implicit security of NAT far outweighs any alternative. Just think back to the pre-broadband/NAT days when hosts were attacked within seconds of dialing into an ISP.

Of the ~1.7 billion publicly addressed Internet devices, the vast majority would be perfectly happy behind *Carrier-Grade NAT* (CGN). In fact, as ISPs begin introducing NAT offerings, millions will stampede to them for their lower cost. Mobile phone networks are the lowest-hanging fruit, followed by residential broadband. ISPs will still offer public IP products, of course, just at a higher price point.

The IETF needs to stop pussy-footing around the issue. CGN is not just an IPv6 transitional technology; it could very well become the de facto operating standard for the next decade.

The IETF desperately needs to:

- Amend RFC 5382 ("NAT Behavioral Requirements for TCP") to allow endpoint-independent mapping. This will improve CGN scalability by several orders of magnitude. For example, rather than 2000 hosts per public IP mentioned in Mr. Huston's "Rough Guide" on address sharing, CGN could support 200,000 or more hosts per public IP.
- Develop an IETF standard for P2P connection establishment. It took 8+ years for the IETF to take an interest in P2P mechanics (RFC 5128). Now it's time to show leadership. If a CGN-compatible P2P establishment standard were drafted, it would be adopted by P2P libraries overnight. While they're at it, look at standards for tying *Universal Plug and Play* (uPnP) into CGN.
- Help coordinate a discussion of operational issues with ISP administration, law enforcement, DMCA enforcement, geolocation services, black/white lists, etc. Perhaps it's time to extol the benefits of millisecond-accurate IPFIX logs with NAT extensions, or develop a new TCP option to embed NAT details?
- Legitimize common ISP self-preservation tactics, such as restricting SMTP, metering connections/sec, and so on.

Most importantly, IPv6 proponents should stop taking CGN as a personal affront. There is no malice; it's simply the path of least resistance for the IPv4 conundrum.

—*Craig Weinhold, Madison, Wisconsin*
craig.weinhold@cdw.com

The author responds:

Thank you for your note, Craig.

The discussion of how far the Internet could scale with integration of NATs into the interior of the network as well as the current pattern of NATs at the edge is not a new discussion. The *Realm Specific IP* (RSIP) Working Group was active over a decade ago in the IETF, looking at how a network would operate that consisted of a union of distinct realms, each of which was, in address terms, a discretely addressed IP network. With the benefit of hindsight, the outcomes of that effort in supporting a case for infrastructure NATs as a long-term architectural direction for the Internet were not overly encouraging.

From the perspective of the technology community, it reinforced the conclusion that IPv6 represented the best possible response to the recognized problem of IPv4 address exhaustion. NATs were a poor compromise in so far as, at the most basic level, NATs add state into the interior of the network. This imposition of state into the network infrastructure imposes a cost in terms of service fragility and network robustness that cannot be avoided.

There was an assumption some years ago that the industry would grapple with the transition to IPv6 well before the exhaustion of IPv4 addresses, and we would never have to deal with a dual-stack transition where one-half of the dual stack, the IPv4 part, would need to operate in a mode that included infrastructure NATs. We now appear to be beyond choice here—for the Internet to continue to grow by a further 300 million new services per year at present, and grow by yet more in the coming years, there is no choice but to operate the IPv4 part of the dual-stack environment with infrastructure NATs.

But this is a short-term hack, as distinct from a tenable longer-term position. The address pool of IPv4 is not getting any larger, and as more and more new services are added into a dual-stack network, the growth in the IPv4 part of the network can be absorbed only by progressive reduction of the number of available ports to each client of the infrastructure NAT. Services become more fragile and the network becomes less resilient. The inevitable next step in progressive scarcity of IPv4 addresses in the face of such inexorable growth is to drop the entire notion of end-to-end service and introduce application-level proxies into the IPv4 network. At this point we lose any ability to further sustain an open IPv4 Internet. The only applications that could be supported are those that are supported by the application-level proxies, and all other applications simply fail. The segregation of one Internet into a number of effectively disconnected "walled gardens" of networking is a rapid outcome in such a scenario.

One of the strengths of the Internet is its openness and neutrality. The open architectural model allows novel services to be added into the network by simply equipping clients and services with the service, leaving the interior of the network untouched. The interior of the network is entirely neutral to such innovations, as it is unaware of the content or intent of the packets that are passed through its switching infrastructure.

So the long-term path of greatest common benefit to all in the Internet is a network that, as far as possible, simply vanishes! It is an Internet where content and services can rendezvous with users without having to negotiate with any network elements. It is a network that is free of toll gates. And the network has now grown to such an extent that the only path from here that can sustain that architectural simplicity and sustain yet more growth is one that shifts determinedly and rapidly to IPv6. With the limited time and resources available, attempting to improve upon NATs is, in my opinion, not the best use of the resources we can apply to this problem.

Regards,

—Geoff Huston, APNIC
gih@apnic.net

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ contains standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

Fragments

RFC Series Editor Search Announcement

The *Internet Engineering Task Force* (IETF) is seeking an *RFC Series Editor* (RSE). The RSE has overall responsibility for the quality, continuity, and evolution of the *Request for Comments* (RFC)[3] Series, the Internet's seminal technical standards and publications series. The position has operational and policy development responsibilities. The overall leadership and supervision of RFC Editor function is the responsibility of the RFC Series Editor. The RSE is a senior professional who must be skilled in leading, managing and enhancing a critical, multi-vendor, global information service. The following qualifications are desired:

- Leadership and management experience. In particular, demonstrated experience in strategic planning and the management of entire operations. Experience that can be applied to fulfill the tasks and responsibilities described in "RFC Editor Model (version 2)"[1].
- Excellent written and verbal communication skills in English and technical terminology related to the Internet a must; additional languages a plus.
- Experience with editorial processes.
- Familiar with a wide range of Internet technologies.
- An ability to develop a solid understanding of the IETF, its culture and RFC process.
- Ability to work independently, via e-mail and teleconf, with strong time management skills.
- Willingness and ability to travel as required.
- Capable of effectively functioning in a multi-actor and matrixed environment with divided authority and responsibility; ability to work with clarity and flexibility with different constituencies.
- Experience as an RFC author desired.

More information about the position can be found on the RFC Editor Webpage[2]. The RSE reports to the *RFC Series Oversight Committee* (RSOC). Expressions of interest in the position, Curriculum Vitae (including employment history), compensation requirements, and references should be sent to the RSOC search committee at **`rse-search@iab.org`**. Questions are to be addressed to the same e-mail address. Applications will be kept confidential. The RSOC will interview interested parties at the IETF meeting in Quebec City that begins July 24, 2011, but the application period is open until the position is filled.

—Fred Baker, Chair, RFC Series Oversight Committee

Global IPv6 Deployment Monitoring Survey 2011

The *Global IPv6 Deployment Monitoring Survey 2011* is now online at: **http://www.surveymonkey.com/s/GlobalIPv6survey2011**

This survey has been designed by GNKS Consult in collaboration with TNO and the RIPE NCC to further understand where the community stands on IPv6 and what needs be done to ensure that the Internet community is ready for the widespread adoption of IPv6.

Anyone can participate in this survey and we hope that the results will establish a comprehensive view of current IPv6 penetration and future plans for IPv6 deployment. The survey comprises 23 questions and can be completed in about 15 minutes. For those without IPv6 allocations or assignments or who have not yet deployed IPv6, there will be fewer questions.

The survey closes July 31, 2011. We thank you for your time and interest in completing this survey. If you have any questions concerning the survey, please e-mail: **info@gnksconsult.com**

For more information about the survey and links to previous year's survey results, please see:

https://www.ripe.net/internet-coordination/news/industry-developments/global-ipv6-deployment-monitoring-survey-2011

RFC 6127 Published

The topic of IPv4 depletion and IPv6 deployment is covered in the recently published RFC 6127 entitled "IPv4 Run-Out and IPv4-IPv6 Co-Existence." From the introduction: "When IPv6 was designed, it was expected that the transition from IPv4 to IPv6 would occur more smoothly and expeditiously than experience has revealed. The growth of the IPv4 Internet and predicted depletion of the free pool of IPv4 address blocks on a foreseeable horizon has highlighted an urgent need to revisit IPv6 deployment models. This document provides an overview of deployment scenarios with the goal of helping to understand what types of additional tools the industry needs to assist in IPv4 and IPv6 co-existence and transition." RFCs can be obtained from the RFC Editor web page, see:

http://www.rfc-editor.org/rfc.html

From The Editor

I recently attended a conference in Japan where the attendee network offered IPv6 service only. In the past, conferences such as the *Asia Pacific Regional Conference on Operational Technologies* (APRICOT) and meetings of the *Internet Engineering Task Force* (IETF) have conducted IPv6 experiments, but these have all been "opt-in" events. The conference in Japan was different: there was no IPv4 service available. Making this work involved a few manual configuration steps, but for the most part everything worked more or less the same as it did under IPv4. Some applications, including my instant message client and Skype did not work, and all connections to IPv4-only hosts needed to use *Fully Qualified Domain Names* (FQDNs) instead of IP addresses, but overall the experience gave me confidence that IPv6 is becoming a reality. As you might expect, this IPv6-only experiment also uncovered a number of bugs and incompatibilities that were duly reported to developers around the world.

Our first article is an overview of *TRansparent Interconnection of Lots of Links* (TRILL). TRILL uses Layer 3 routing techniques to create a large cloud of links that appear to IP nodes to be a single IP subnet. The protocol has been developed in the IETF and is currently being refined and enhanced in the TRILL working group. The article is by Radia Perlman and Donald Eastlake.

Developments in Internet technologies have lead to changes that go beyond the Internet itself. Not only is *Voice over IP* (VoIP) often used in place of traditional circuit-switched telephony, the telecommunication networks themselves are evolving to incorporate IP routers in place of traditional telephone switches. This evolution also applies to cellular telephone networks, specifically to what is known as *backhaul*—the transportation of voice and data from the cell sites to the mobile operators' core networks. Jeff Loughridge explains more in "The Case for IP Backhaul."

Once again I would like to remind you about the IPJ subscription renewal campaign. Each subscriber to this journal is issued a unique subscription ID that, coupled with an e-mail address, gives access to the subscription database by means of a "magic URL." If your subscription has expired or you have lost your subscription ID, changed e-mail, postal mail, or delivery preference, just send an e-mail to ipj@cisco.com with the updated information and we will take care of the rest.

—Ole J. Jacobsen, Editor and Publisher
ole@cisco.com

Introduction to TRILL

by Radia Perlman, Intel Labs, and Donald Eastlake, Huawei Technologies

Transparent Interconnection of Lots of Links (TRILL)[1] is an *Internet Engineering Task Force* (IETF) protocol standard that uses Layer 3 routing techniques to create a large cloud of links that appear to IP nodes to be a single IP subnet. It allows a fairly large Layer 2 cloud to be created, with a flat address space, so that nodes can move within the cloud without changing their IP addresses, while using all the Layer 3 routing techniques that have evolved over the years, including shortest paths and multipathing. An early problem and applicability statement for TRILL can be found in [6]. Additionally, TRILL supports Layer 2 features such as V*irtual Local-Area Networks* (VLANs), the ability to autoconfigure (while allowing manual configuration if so desired), and multicast/broadcast with no additional protocol.

Additionally, TRILL is evolutionary in the sense that an existing Ethernet deployment, where the links are connected with bridges, can be converted into a TRILL cloud by replacing any subset of the bridges with devices implementing TRILL. Devices implementing TRILL are called *Routing Bridges,* or *RBridges*. As bridges are replaced, nothing changes for the IP nodes connected to the cloud except that the cloud becomes more stable and uses available bandwidth more effectively.

To understand why TRILL was needed, it is helpful to explore the history of Ethernet and IP.

Network protocols are usually described in terms of *layers*. The description usually quoted in textbooks is the *Open Systems Interconnection* (OSI) *Reference Model,* which describes seven protocol layers[4]. It is important to realize that the layers are useful primarily as a way to think about networking, but actual network protocols are far more complex. Layers get subdivided or combined, and often a technology usually thought of as belonging to a lower layer (for example, Layer 2) can be layered on top of a higher layer (for example, Layer 3). Most descriptions of network layers agree on the bottom four layers, and vary according to details such as whether syntax (for example, *Extensible Markup Language* [XML][7]), which would be a *Presentation Layer* in the OSI model, is a layer or not. Such descriptive choices do not affect how protocols are built, and luckily, for understanding of TRILL, the relevant layers to focus on are just the bottom three:

- Layer 1, *Physical Layer:* Physical, electrical, and optical specification for connectors, bit signaling, etc.
- Layer 2, *Data Link Layer:* The protocol that lets neighbor nodes on a link exchange packets
- Layer 3, *Network Layer:* The protocol that provides routing to create a path from a source node to a destination node

TRILL, as we will see, is a Layer 2 and ½ protocol: It glues links together so that IP nodes see the cloud as a single link. Therefore, TRILL is below Layer 3; but, it is above Layer 2 because it terminates traditional Ethernet clouds, just like IP routers would do.

It is definitely time to be confused. Why are there multiple links at Layer 2? Isn't that the job of Layer 3?

Evolution of Layer 2 from Point-to-Point Links to LANs

In the beginning (the 1970s or so for the purposes of this article), Layer 2 really was a direct link between neighbor nodes. Most links were point-to-point, and Layer 2 protocols primarily created *framing*—a way to signal the beginning and end of packets within the bit stream provided by Layer 1—and *checksums* on packets[11]. For links with high error rates, Layer 2 protocols such as *High-Level Data Link Control* (HDLC)[12] provided message numbering, acknowledgements, and retransmissions, so the Layer 2 protocol resembled, in some ways, a reliable protocol such as TCP. HDLC and other Layer 2 technologies sometimes provided an ability to have multiple nodes share a link in a master/slave manner, with one node controlling which node transmits through techniques such as polling.

Then the concept of *Local-Area Networks* (LANs) evolved, the most notable example being Ethernet. Ethernet technology enabled interconnection of (typically) hundreds of nodes on a single link in a peer-to-peer rather than master/slave relationship. Ethernet was based on *CSMA/CD,* where CS = *Carrier Sense* (listen before talking so you don't interrupt); MA = *Multiple Access;* and CD = *Collision Detect* (listen while you are talking to see if someone starts talking while you are so you are both interfering with each other). Interestingly, although IP had a 4-byte address and was the basis of addressing for the entire Internet, Ethernet had a larger 6-byte address, with aspirations for connecting only a small number of nodes in a fairly small region such as a single building.

The reason for the larger address space for Ethernet was to avoid the need to configure addresses when plugging nodes into a network. Instead, manufacturers of equipment would purchase blocks of Ethernet addresses and embed a unique address for each device in their hardware (the "MAC address"), and an Ethernet node would then be able to use that address in any Ethernet without fear of address collision.

Evolution of Ethernet to Spanning Tree

LANs came onto the scene with such fanfare that people came to believe that LAN technology was a replacement of traditional Layer 3 protocols such as IP. People built applications that were implemented directly on Layer 2 and had no Layer 3. This situation meant that the application would be limited by the artifacts of the Layer 2 technology, because a Layer 3 router cannot forward packets that do not contain the Layer 3 header implemented by the router.

In the case of the original Ethernet, it meant the application would work only within a maximum distance of perhaps a kilometer.

When people using technologies built directly on a LAN realized they wanted networks larger (in distance and total number of nodes) than the LAN technology allowed, the industry invented the concept of "bridges"—packet-forwarding devices that forwarded Layer 2 packets.

Forwarding Ethernet packets might seem easy because the Ethernet header looks similar to a Layer 3 header. It has a source and destination address, and the addresses are actually larger than IP addresses. But Ethernet was not designed to be forwarded. Most notably absent from the Ethernet header is a *hop count* (also sometimes referred to as a "time to live," or TTL) to detect and discard looping packets. But other features of a typical Layer 3 protocol were also missing in Ethernet, such as an address that reflects where a node is in the topology, node discovery protocols, and routing algorithms. These features were not in Ethernet because the intention of the Ethernet design was that it be a Layer 2 protocol, confined to operation on a single link.

The transparent bridge was invented as a mechanism to forward Ethernet packets emitted by end nodes that did not implement Layer 3. Ethernet at the time had a hard packet size limit, so bridges could not modify the packet in any way.

The transparent bridge design, which met those constraints, consisted of having bridges listen promiscuously, remember the source addresses seen on each port, and forward based on the learned location of the destination address. If the destination was unknown, the packet would be forwarded onto all ports except the one that it was received on.

This simple method worked only if there was only one path between any pair of nodes. So the concept was enhanced with a protocol known as the *Spanning Tree Algorithm*.[8] The physical topology could be an arbitrary mesh, but bridges, using the spanning-tree algorithm, would prune the topology into a loop-free (tree) topology on which data packets were forwarded. ("Spanning" means that packets can reach all the nodes.)

As Figure 1 shows, the spanning-tree concept is that an arbitrary topology could be built using Ethernet links (horizontal lines) and bridges (circles). Bridges running the spanning-tree algorithm determine a loop-free subset of the topology, and put some ports into standby (the ones that are shown in Figure 2 as dotted lines). Data packets flow on the ports that spanning tree determines should be active. This model does not yield optimal routes, as indicated in Figure 3, where packets between A and X go through the path of bridges 11, 7, 6, 2, 14, 4, and 3.

Figure 1: A Bridged Network

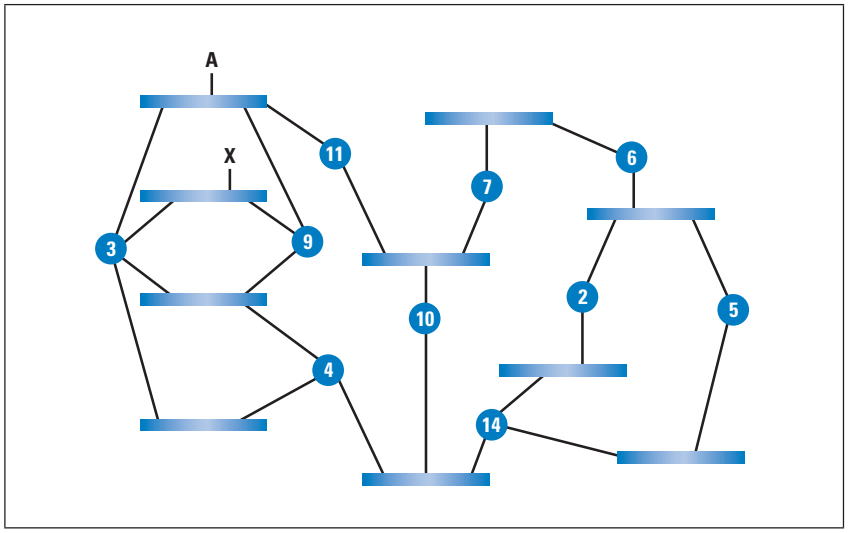

Figure 2: Bridged Network with Spanning Tree

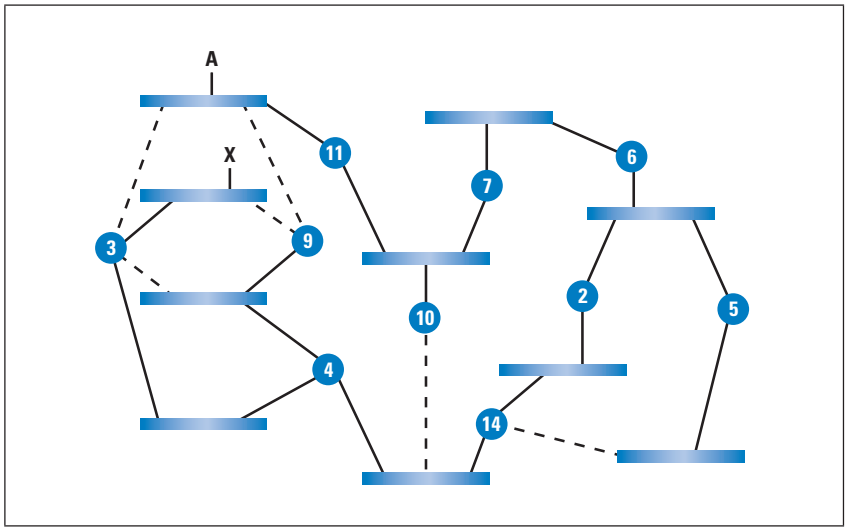

Figure 3: A Sub-Optimal Path

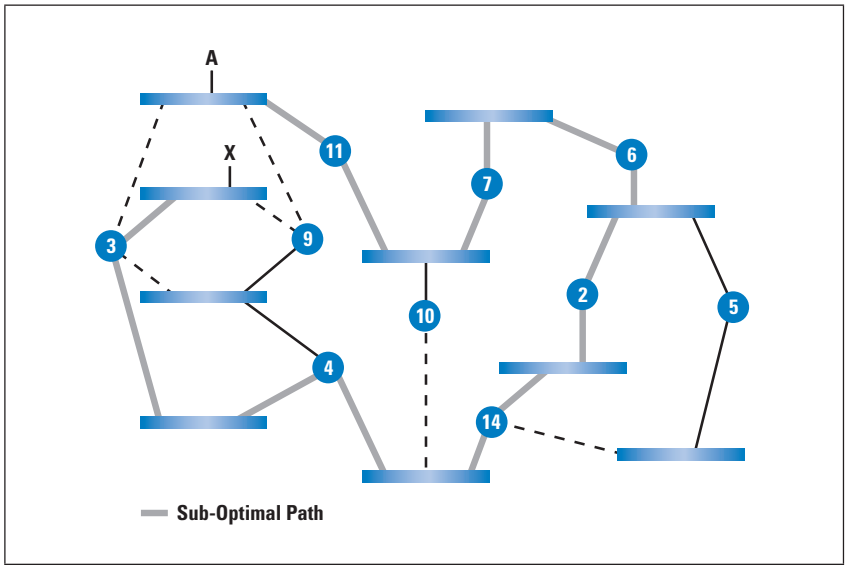


The spanning-tree algorithm is also inherently unstable. It requires bridges to be engineered to be able to examine every incoming packet at wire speed, to determine if the packet is a spanning-tree message, and if so, process it. The spanning-tree algorithm requires a bridge to forward unless there is a "more qualified" neighbor bridge on the link. Details of the spanning-tree algorithm, fascinating as they are, are beyond the scope of this article. If a bridge loses enough spanning-tree messages from its "more qualified" neighbor bridge because congestion overwhelms its ability to process incoming messages, the bridge will conclude that it does not have a more qualified neighbor, and therefore should start forwarding onto the link. This situation is extremely dangerous without a hop count, a field that would naturally be included in a protocol designed to be Layer 3 and forwardable.

The originally invented Ethernet, CSMA/CD, is pretty much nonexistent. Almost all Ethernet today consists of bridges connected with point-to-point links. The header still looks like Ethernet, but new fields have been added, such as VLANs discussed later in this article.

Characteristics of IP

Transparent bridging was necessitated by a quirk of history, in that applications were being built without Layer 3. But today, applications are almost universally built on top of IP. So why not replace all bridges with IP routers?

The reason is an idiosyncrasy of IP. In IP, routing is directed to a *link,* not a *node.* Each link has its own block of addresses. A node connected to multiple links will have multiple IP addresses, and if the node moves from one link to another, it must acquire a new IP address within the block for that link.

This property is not an inherent property of Layer 3, just a characteristic of IP. An alternative technology, proposed in 1992 as a replacement to IPv4, was *Connectionless-mode Network Protocol* (CLNP), an ISO packet format that had 20-byte addresses (actually, variable length). Its address, like IP, was hierarchical, routing to the longest matching address prefix in the forwarding table that matched the destination address. But in IP, the bottom level of routing was to a single link. In CLNP, the bottom level of routing consisted of routing to a cloud known as an "area," that included lots of links (typically hundreds). Within the area, end nodes announced themselves and routers routed directly to the end node. An end node could move within an area without changing its Layer 3 address. Routers within an area would not need to be configured.

In contrast, with IP, a block of IP addresses needs to be carved up to assign a unique block to each link, IP routers need to be configured with the address block for each of their ports, and nodes that move from one link to another have to change their Layer 3 addresses. Therefore, it is still popular to create large bridged Ethernets, because a bridged set of links looks to IP like a single link.

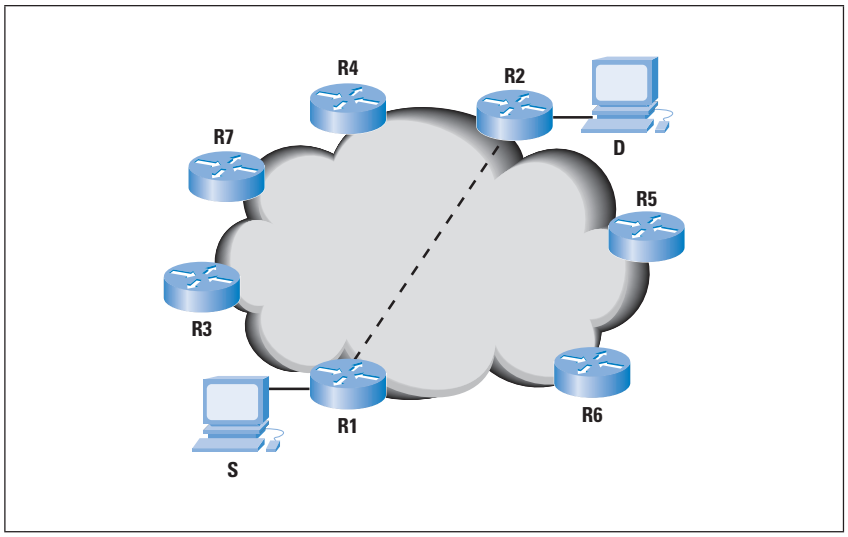
TRILL: Best of Both Worlds

TRILL allows the ease of configuration of Ethernet while benefitting from the routing techniques provided at Layer 3. It also coexists with existing bridges; it is not necessary to replace all the bridges in an Ethernet, but the more bridges replaced by RBridges, the better the bandwidth usage and the more stable the cloud becomes (because the spanning trees get smaller and smaller, and ultimately disappear if all bridges are replaced by RBridges).

Figure 4 shows the basic concepts in TRILL handling a unicast packet where the location of the destination is known:

- RBridges run a link state routing protocol, which gives each of them knowledge of the topology consisting of all the RBridges and all the links between RBridges. Using this protocol, each RBridge calculates shortest paths from itself to each other RBridge, as well as trees for delivering multidestination traffic.
- When an RBridge, R1, receives an Ethernet frame from an end node S, addressed to Ethernet destination D, R1 encapsulates the frame in a TRILL header, addressing the packet to the RBridge R2, to which D is attached. The TRILL header contains an "ingress RBridge" field (R1), an "egress RBridge" field (R2), and a hop count.
- When R2 receives the encapsulated packet, R2 removes the TRILL header and forwards the Ethernet packet on to D.

Figure 4: RBridging



What the TRILL header looks like, how R1 knows that R2 is the correct "egress RBridge," and some of the concepts in the link state protocol *Intermediate System-to-Intermediate System* (IS-IS) are described in the next section. We also explain how TRILL handles multidestination frames, VLANs, and IP Multicast.

The TRILL Header

The main fields in the TRILL header are: ingress RBridge nickname (16 bits), egress RBridge nickname (16 bits), hop count (6 bits), and a multidestination flag bit (1 bit). A typical Layer 3 header would contain a source, a destination, and a hop count. So TRILL is basically an encapsulation header with flat 16-bit addresses. How RBridges obtain "nicknames" is described later in this article.

This header is very simple for core RBridges to forward, compared with either an IP or an Ethernet header. The destination field is just 16 bits, so it can be a simple table lookup to find the entry in the output port, as opposed to the Ethernet 6-byte destination, which typically requires content-addressable memory or hashing, or the longest prefix matching of IP.

Learning End-Node Locations

How does R1 know that R2 is the correct egress RBridge for some destination D? The default mechanism is learning the correspondence between (ingress RBridge, source MAC address) when the egress RBridge decapsulates a packet. If R1 does not know where the destination MAC is located, R1 encapsulates the packet in a TRILL header with the multidestination flag set, indicating that it should be transmitted through a tree to all the RBridges.

An additional mechanism, which is optional, is known as *End-Station Address Distribution Information* (ESADI). ESADI allows R1 to announce some or all of the end nodes that are attached to R1. Both announcing to and listening to ESADI are optional. This mechanism has advantages over flooding and learning from data packets:

- ESADI packets can have cryptographic protection.
- R1 might have a more definite reason to know that S is attached to R1 than simply seeing a packet with the S address in the header. For instance, R1 might have been configured to lock down a port to the S MAC address. Or there might be a cryptographically protected enrollment protocol when S attaches to R1.
- R1 might be able to have tighter timers on verifying the location of local end nodes; for instance, if they are IP nodes, R1 might be able to ping them.

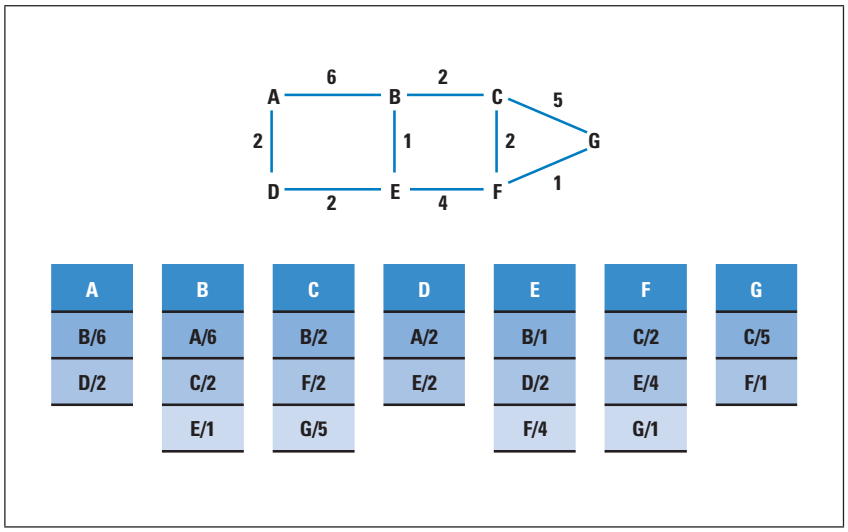
It is also possible to have a directory that lists not only (RBridge nickname, {set of attached end-node MAC addresses}) but also {(end-node IP address, end-node MAC address)} pairs. The first RBridge, or a *hypervisor,* or the end-node process itself, might query the directory about the destination, and encapsulate packets, rather than flooding, and thus also be able to bypass the IPv4 *Address Resolution Protocol* (ARP) and the *IPv6 Neighbor Discovery* (ND) protocols.

Link State Protocols

A *link state* protocol is a routing protocol in which each router R determines who its neighbors are, and broadcasts (to the other routers) a packet, known as a *Link State Packet* (LSP), that consists of information such as "I am R," and "My neighbor routers are X (with a link cost of c1), Y (cost c2), and Z (cost c3)." The commonly deployed link state protocols are *Intermediate System-to-Intermediate System* (IS-IS)[2][9] and *Open Shortest Path First* (OSPF)[10]. IS-IS, designed in the 1980s to route DECnet, was adopted by the *International Organization for Standardization* (ISO). IS-IS can route IP traffic and is used by many *Internet Service Providers* (ISPs) to route IP. IS-IS was a natural choice for TRILL because its encoding easily allows additional fields, and IS-IS runs directly on Layer 2, so that it can autoconfigure, whereas OSPF runs on top of IP and requires all the routers to have IP addresses.

Figure 5 shows a small network (at the top), consisting of 7 routers. In the bottom half of the figure, the LSP database is shown; all the routers have the same LSP database because they all receive and store the most recently generated LSP from each other router. The LSP database gives all the information necessary to compute paths. It also gives enough information for all the routers to calculate the same tree, without needing a separate spanning-tree algorithm. As we will see, TRILL requires a tree (at least one tree) for distribution of multidestination packets.

Figure 5: Router Network and Link State



Acquiring Nicknames

Given that the most recently generated link state packet of each RBridge is broadcast to, and stored by, each other RBridge, it is possible to spread other information through the link state packets, such as a protocol for acquiring a unique nickname. Each RBridge chooses a nickname at random, avoiding nicknames already acquired by other RBridges (as discovered by examining the LSP database).

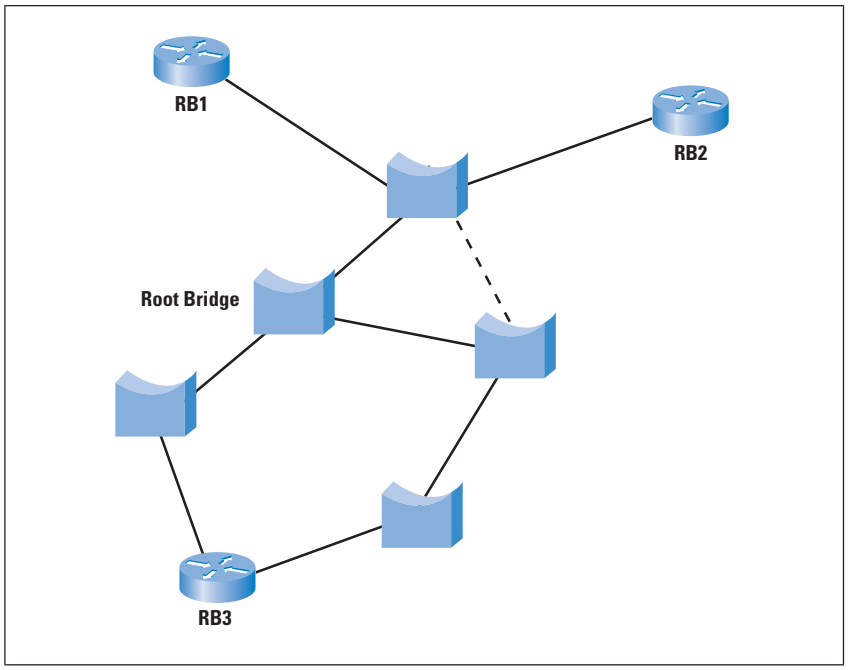
If two RBridges choose the same nickname, there is a tie-breaker, based on configured priority and 6-byte system ID. One of the RBridges gets to keep the nickname and the other RBridge has to choose another nickname that appears not to be in use.

It is possible to configure RBridges with nicknames, in which case a configured nickname takes priority over one that was randomly chosen. And in the case of misconfiguration, where two RBridges have been configured with the same nickname, again, ID and priority choose a winner, and the other one has to choose a different nickname.

Mixing RBridges with Bridges

TRILL is designed so that any subset of bridges in an Ethernet can be replaced by RBridges. A set of links connected by bridges will be perceived by RBridges as a single shared link connecting the RBridges on that link. The bridges inside that link will behave as ordinary bridges, forming a spanning tree and forwarding packets along that tree. Figure 6 illustrates an Ethernet connected by several bridges, with one port (indicated by the dashed line) selected by the spanning tree as being in backup.

Figure 6: RBridges Connected by Bridged LAN



The RBridges RB1, RB2, and RB3 perceive the link as in Figure 7, a single shared link, on which RB3 has two ports.

Introducing RBridges into a bridged Ethernet partitions the spanning trees into smaller spanning trees. RBridges operate on a topology consisting of the RBridges themselves, connected with "links" that are either bridged Ethernets or point-to-point links.

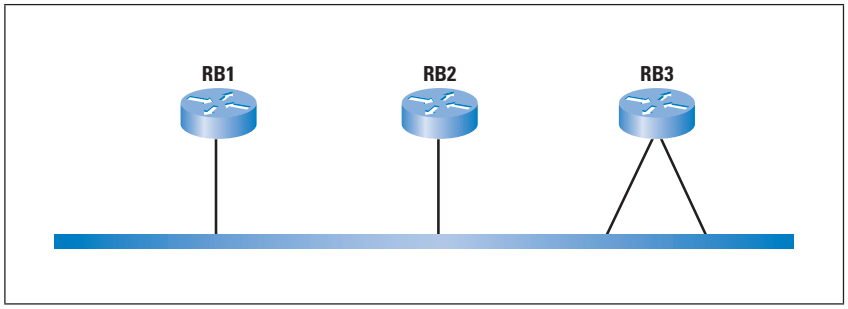


Figure 7: Figure 6 as Perceived by RBridges: a Single Shared Link Where RB3 Has 2 Ports onto the Same Link

Link Types and the Hop-by-hop Header

In addition to the TRILL header, when RBridge R1 is forwarding a TRILL-encapsulated frame to neighbor RBridge R2, there is an additional header that is specific to the type of link connecting R1 and R2. Although TRILL carries Ethernet inside, a link between two or more RBridges could be an arbitrary type of link; for example, besides Ethernet, it could be a *Point-to-Point Protocol* (PPP) link[13], an IP or *IP Security* (IPsec) tunnel, *Multiprotocol Label Switching* (MPLS) path, etc.

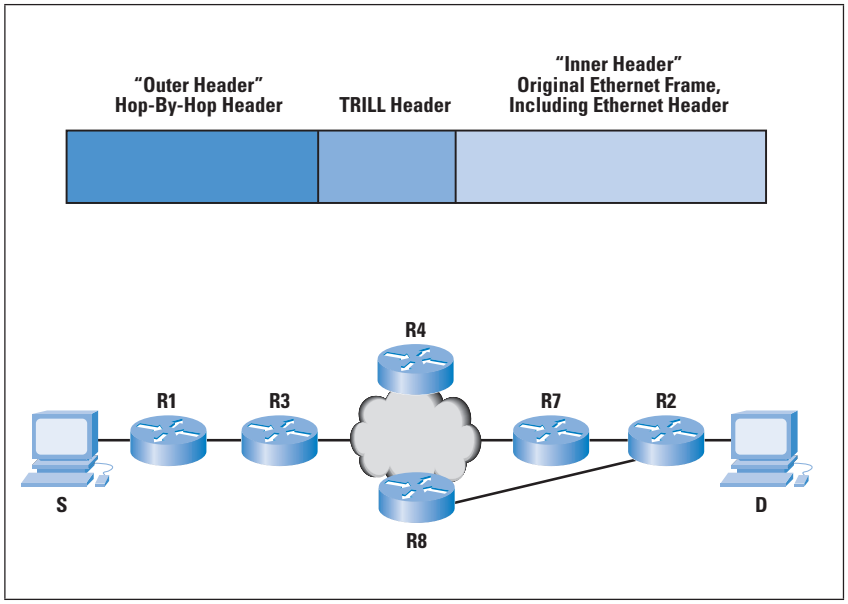
If the link is an Ethernet link, the "outer" header is an Ethernet header. If it is a PPP link, the outer header is a PPP header. The outer Ethernet header (on an Ethernet link) serves two purposes:

- If there are bridges on the link, they will perceive the packet as a normal Ethernet packet, and forward it through the spanning tree. The learning tables of the bridges on the link will see only the addresses of the RBridges on that link.
- It allows R1, when forwarding onto a link with multiple neighbors (say R2 and R3), to specify which of R2 or R3 is chosen by R1 to forward the packet by unicasting the packet to the chosen next-hop RBridge. For example, it could be that both R2 and R3 are equal costs to the destination, so R1 would need to specify which of them should forward the packet. Otherwise, both might forward the packet, and the packet would be duplicated.

So, as illustrated in Figure 8, a TRILL-encapsulated packet might have three headers:

- The outer header, or hop-by-hop header, which is stripped off at each hop, is specific to the type of link connecting neighbor RBridges, and, when forwarded between R1 and R2, it specifies R1 as source and R2 as destination
- The TRILL header, which similarly to a Layer 3 header remains in place as the packet travels from the first RBridge to the last RBridge, specifying the first RBridge (the one that encapsulated the packet with a TRILL header) as the ingress RBridge, and the last RBridge (the one that will decapsulate the packet) as the egress RBridge
- The inner Ethernet header, which specifies the communicating end-node pair as source and destination

Figure 8: TRILL Packet Headers



Again referring to Figure 8, assume S transmits an Ethernet packet to D. In the inner Ethernet header, Source = S, Destination = D.

R1 encapsulates it with a TRILL header, where ingress RBridge = R1 and egress RBridge = R2. R1 forwards it to R3, putting on a link header appropriate to the link. If the link is an Ethernet link, the outer Ethernet header will indicate S = R1, D = R3. When R3 forwards to R7, R3 leaves the TRILL header as is (other than decrementing the hop count), strips the outer header, and puts in a new outer header indicating S = R3, D = R7. Likewise, R7 forwards to R2. If it is a PPP link, there is no source or destination. When R2 forwards to D, R2 strips off the TRILL header and D sees the Ethernet packet exactly as transmitted by S.

VLANs

Ethernet has a concept known as a *Virtual LAN* (VLAN), which partitions communities of end nodes sharing the same infrastructure (links and bridges), such that end nodes in the same set can talk directly to each other (using Ethernet), whereas those in different VLANs have to communicate through a router. IP nodes, although generally unaware of Ethernet VLAN tags, perceive different VLANs to be different IP subnets.

Typically, a bridge is configured with a VLAN for each port, and the bridge adds a tag to the Ethernet header that indicates which VLAN the packet belongs to. A bridge with a port that is configured to be VLAN x will deliver only packets tagged as VLAN x to that port, and will usually strip the VLAN tag before forwarding.

The original Ethernet did not have a VLAN concept. In today's Ethernet standard, each packet must be associated with a VLAN. A bridge might be configured with a default VLAN for a port, meaning that if no VLAN tag is in the packet, the bridge will treat it as if it is that default VLAN. A bridge B might be configured in various ways that make VLANs more complex:

- B might be configured to drop a set of VLANs rather than forward them onto a particular port, even though the port is a transit port.
- B might be configured to modify the VLAN tag to a different value when forwarding from one port to another.
- B might be configured to remove the VLAN tag when forwarding onto a particular port.

Appointed Forwarders

If there are multiple RBridges on the same link, together with end nodes, it is important that only one of them encapsulate a packet from an end node. As illustrated in Figure 9, if both R1 and R2 were to encapsulate a unicast packet from S, two copies would be delivered to the destination. However, if S were to transmit a multidestination packet (such as a multicast, or an unknown destination), then the copy that R1 encapsulates would be forwarded through the campus, received by R2 (which likely would not know that the packet originated on its port to R1), and R2 would decapsulate it. Then R1 would see a native packet from S, exactly as the first copy, and again encapsulate it and send it into the campus.

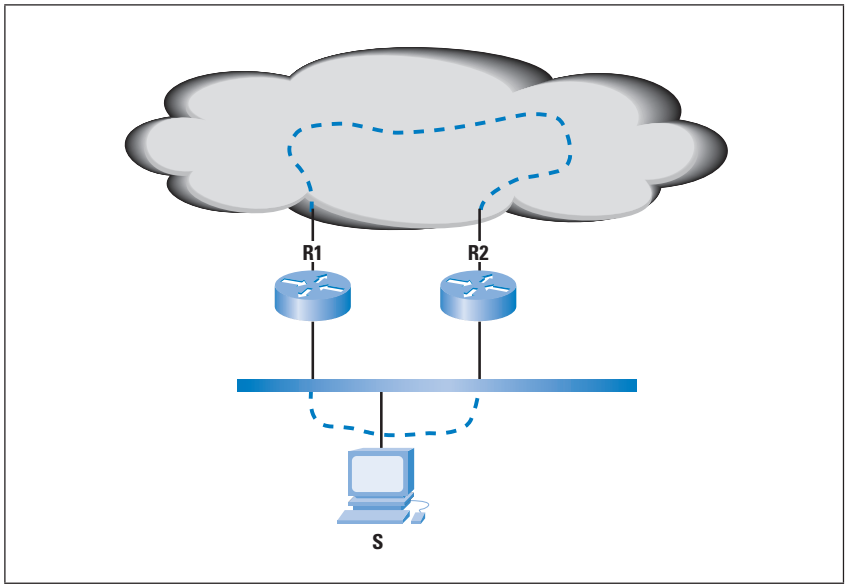


Figure 9: Link with Multiple RBridges. Note: No Hop Count Protection on Native Frame.

The hop count in the TRILL header would not solve this loop, because the hop count does not exist while the packet is not encapsulated with a TRILL header.

IS-IS has an election protocol in which one of the RBridges is elected as the *Designated RBridge* (DRB). In order to allow load-splitting the task of encapsulating and decapsulating traffic, the DRB may delegate the job of encapsulation/decapsulation based on VLAN. In other words, if R1 is DRB, R1 can delegate to R2 the task of encapsulating/decapsulating traffic for a set of VLANs, say VLANs x, y, and z, and delegate to R3 a different set of VLANs, and R1 might handle the rest.

Implications of VLANs on TRILL

TRILL treats VLANs strictly as a way of partitioning the end nodes, in contrast with IEEE, which allows bridges to drop transit traffic based on VLAN. Consequently, an Ethernet link connecting TRILL RBridges R1 and R2 might be able to deliver packets tagged with VLAN x, but not deliver packets tagged with VLAN y.

It is important, as shown in Figure 9, that all the RBridges on a link know about each other; otherwise they might both encapsulate a packet.

The IS-IS election is done through Hello messages, whereby RBridges announce themselves. Unfortunately, possible configuration of bridges, whether intentional or by mistake, can partition a link for traffic marked as VLAN y, but have the link be connected for traffic marked as VLAN x. This situation complicates the IS-IS election. When transmitting a Hello message onto an Ethernet link, an RBridge R1 must assign it to a VLAN. If R1 chooses VLAN y, its neighbor R2 might not see the Hello message. And then, unaware that there were multiple RBridges on the link, both R1 and R2 might encapsulate a VLAN x packet.

TRILL handles this situation by having the DRB (by default) transmit Hello messages on all the VLANs for which it is enabled on the port. The DRB chooses a VLAN, say VLAN A, for inter-RBridge communication on the link, and informs the other RBridges on the link that they should use VLAN A. The other RBridges transmit IS-IS messages (including Hello messages and LSPs) and encapsulated TRILL packets, putting VLAN A in the outer header. The VLAN tag in the inner header is the one that represents the community that the end node belongs to. The VLAN tag in the outer header is only for the purpose of traversing an Ethernet hop between RBridges.

Additionally, (by default), an RBridge that is Appointed Forwarder for a VLAN, transmits Hello messages on that VLAN.

If it is known that there are no bridges, the RBridges (including the DRB) can be configured to send Hello messages only on the single VLAN specified by the DRB.

Modified Hello Protocol

IS-IS has an election protocol in which routers (or RBridges in the case of TRILL) send Hello messages. Not only does the Hello message transmitted by R1 announce R1 to its neighbors, but the R1 Hello message contains a list of neighbors that R1 has heard Hello messages from. R2 will not consider R1 to be a neighbor unless R2 sees itself listed in the Hello messages of R1, indicating connectivity is two-way. When choosing a DRB, R2 ignores any routers for which connectivity to R2 is not two-way. Therefore, if there were a shared link with strange connectivity properties, the routers on the link might partition into cliques, each with its own DRB, each clique representing a separate link to the rest of the routers.

A surprising aspect of the use of IS-IS for TRILL was that the Hello protocol had to be modified slightly. In Layer 3 IS-IS, Hello messages are padded to the maximum size, because a possible hardware failure mode was that a link between R1 and R2 might be able to transmit small packets, but not large packets. In Layer 3, the IS-IS assumption was that R1 and R2 would rather not see that they were potential neighbors than use a flaky link. In IS-IS, LSP packets can be fragmented only by the source R1. All routers agree upon the maximum size of an LSP fragment that is guaranteed to be able to traverse all the links. Links that cannot forward packets of that size are not reported in the topology, and indeed, in Layer 3 IS-IS, would not even be discovered in the topology, because the Hello message (padded to that size) would not be seen by the neighbor router.

But with TRILL, it is important that only a single RBridge be elected DRB, because the DRB determines which RBridge will encapsulate/decapsulate packets for each VLAN. One of the first implementations of TRILL wound up forming a loop, where two RBridges, R1 and R2, both performed encapsulation/decapsulation. This situation resulted because neighbors R1 and R2 did not see each other's Hello messages, because the R1 Hello, padded to classic Ethernet maximum size by R1, became too large to forward when a VLAN tag was added, so did not reach R2.

To ensure that only a single RBridge on a link would be elected DRB, TRILL modified the Hello protocol as follows:

- Limit the size of Hello messages and do not pad them (in order to remove artificial impediments to receipt by neighbors).
- Elect a DRB based solely on priority (not two-way connectivity as in Layer 3 IS-IS). In other words, defer to a higher-priority RBridge R1 even if R1 does not list you as a neighbor.
- Have a separate mechanism for probing, using packets of different sizes, to see what size packets can be forwarded on the link.

In addition to solving the multiple-DRB problem, this design enables TRILL to discover which links can handle jumbo-grams, so that paths can be engineered that can forward jumbo-grams.

If the link between R1 and R2 is not acceptable because it cannot handle the assumed LSP fragment size, or because connectivity is not two-way, the link is not reported in LSPs. The capability of a link to handle larger sizes can be reported in LSPs.

There was enough confusion about this minor change to the Hello protocol, and skepticism that the Hello mechanism, which has worked correctly for Layer 3 for decades, would need to be modified for TRILL, that an additional RFC was written [3] to specifically explain the TRILL Hello mechanism.

Multidestination Frames

Multiple Trees

The original design for TRILL had the RBridges compute a single, shared tree, based on the LSP database, and all multidestination traffic was forwarded along that tree. But, to be able to load-split the use of links for multidestination traffic, a facility for using multiple trees was added early in the development of the TRILL standard.

In TRILL, the RBridge with the highest priority to be a TREE root announces to the other RBridges (through its LSP) how many trees, and which trees, should be calculated. A tree is calculated as a tree of shortest paths from a given Root, with a deterministic tie-breaker so that all RBridges calculate the same tree. The Root can be an RBridge or a pseudonode. In some cases, a Root is particularly well-situated in the topology such that its tree forms good paths for all pairs of nodes, but it is desirable to have multiple different trees, choosing different tie-breaker links, calculated from the same Root. TRILL accomplishes this setup by having that Root acquire multiple nicknames, one for each tree, and using the tree number in the tie-breaker algorithm, so that although all the trees from that Root will still be shortest-path trees, different links will be chosen in the different trees.

When R1 encapsulates a multidestination frame, R1 sets the "multi-destination" flag and specifies the tree Root nickname in the "egress RBridge" field in the TRILL header.

Filtering

A multidestination frame will be tagged with a VLAN (in the inner header). The frame need not be delivered to all RBridges—just those that are connected to a port with end nodes in that VLAN. So RBridges announce, in their LSPs, which VLANs they are attached to, where "attached to," means that they are acting as Appointed Forwarder.

Additionally, TRILL provides for filtering based on Layer 2 MAC addresses derived from IP Multicast groups. RBridges announce the set of such MAC addresses they wish to receive. The first RBridge that accepts an IP Multicast control message, such as *Internet Group Management Protocol* (IGMP), snoops on it [5] and learns what multicast listeners or multicast router is attached. This snooping is used so R1 can report in its LSP the IP Multicast groups it wishes to receive (or all groups if a multicast router is attached).

One other refinement to multidestination is the *Reverse Path Forwarding* (RPF) check. To safeguard against loops, when R is calculating which subset of its ports belong to a particular tree, R also calculates, for each port, the set of ingress RBridges whose traffic on that tree should arrive on that port.

So, the processing of a multidestination frame received by R, with TRILL header indicating Ingress = R1 and Egress/tree Root = R2, is as follows:

- If the port on which R receives the packet is not included in the tree "R2," discard the packet.
- If the port on which R receives the packet is in tree R2 but R1 is not listed in the RPF information for that port for tree R2, discard the packet.
- For each other port in R2, if the specified VLAN is reachable through that port and the IP Multicast address is requested by an RBridge along the path through that port, forward the packet on that port.

IS-IS Pseudonodes

If there is a link with N RBridges, rather than modeling the link as having on the order of N^2 links to be reported in LSPs, IS-IS has the DRB model the link as a pseudonode. The DRB gives the pseudonode a name, and the RBridges on the link report connectivity just to the pseudonode. The DRB generates an LSP on behalf of itself, reporting connectivity to the pseudonode, but additionally generates an LSP on behalf of the pseudonode, reporting connectivity to all the RBridges on the link. This portion of IS-IS is as designed from the beginning (from its origin as Phase V DECnet routing).

When IS-IS was originally designed, Ethernets tended to be very large shared links. But today, most Ethernets are simply point-to-point links (unless there are bridges making them appear to be shared links). So it would be wasteful for RBridges to always create a pseudonode for each Ethernet link. In Layer 3 it is not as unreasonable to always treat an Ethernet as a large shared link because an "Ethernet" link, as perceived by Layer 3, is likely to be a large collection of point-to-point links glued together with either bridges or RBridges.

But RBridges are likely to often see Ethernet links with just a single neighbor, especially in a topology with no bridges. So TRILL has the ability for the DRB to specify to its neighbor RBridges whether to report the link as a pseudonode or to report connectivity to all the RBridge neighbors as separate links. By default, the DRB R sets a flag known as the "bypass pseudonode" flag in its Hello message on the link, unless at some point since R rebooted R has seen two simultaneous neighbor RBridges on that link. With this mechanism, true point-to-point Ethernet links will be reported as a link between R1 and R2 rather than a pseudonode P, with links R1–P, R2–P, and P–R1 and P–R2 reported.

TRILL Implementations

TRILL is being widely implemented. TRILL fast-path hardware is included in chips available from all major merchant silicon manufacturers. A successful interoperability test was held at the University of New Hampshire *InterOperability Laboratory* in late 2010, and TRILL products are announced and shipping.

Future Potential TRILL Enhancements

Here are just three enhancements to TRILL being considered:

- Data centers require more VLANs than can be specified in 12 bits with a single VLAN tag. A TRILL extension to optionally include the ability to encode 24 bits of VLAN-like labeling in TRILL data frames is being considered.
- By optionally giving a pseudonode a nickname and having the appointed forwarder use that nickname in the ingress RBridge field, if the appointed forwarder changes, the end-node learning cache of distant RBridges will still be correct.
- A proposal is being made allowing IS-IS to be hierarchical in a TRILL campus. IS-IS hierarchy partitions the LSP database so that any single RBridge LSP database will be smaller, its path computation will be less computation-intensive, and it will lower the amount of LSP traffic. In particular, it shields the effects of a link that is cycling quickly from most of the campus, because only the RBridges in the region with the link will see reports of the state of that link.

Summary

The TRILL standard creates a cloud with a flat Ethernet address, so that nodes can move around within the cloud and not need to change their IP address. Although nodes attached to the cloud perceive the cloud as an Ethernet while the packet is traversing the cloud, it is encapsulated with a TRILL header, which like a Layer 3 technology, contains a source (ingress RBridge), destination (egress RBridge), and hop count. The addresses in the TRILL header are 16 bits, enabling a TRILL campus to support 64,000 RBridges. Transit RBridges do not learn about location of end nodes—only the existence of, and path to—other RBridges.

TRILL can use all the Layer 3 techniques, including shortest paths, *Equal Cost Multipath* (ECMP), and traffic engineering. It also supports VLANs and multicast. TRILL can calculate multiple trees, so that multidestination traffic can be split across links. Multi-destination frames can be filtered based on VLAN and IP (v4 or v6) Multicast groups.

TRILL is compatible with existing Ethernet bridges (switches), so a bridged Ethernet can be gradually upgraded by replacing any subset of the bridges with RBridges. The more that are upgraded, the better the bandwidth usage, and the more stable the network becomes.

The Case for IP Backhaul

by Jeff Loughridge, Brooks Consulting LLC

In any hierarchical network, designers must specify how the access layer delivers traffic to the core. In *Mobile Network Operator* (MNO) networks, the transport of voice and data from the cell sites to the wireless MNOs' core networks is called *backhaul*. *Time Division Multiplexing* (TDM) backhaul has dominated backhaul deployments since the inception of wireless communication. Leasing the backhaul access of multiple T1s/E1s for every cell site becomes prohibitively expensive in terms of operating expenses, particularly for providers that do not own the last mile. Today's 3G/4G cellular technologies have spurred a major change in the backhaul network: the transition from TDM to packet backhaul.

Ethernet is the most widespread packet-based backhaul technology. While this service is a vast cost and scale improvement over TDM backhaul, carrier Ethernet is a stepping stone in the evolution of backhaul networks. Expect MNOs to move to true IP backhaul networks to meet the scalability needs of their expanding networks. In this article, we will explain mobile backhaul evolution, shortcomings in carrier Ethernet backhaul, and how evolving service requirements will motivate cell site backhaul vendors to add IP-awareness to their networks.

Legacy Backhaul

Cellular systems were initially designed to carry only voice traffic. Since transporting digitized voice was a mature and well-understood technology, there was no need to take a divergent path for the backhaul of voice traffic in early cellular systems. Using TDM had obvious advantages among those being:

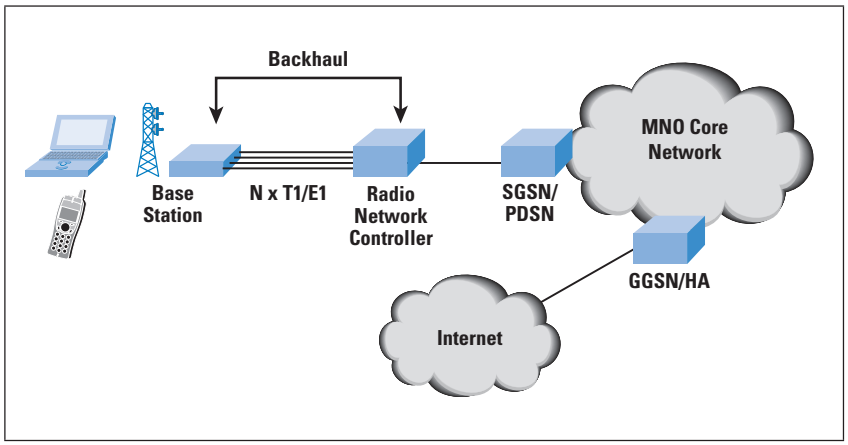
- Use of the same equipment used in wireline voice transmission
- Technical staffs' familiarity with TDM concepts and troubleshooting
- Ability to use existing *Operations, Administration, Maintenance, and Provisioning* (OAM&P) systems
- Ubiquity of the T1/E1 service

The initial work to offer data service on cellular systems naturally focused on adding data transmission to the existing voice infrastructure. Standards such as *Global System for Mobile Communications* (GSM) and *Interim Standard 95* (IS-95) took similar approaches in borrowing TDM time slots for data. The data services of the 1990s were very slow, even when compared to consumer modems of the time. Standards developed in the late 1990s and deployed in the early 2000s (*Enhanced Data rates for GSM Evolution* [EDGE] and *CDMA2000*) improved data transfer speeds.

TDM was clearly entrenched as a foundational technology for data communication in cellular networks going into the early 3G technology deployments (*Universal Mobile Telecommunications System* [UMTS] and *Evolution Data Optimized* [EV-DO]).

Figure 1 depicts the backhaul portion of the MNO network and how it fits into the broader architecture.

Figure 1: The Backhaul Network in the MNO Architecture



As data traffic usage for 3G networks grew, shortcomings of TDM backhaul began to materialize. The two prominent areas were bandwidth and cost. Cell sites with TDM access are typically equipped with multiple T1/E1s. With faster radio interfaces, the backhaul became the bottleneck in the network. Some smartphones became consumers of multi-megabyte data rates. User experiences were poor on some wireless networks as a result of a dearth of bandwidth in the backhaul segment. Continuing to increase the number of TDM lines or increase their capacity was not a viable option since the growth increments were too small and the operating expenses were too high.

The second limitation of TDM in 3G networks is cost. Although the cost of T1/E1s decreased considerably over the years, the costs piled up given the number of cell sites and number of T1/E1s per site. This figure became the highest contributor to the cost of the backhaul network. The MNOs that owned the last mile were at a distinct competitive advantage compared with the carriers who had to pay another party (often in a minimally competitive marketplace) for TDM access. For MNOs to continue their incredible traffic growth rates, a new access model was needed.

Carrier Ethernet Adoption

Ethernet quickly emerged as the most popular backhaul technology to replace TDM access infrastructure (other providers moved forward with microwave access with varying levels of success). The various iterations of Ethernet from 1970s to 2000s had trumped other LAN technologies in the market, and at the turn of the century gigabit Ethernet leveraged its success in the LAN to become popular in the WAN. The technology had several major advantages:

- *Large drop in cost per bit:* Ethernet would allow providers to drastically alter their access cost model by supplanting the aging and costly TDM infrastructure. With the price that consumers were willing to pay per month of data service staying relatively stagnant, this adjustment to the cost model was critical.
- *Ethernet can be carried over more underlying technologies: Synchronous Optical Networking/Synchronous Digital Hierarchy* (SONET/SDH), *Generic Framing Procedure* (GFP), *Dense Wavelength Division Multiplexing* (DWDM), and *Multiprotocol Label Switching* (MPLS) are a few examples. A key benefit Ethernet's ability to operate over these technologies was that many providers could consolidate their wireless access with their existing and speedier wireline access networks.
- *Ethernet interfaces ubiquitous and inexpensive:* Ethernet won the battle for LAN dominance. The technology was not restricted to traditional personal computers and servers—printers, phones, game consoles, *Digital Video Recorders* (DVRs), and home media center hubs are some examples of other equipment that often included Ethernet interfaces. This ubiquity in the business and consumer spaces results in a diverse supplier set and economies of scale for the vendors and suppliers.
- *Ease of bandwidth upgrade:* TDM circuits have an implementation time measured in months. This slow turn-around time for upgrades is a poor fit for an environment in which data usages is increasing at fast rates. Ethernet is much different. An increase in bandwidth to a network end-point will not require a change in equipment unless moving between the established tiers of 10, 100, 1000 Mb/s. Since the Ethernet service vendor likely uses a "policer" to keep customers within the purchased bandwidth level, a change in software configuration is usually all that is required to upgrade bandwidth. Another advantage is that bandwidth can be upgraded in granular increments. With the right back-end systems, an upgrade will take a matter of minutes. For companies looking to increase the velocity of service deployment, the ability to quickly move to high speeds is very favorable.

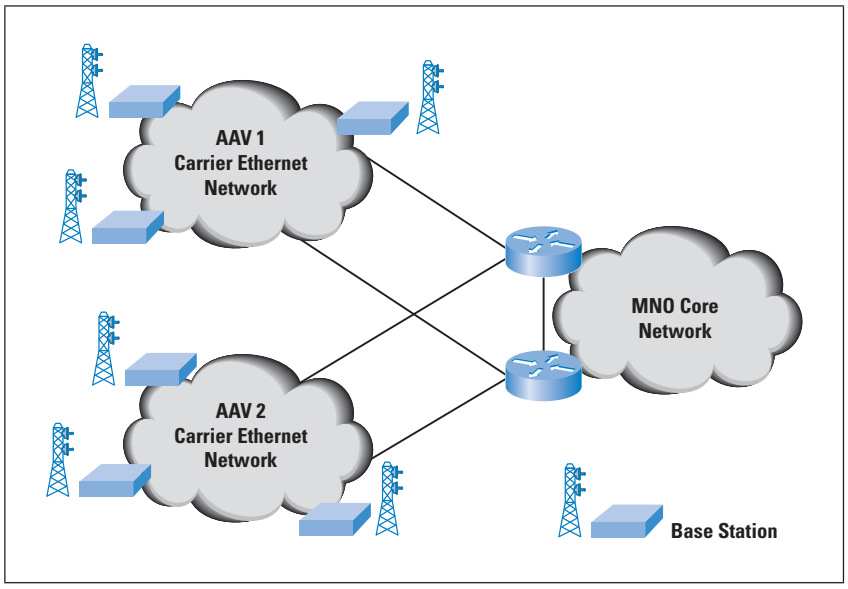
Established in 2001, the *Metro Ethernet Forum* (MEF) played a critical role in the acceptance of carrier Ethernet by wireless and wireline providers. The MEF is not a standards organization like the *Internet Engineering Task Force* (IETF). Instead, the MEF builds upon the work of standards bodies to establish common terminology, service requirements, and network interface requirements. The MEF created an architecture framework along with measurement and testing specifications. Although the MEF did not eliminate wireless providers' concerns about packet backhaul—particularly in the areas of jitter, delay, and packet delivery, the forum did increase the comfort level associated with metro Ethernet services. The MEF's E-LINE service definition established a connection-oriented path, a concept much more pleasing to traditional telcos than the perceived "anything goes" nature of packet switched networks. For more detail on the MEF's service definitions, see [0].

By the second half of the 2000s, many wireless providers were planning the deployment of Ethernet-based backhaul for new *High Speed Packet Access* (HSPA), *Worldwide Interoperability for Micro-wave Access* (WiMAX), and *Long-term Evolution* (LTE). In making this radical change, the providers often had to consider protecting existing revenue streams from voice and data (providers electing to move forward with greenfield deployments were at a luxury). Pseudowire technologies enabled the carriage of TDM traffic over IP/Ethernet networks, thus preserving investment in existing infrastructure.

Rather than build carrier Ethernet infrastructure, the MNOs that were not facilities-based (or had limited last mile footprints) purchased services from other parties, known as *Alternate Access Vendors* (AAV) in telco parlance In the United States, the *Local Exchange Carriers* (LECs) and cable companies were well positioned for this business. MNOs often used multiple AAVs in a given market to cover the cell site footprint. Getting fiber to cell sites outside of major metropolitan areas was not always possible, which led some MNOs to use hybrid backhaul solutions that included microwave and TDM inverse muxing in addition to carrier Ethernet.

Figure 2 illustrates how MNOs rely on AAVs to cover their cell site footprint in a given market.

Figure 2: Alternative Access Vendors



The adoption of carrier Ethernet services by MNOs was not without challenges. Mobility gear such as *Radio Network Controllers* (RNC), base stations, and *Home Location Registers* (HLR) historically relied on T1/E1 interfaces for connection to the network. Telecom vendors had to implement Ethernet interfaces along with IP stacks. The providers had to completely revamp provisioning, service monitoring, performance monitoring, and service assurance systems and processes. Consider the following example.

For years, operations groups at telcos counted on near-immediate notification with an alarm indication signal in the *Time Division Multiple Access* (TDMA) frame. TDMA frames arrive every 125 µsec (8,000 times a second). Packet-switched networks do not share the synchronous nature of TDM and do not have OAM fields in framing bits. The operators now had to rely on nascent specifications such as Y.1731 and 802.1ag for service monitoring.

Timing and synchronization—necessities in mobile networks—are gleaned from the physical layer in TDM networks. Asynchronous networks such as Ethernet/IP do not have an inherent mechanism for timing and synchronization. Keeping a single T1/E1 at the cell site is one method to ensure timing and synchronization in a carrier Ethernet scenario; however, the use of upper layer protocols is more appropriate, particularly for new builds that have no legacy TDM circuits. *Synchronous Ethernet* (SyncE), *Precision Time Protocol* (PTP, also known as IEEE 1588v2), and *Network Time Protocol version 4* (NTPv4) were deployed in backhaul networks to provide timing and synchronization. Note that SyncE transports timing information over the physical layer much like the TDM timing model, while PTP and NTP use IP for transport and are not dependent on an Ethernet physical layer.

The learning and flooding aspects of all Ethernet networks present inherent scaling challenges for very large networks. Spanning tree and its derivatives are commonly used to address these issues at low and medium scale. For larger networks that provide service to multiple customers, the service must scale in terms of its ability to offer service to multiple entities and in terms of the many switches required for an expansive footprint. Many protocols have arisen to solve one or both of these challenges. Examples are *Virtual Private LAN Service* (VPLS), *Multiprotocol Label Switching–Transport Profile* (MPLS-TP), and *Provider Backbone Bridging–Traffic Engineering* (PBB-TE). Being relatively new technologies, these can and do present challenges for operations groups. The breakages can occur in ways that are very difficult for the Carrier Ethernet provider and wireless provider to jointly troubleshoot.

The Next Step – IP Backhaul

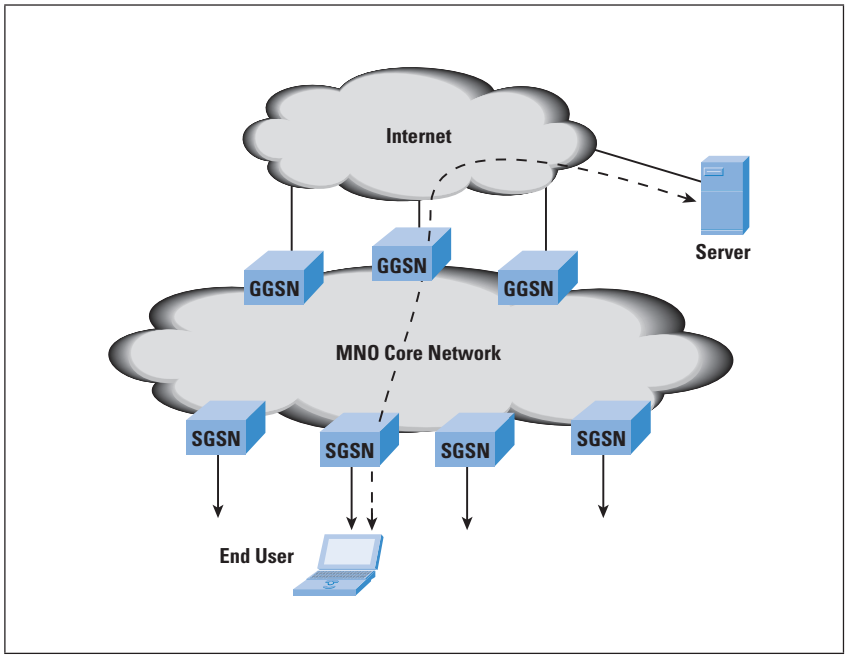
The phrase "all-IP" is frequently used to describe the most recent wireless technologies such as HSPA+, WiMAX, and LTE. This is applicable as the majority of network elements, including the handsets, are IP enabled. The existence of large-sized carrier Ethernet networks in the network architecture undermines the IP-centric argument. IP has superior scaling properties over Layer 2 networks. The footprint and number of nodes for carrier Ethernet networks continues to expand rapidly as the MNOs deploy 3G and 4G networks. The author sees evidence that protocols used to overcome Ethernet scalabilities issues will become increasingly complex and push MSOs and AAVs toward Layer 3-centric backhaul networks.

Before delving into the drivers of IP backhaul, let's examine a typical data traffic flow for today's wireless networks. We'll use the 3GPP's *GSM Packet Radio System* (GPRS) as this is the most common in world-wide deployments. Data flows are very centralized in this architecture. Macro-level mobility is controlled by two types of *GPRS Support Nodes* (GSN): *Gateway GPRS Support Nodes* (GGSN) and *Serving GPRS Support Nodes* (SGSN). GGSNs are typically deployed within the mobile core network at locations with Internet access. This is often at centralized mobile switching centers. SGSNs can be deployed closer to the network edge and multiple SGSNs can be served by a single GGSN.

The GGSN is the mobility anchor, much like the home agent in wireless networks that use Mobile IP. The SGSN is akin to the foreign agent in Mobile IP. GPRS network tunnel traffic between SGSN and GGSN using an IP-in-IP tunneling protocol called *Generic Tunneling Protocol* (GTP). Although GTP has several purposes in the GPRS core network, our focus will be on its tunneling of packets between SGSN and GGSN (called the *Gn* interface). The movement of the subscriber to a region served by another SGSN will trigger a macro-mobility event. A new GTP tunnel is formed using the original GGSN for session continuity [2].

Since all traffic from the *Mobile Subscriber* (MS) must traverse the GGSN as the mobility anchor, the traffic flow from the MS follows a very predictable path to a centralized location. Note that there is not a 1:1 relationship between SGSNs and GGSNs. As mentioned earlier, typical deployment of GGSNs is very centralized. Figure 3 depicts the flow.

Figure 3: Data flow in a GPRS Network



Although technologies like LTE are touted as flat IP networks, this only holds true from a *Radio Access Network* (RAN) perspective. What if a subscriber wants to communicate with another subscriber in the same building or local machine-to-machine traffic is highly sensitive to latency? The packets will be sent to the mobility anchor, perhaps hundreds of kilometers away. Routing decisions can be made in the RAN and core network; however, the decision is restricted since traffic must traverse the predefined tunnel endpoints.

Wireless networks will gradually decentralize and distribute mobility management. In 3G networks, some providers have been extending the core network closer to the subscriber as mobile gateways (GSNs and their equivalents in non-3GPP networks) become more cost-competitive. By deploying mobile gateways at what were previously aggregation *Points Of Presence* (POPs) and buying Internet connectivity at these locations, Internet-bound traffic exits the network quickly, consuming fewer resources for the provider. Other signs of this shift are evident in LTE and WiMAX. LTE's S1-flex interface allows the RAN to be connected to multiple core networks. The WiMAX reference model separates the *Network Access Provider* (NAP) and *Network Service Provider* (NSP). The NAP, which provides radio access functionality, can connect to multiple NSPs for Internet connectivity.

To fully realize the benefits of an IP-centric backhaul, steps must be taken to go beyond simply distributing mobility management. New solutions are needed to eliminate mobility anchoring via tunneling. Vendors, providers, and universities have already started to examine how to dispose of tunneling in the mobile environment [2].

The IP-centric backhaul network has many advantages over the carrier Ethernet networks that enable many of today's packet backhaul networks. Various advantages benefit the wireless providers, the IP backhaul provider, or both. These advantages are most prevalent when the MSOs have a highly distributed mobility management architecture.

- *Backhaul Offload:* Today's mobile elements at the cell tower have no ability to influence routing decisions; there is only one path to the core network. Adding egress points to the cell site or backhaul network reduces the distance and amount of traffic that must be backhauled. To accomplish the addition of egress points in a carrier Ethernet network, connection-oriented mechanisms such as Ethernet Virtual Circuits would require that the MSO and AAV modify multiple network elements' configurations. Offloading traffic with an IP network is substantially more simple and scalable. Offloading packets from the backhaul will represent a huge savings in access costs. The base station could be capable of hot potato routing traffic directly to an ISP instead of backhauling commodity Internet traffic to the MSO, where the costs of equipment, power, and software licenses quickly accumulate.

- *Multicast:* The reliance on tunneling as described earlier in this piece severely restricts the usefulness of multicast in current wireless networks. Distributing the mobility elements controlling the tunneling closer to the subscriber will mitigate these effects as would the elimination of mobility anchoring via tunneling techniques. The implementation of a true flat IP network would extend multicast capability into the RAN and position both MNOs and IP backhaul providers to realize the efficiency gains of multicast.
- *Localized Content and Peering:* With localized egress points, local content could be reached directly rather than traversing the core network. This would position wireless providers to peer with other providers at the local or regional level, a benefit that would be substantial for wireless providers operating in countries with non-meshy Internet infrastructure and expensive wide-area communications lines. In addition, caches could be implemented much closer to the subscriber to improve the user experience for video and other content types.
- *Machine-to-Machine (M2M) and Peer-to-Peer (PtP):* When the communication is device to device in close geographic proximity, the traversal of the core network only adds latency, complexity, and cost. A distributed mobility management architecture and IP backhaul network engender an optimized path for M2M and PtP. The mobility anchor point could be placed at the cell tower or local aggregation point, providing a much improved communication path for subscribers and machines connected to the wireless network.
- *Uptime and Reliability:* Wireless providers have experienced challenges with carrier Ethernet service. Some of these problems can be chalked up to the relative newness of using carrier Ethernet for cell site backhaul. One has to wonder though, what experience exists in the industry for maintaining giant Layer 2 networks? The number of mobile devices will expand exponentially, triggering the deployment of thousands of new cell sites, microcells, and picocells. The author is less than confident that any underlying technology that enables carrier Ethernet will scale to the necessary degree while maintaining the uptime and reliability that users expect from their data service.

For large IP networks, the industry has over fifteen years' experience in designing, engineering, and operating IP networking carrying traffic at staggering capacities. The staff expertise, software maturity, and systems support exists today to maintain sizable IP networks. There are established best practices for Tier 1 ISPs that help ensure long uptime, speedy convergence upon failure, and sound network design.

Delivering an IP Backhaul Service

IP backhaul offerings could be delivered in a variety of ways. The simplest design for IP backhaul providers would be a shared IP transport network that commingles traffic between customers.

The wireless providers could then use protocols such as *Layer 2 Tunneling Protocol version 3* (L2TPv3) to build an MPLS/VPN-like overlay to provide logical separation and address overlap prevention. The preferred approach for MNOs would likely be a Layer 3 VPN service from the AAV, thereby offloading much of the routing complexity from the MNO.

An IP backhaul service must be capable of routing IPv6 packets, as the useful lifetime of an IPv4-only service is limited. MNOs cannot obtain new IPv4 addresses to number the base stations, and using RFC 1918 space is not a scalable approach. Using IPv6-only to address mobility equipment at cell sites (and equivalent radio interfaces) is the preferred method for overcoming the scarcity of IPv4 addresses.

The shift from carrier Ethernet to IP backhaul should not be a monumental one for many carrier Ethernet providers. The heavy lifting of installing fiber and deploying a packet switched infrastructure has already been accomplished. In addition, carriers that implement carrier Ethernet with protocols like VPLS already have an infrastructure that is ready for IP. The most challenging aspect of the transition will be the work needed to prepare OAM&P systems for an IP service. Of course, this may vary based on carrier Ethernet implementation and systems.

Conclusion

Carrier Ethernet service for cell site backhaul is a vast scale and cost improvement over TDM backhaul and has been extremely successful. OSI Layer 3 IP networks have superior scaling properties that will replace Layer 2 backhaul networks of today. Advances in wireless networking systems, the proliferation of new devices, and the development of new mobility services will be best served with a truly IP-centric backhaul network.

Global INET 2012

To help mark its 20-year-anniversary, the *Internet Society* (ISOC) is hosting a global forum that will bring together visionaries and thought leaders from around the world to focus on issues that will impact the future of the Internet.

The *Global INET 2012,* which is scheduled to take place in Geneva, Switzerland from April 22–24, will feature high-powered speakers, thought-provoking panel discussions, and interactive workshops to develop a vision for the explosive growth of the Internet over the next 20 years.

Thought leaders from across the Internet community will collaborate on topics critical to the global Internet's future, including privacy, net neutrality, IPv6, security, digital content and innovation, and human rights and freedom of expression.

Since its beginnings in 1992, ISOC has been dedicated to helping keep the Internet open, accessible, and defined by users—regardless of where they live, what they do, their abilities, or who they are.

Registration for Global INET 2012 is scheduled to begin in October 2011.

IPv6 Week

IPv6 Week will be a coordinated test of the new Internet Protocol, held February 6–12, 2012. Websites, content providers, Internet Services Providers, Network Service Providers, as well as end users are invited to participate. This is a Brazilian initiative, but anyone can participate.

For more information visit: **http://www.ipv6.br/IPV6/WeekIPv6**

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ contains standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

From The Editor

Depletion of the IPv4 address space and the transition to IPv6 has been a "hot topic" for several years. In 2011, interest in this topic grew considerably when the *Asia Pacific Network Information Centre* (APNIC) became the first *Regional Internet Registry* (RIR) to start allocating addresses from its final /8 IPv4 address pool. Although depletion dates are difficult to predict accurately, there is no question that the day will come when it will no longer be possible to obtain IPv4 space from the RIRs. News stories about IP addresses being sold for considerable sums of money are becoming more common.

Numerous organizations have been working diligently to promote, test, and deploy IPv6 through efforts such as the *World IPv6 Day,* while the *Internet Engineering Task Force* (IETF) continues to develop solutions to aid in the transition. One such effort, the *Port Control Protocol* (PCP), is described in our first article by Dan Wing.

The *Internet Corporation for Assigned Names and Numbers* (ICANN) will soon begin accepting applications for new *Top-Level Domains* (TLDs). It is not yet known how many new TLDs will eventually be deployed, but the plans have prompted several studies focused on the resiliency and scalability of the *Domain Name System* (DNS). Bill Manning discusses some of the technical challenges associated with a vastly expanded TLD space.

The IETF *Homenet Working Group* "...focuses on the evolving networking technology within and among relatively small 'residential home' networks. For example, an obvious trend in home networking is the proliferation of networking technology in an increasingly broad range and number of devices. This evolution in scale and diversity sets some requirements on IETF protocols." Geoff Huston gives an overview of some of the challenges facing this Working Group.

The product of the IETF is a set of documents, mainly protocol specifications and related material. These documents start life as *Internet Drafts* and proceed through a series of iterative refinements toward eventual publication as *Request For Comments* (RFCs). Over time, several *tools* have been developed to aid in the document development process, and they are now organized at the IETF Tools webpage. We asked Robert Sparks to give us an overview of some of the most important tools and the process involved in their development.

Port Control Protocol

by Dan Wing, Cisco Systems

After the transition to *Internet Protocol Version 6* (IPv6), hosts will often be behind IPv6 firewalls. But before the transition, mobile wireless devices will want to reduce their keepalive messages, and hosts of all sorts will share IPv4 addresses using a variety of address-sharing technologies. To meet these needs, the IETF formed the *Port Control Protocol Working Group* in August 2010 to define a new protocol for hosts to communicate with such devices. The initial output of this Working Group is the *Port Control Protocol* (PCP)[1]. Interoperability between two independently developed implementations of PCP was demonstrated at the IETF meeting in July 2011, highlighting the importance of this protocol to the industry. After it becomes a standard, PCP is expected to be deployed in various operating systems, IPv6 home gateways, IPv4 home gateways (*Network Address Translators* [NATs]), mobile third- and fourth-generation (3G and 4G, respectively) gateways (*Gateway GPRS Support Nodes* [GGSNs]), and *Carrier-Grade NATs* (CGNs).

Introduction to PCP

PCP performs two major functions: It allows packets to be received from the Internet to a host (such as to operate a server), and allows a host to reduce keepalive traffic of connections to a server. PCP can be extended in two ways: with new *OpCodes* or with new *Options*. The base PCP specification defines two OpCodes: MAP and PEER, and defines several Options that can be carried with those OpCodes.

To operate a server, packets are sent from a host on the Internet to a server. The IP model expects devices to be connected to a network and be able to exchange packets with each other. However, few deployed networks actually permit hosts to receive packets from the Internet because of business needs (for example, to protect wireless spectrum from malicious or accidental packets originated on the Internet) or because of technology restrictions (for example, IPv4 address-sharing devices such as *Network Address and Port Translators* [NAPT]). To operate a server, a host uses the MAP OpCode.

To reduce keepalives, a host needs to send traffic before a middlebox will destroy an idle connection. Many middleboxes, such as firewalls or NATs, maintain state and will destroy mappings if the connection has been idle. Today, in order to prevent destruction of mappings, hosts send keepalive traffic to keep those mappings alive. The keepalive traffic has several disadvantages, including reduction of battery lifetime, network chatter, and server scalability (servers have to discard the keepalive traffic). PCP allows a host to determine how aggressively a middlebox will destroy an idle connection, allowing the host to reduce its keepalive traffic with the PEER OpCode.

PCP is encoded in binary and carried over the *User Datagram Protocol* (UDP), which eases implementation on clients and servers. The client is responsible for retransmitting messages, and all messages are idempotent. The PCP client can be part of the operating system (much like a *Dynamic Host Configuration Protocol* [DHCP] client or a *Universal Plug and Play* [UPnP] *Internet Gateway Device Protocol* [IGD] client) or the PCP client can be coded entirely in an application (much like any other application-level protocol such as the *Network Time Protocol* [NTP]). A major feature of PCP is its flexibility and simple messaging, so it can be implemented easily in a variety of systems and at high scale.

Security

When installing an IPv4 NAPT on a residential network, the NAPT has a side effect: it prevents unsolicited incoming traffic from reaching hosts inside the home. Traffic that originates inside the home can traverse the NAPT toward the Internet. This function is expected by many users to such a degree that when IPv6-capable routers were first installed on residential networks, users complained that their IPv6 hosts were seeing traffic from the Internet. This visibility meant that IPv6 printers, webcams, and other hosts had to be protected from malicious traffic from the Internet. Based on this experience, IPv6 *Customer Premises Equipment* (CPE) routers intended for installation in the residential market filter most unsolicited incoming traffic by default[3]. Thus, IPv6 CPE routers provide filtering similar to what users experience today with IPv4 NAPT devices.

With both IPv4 NAPT and RFC 6092 IPv6 routers, outgoing traffic from a host creates a mapping that then allows bidirectional traffic to a specific (*Transmission Control Protocol* [TCP] or UDP) port on the internal host, meaning when a host sends a TCP SYN, a SYN ACK can be returned to the host. Neither IPv4 NAPT devices nor RFC 6092 IPv6 routers have to do any additional filtering of that mapping, and after that mapping is created will allow traffic from any host on the Internet to reach the internal host—not just traffic from that particular host. This lack of filtering is necessary for certain applications to function.

PCP was built with a security model similar to that deployed on home networks. With PCP, a host can send a PCP packet requesting a mapping so that any host on the Internet can now initiate communications with the internal host. Similarly, without PCP, a host could send a TCP SYN from a specific port (for example, port 80), thereby creating a mapping nearly identical to a PCP mapping. As with sending a TCP SYN, PCP allows a host to open mappings only for itself, unless the network administrator has taken the extra step to enable the PCP THIRD_PARTY option.

You may wish to have additional restrictions for some networks. PCP is extensible to support authorization, and there is ongoing work to support authentication and authorization within PCP[8].

PCP is extensible and there are already several proposed extensions to the protocol, including a way to control which IP address pool is assigned to a mapping[5], bulk port allocation to optimize acquiring a large set of ports[6], and rapid recovery after NAT failure or network renumbering[7].

PCP Scenarios

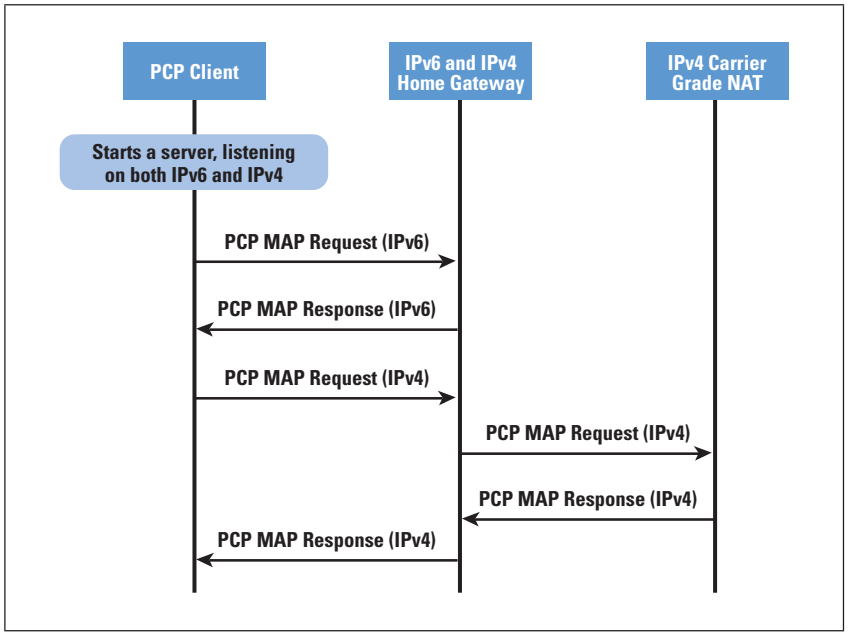
PCP works in all scenarios with IPv4 address sharing (using an IPv4 NAT or using other techniques), an IPv4 or IPv6 firewall, and NATs that translate from IPv6 to IPv4, IPv4 to IPv6, or IPv6 to IPv6. When working with nested NAT, such as a NAT in the home and a NAT operated by the *Internet Service Provider* (ISP), PCP can create the NAT mappings in both devices. When working with IPv6, PCP can create mappings in an IPv6 CPE router. In some networks we expect to see IPv6-only devices that IPv4 clients may need to access. For those devices to work, an IPv6/IPv4 translator (NAT64)[10, 11] can translate between IPv6 and IPv4. PCP can work with an IPv6/IPv4 translator as well. In other scenarios IPv6/IPv6 translation may be necessary, and although translating IPv6 to IPv6 is far from desirable, PCP can also support IPv6/IPv6 (NPTv6)[12].

A server, such as a one running on a sensor (for example, thermometer or electric meter), can use PCP to determine its publicly routable IPv4 or IPv6 address and port, and then populate a *Rendezvous* server with that IP address and port. For example, an IPv6-only thermostat might want to be accessible over IPv6 and IPv4, so it can be accessed by both the power company (to push new electricity rate information to the thermostat) and the homeowner (who might have IPv4 access only at work). The thermostat can use PCP to create a TCP mapping in the IPv6 CPE router (necessary because the IPv6 CPE router will, by default, filter unsolicited incoming IPv6 packets) and use PCP to create a TCP mapping in a NAT64 (necessary so the homeowner can access the thermostat). The IPv6 address and its TCP port, and the IPv4 address and its TCP port, can be published to the *Domain Name System* (DNS) (using DNS Server [SRV] records) or published to some other Rendezvous server. Then the power company or the homeowner can use the DNS (or the other Rendezvous server) to communicate directly with the thermostat.

Because PCP can inform the PCP client of address changes, network renumbering can be communicated immediately to hosts—something that cannot be done with most other NAT or firewall control mechanisms. Therefore, devices running on nomadic networks, such as in a connected vehicle, that use PCP will immediately learn when they have connected to a new network. This knowledge can allow them to update information in the DNS or in some other Rendezvous server so they remain accessible from the Internet.

PCP is expected to be implemented in home gateways and Carrier-Grade NATs, which provide value for both IPv6 (to operate a server and learn keepalive timeouts) and IPv4. Figure 1 shows how a dual-stack host would use PCP to operate an IPv6 or IPv4 server.

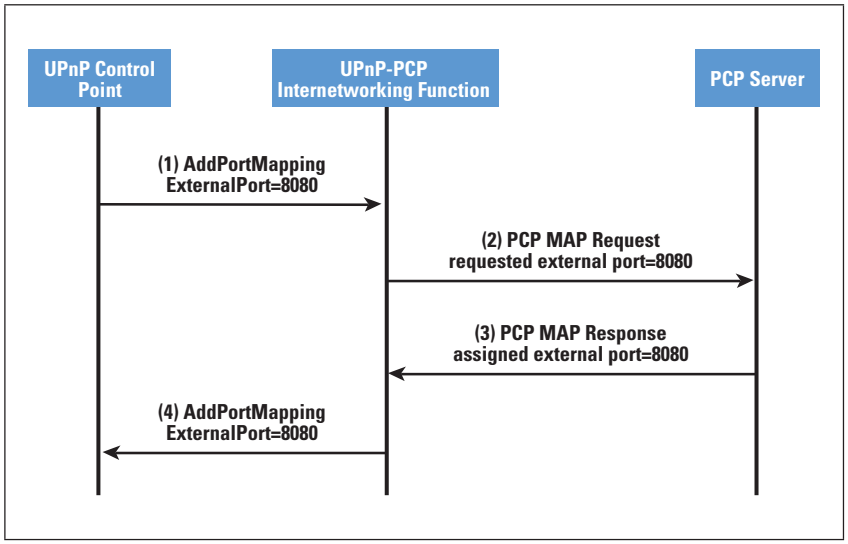
Figure 1: PCP Mapping IPv6 and IPv4



PCP Interworking with UPnP IGD

UPnP IGD Version 1 is widely available on residential-class NAT devices and host operating systems (Windows and OS X). However, because of security concerns it is often disabled by vendors, ISPs, or end users. UPnP IGD itself only works with a single layer of NAT, but it is possible to interwork between UPnP IGD and PCP[4]. To do this interworking, a home gateway (NAT) processes UPnP IGD messages on its LAN interface and translates those messages to PCP messages on its WAN interface, as depicted in Figure 2.

Figure 2: UPnP-to-PCP Interworking, Showing AddPortMapping Success



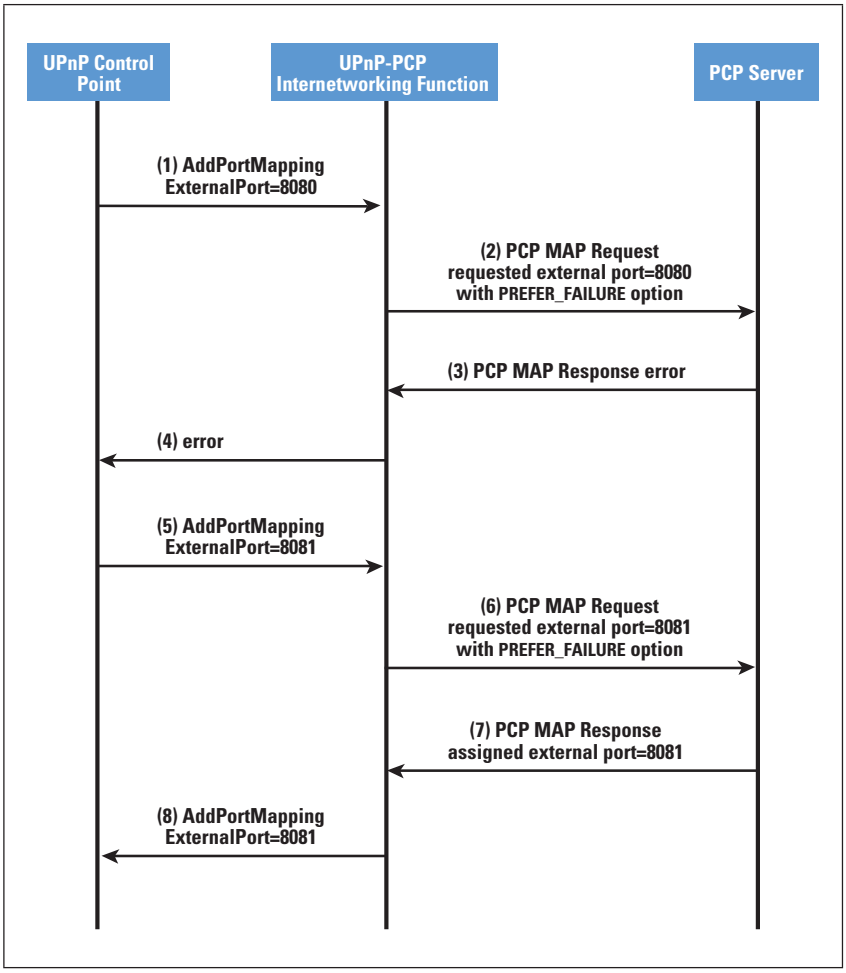
One difficulty with UPnP IGD is its AddPortMapping action, which maps a specific port on the home gateway. If that requested port is already mapped to another host, that port cannot be mapped to a new host (because it is already mapped to a different host). This problem exists today with UPnP IGD if two hosts in a home need the same port (for example, TCP port 80) because only one of them can map the port. In a CGN environment, where many subscribers share one IPv4 address, it is almost guaranteed that another subscriber has already mapped a "good" port (for example, 80 for HTTP, 8080 for HTTP, 5001 for Slingbox, 5060 for *Session Initiation Protocol* [SIP], etc.). Today, when a UPnP IGD port mapping is refused, the application may overwrite the first host's mapping (causing significant problems), "hunt" for an available port, or simply give up and display an error to the user. The "hunting" is often sequential (trying the next-higher port number) but is sometimes random, and is done by the application itself, the operating system UPnP framework, or both.

UPnP IGD Version 2[2] introduced the *AddAnyPortmapping* action, which avoids the need to "hunt" for an available port and allows the NAT to assign an available port. But UPnP IGD Version 2 is not yet widely available in home gateways, operating systems, or applications. Until IPv6 is ubiquitously available, applications (and users) will need to practice better port agility than has been practiced in the past, because "good" ports will simply not be available when IPv4 addresses are shared.

To ease the interworking with the UPnP IGD AddPortMapping action, the base PCP specification includes a PREFER_FAILURE option, which avoids creating a mapping if the requested port is unavailable. A message flow of this behavior is shown in Figure 3.

In a *Dual-Stack Lite*[9] deployment, the home gateway is typically operated without a NAT function. In that configuration, the home gateway is expected to interwork between UPnP IGD (within the home) and PCP (toward the service provider's CGN). The PCP packets sent by the home gateway will have the source IP address of the home gateway, rather than the IP address of the host that initiated the UPnP IGD action. To accommodate that situation, the home gateway populates the THIRD_PARTY option with the IP address of the internal host needing the mapping. The THIRD_PARTY option is useful in other scenarios as well, including interworking with other protocols (such as the *NAT Port-Mapping Protocol* [NAT-PMP][13]) to PCP, using PCP to create mappings for a device that does not support PCP (for example, an IP-enabled webcam), or using it as the protocol between a web portal operated by the ISP and its CGN.

Figure 3: UPnP-to-PCP Interworking, Showing AddPortMapping Failure



Conclusion

PCP provides functions necessary for IPv6 hosts on home networks; it is a simple, scalable protocol that supports simple firewalling of IPv6 and IPv4 hosts, and to accommodate the transition to IPv6 also supports every conceived IPv4/IPv6 translation mechanism.

Infrastructure Challenges to DNS Scaling

by Bill Manning

This article looks a few steps beyond the *Root Scaling Study* report from 2009.[1] In 2009, the *Internet Corporation for Assigned Names and Numbers* (ICANN) board commissioned a report to evaluate the effect of scaling the root zone from its current size to an undefined but larger root zone. Attributes considered were *Domain Name System Security Extensions* (DNSSEC), *Internet Protocol Version 6* (IPv6), *Internationalized Domain Names* (IDNs), and a larger number of entries in the zone. The report itself focused on the editorial processes and presentation of the finished root zone to the greater Internet. The report concluded that with prudence and with the addition of some "watch & warn" systems in place, the root zone could accommodate adding IPv6, DNSSEC, and IDNs along with other new *Top-Level Domain* (TLD) entries in a controlled manner. What the report did not consider was the effects of the deployed Internet infrastructure on the ability to get this new information into the rest of the *Domain Name System* (DNS) infrastructures of the Internet. Early experimental evidence[7, 8] suggests that the current state of infrastructure deployment will create problems for the deployment of these attributes.

Until recently the root zone of the DNS has enjoyed two important stabilizing properties:

- It is relatively small—currently the root zone holds delegation information for 280 generic, country-code, and special-purpose TLDs, and the size of the root zone file is roughly 80,000 bytes.
- It changes slowly—on average, the root zone absorbs less than one change per TLD per year, and the changes tend to be minor.

The root system has therefore evolved in an environment in which information about a small number of familiar TLDs remains stable for long periods of time. However, the type, amount, and volatility of the information that is contained in the root zone are expected to change as a result of the following four recent or pending policy decisions:

- Support for DNSSEC, or "signing the root"
- The addition of IDN TLDs
- Support for the additional larger addresses associated with IPv6
- The addition of new TLDs

These changes are placed in a backdrop of an infrastructure that is fundamentally changing, removing a third attribute of a stable DNS that was the presumption of a common transport protocol with well-defined constraints.

Core Design Principles

The DNS was designed so that queries and responses would have the greatest chance of survival and broadest reachability by using an IPv4 default *User Datagram Protocol* (UDP) packet size of 512 bytes for the initial bootstrapping. Larger packet sizes are supported and the *Transmission Control Protocol* (TCP) was defined and used as an alternate transport protocol—but expected to be infrequently used.

With these core principles intact, the DNS was able to successfully evolve into a highly decentralized dynamic system. The geographic and organizational decentralization of the root system arises from a deliberate design decision in favor of diversity and minimal fate-sharing coordination, which confers substantial stability and robustness benefits on the global Internet.

Simple quantitative extrapolation from a baseline model of the current DNS does not predict realistic future states of the system beyond the very short term, because:

- Each part of the system adapts in different ways to changes in the quantity, type, and update frequency of information, while also responding to changes in the rest of the Internet.
- These adaptations are not—and cannot be—effectively coordinated.
- For some, if not all, of the actors, nonquantifiable considerations dominate their individual adaptation behavior (both strategically, in a planning context, and tactically, in an operations context).

The risks associated with adding DNSSEC and IPv6 addresses to the DNS simultaneously change the basic assumption for DNS Query/Response reachability. Signing DNS data would, by itself, immediately increase the size of any zone by roughly a factor of 4 and increase the size of the response message[2]. The consequences of the second of these effects could be absorbed by replanning in order to recover lost headroom by adding bandwidth. Adding IPv6 addresses would in addition increase the size of any response. However, simply adding additional bandwidth may be insufficient when there are middleboxes, application layer gateways, or divergent transport options between the query path and the response path.

In these cases more information has to be carried in the packets that are returned in response to a query, meaning that the required amount of network bandwidth needed to support the operations of the server increases. As the DNS messages get bigger, they will no longer fit in single 512-byte packets forwarded by the UDP transport mechanism of the Internet. This situation will lead to clients being forced to resend their queries using UDP "jumbograms" or the TCP transport mechanism—a mechanism that has much more overhead and requires the end nodes to maintain much more state information. It also has much more overhead in terms of "extra packets" sent just to keep things on track. The benefit is, of course, that it can carry much larger pieces of information.

Moving the root system from its default UDP behavior to UDP "jumbograms" or TCP will not only have the undesirable effects mentioned previously, it will also affect the current trend of deploying servers using IP *anycast*[10]. Anycast works well with single packet transactions (such as UDP), but is much less well suited to handle TCP packet streams. If TCP transactions become more prevalent, the anycast architecture may require changes.

The point of view from the client side is worth mentioning. In certain client configurations, where firewalls are incorrectly configured[3], the following scenario can occur:

A resolver inside the misconfigured firewall receives a DNS request that it cannot satisfy locally. The query is sent to the root servers, usually over UDP, and a root server responds to this query with a referral, also over UDP. Today, this response fits nicely in 512 bytes. It is also true that for the past 6 years, the *Internet Systems Consortium* (ISC) has been anticipating DNSSEC and has shipped resolver code that, by default, requests DNSSEC data. After the root is signed, the response no longer fits into a 512-byte message. Estimates from the *National Institute of Standards and Technology* (NIST), using standard key lengths, indicate that DNSSEC will push the response to at least 2048 bytes or larger. This larger response will not be able to get past a misconfigured firewall that restricts DNS packets to 512 bytes, not recognizing the more modern extensions to the protocol that allow for bigger packets.

Upon not receiving the answer, the resolver on the inside will then retry the query, setting the buffer size to 512 bytes. The root will resend the response using smaller packets, but because it does not fit in a 512-byte packet, will fragment the response into a series of 512-byte replies, and the root server will set the "fragmented" and "truncated" flags in the packets, indicating to the resolver that the answer was fragmented and truncated, and encouraging the resolver to retry the query once more using TCP transport. The resolver will do so, and the root server will respond using TCP, but the misconfigured firewall also will reject DNS over TCP, because this transport has not been considered a normal or widely used transport for DNS queries.

In this worst case, a node will be unable to get DNS resolution after the root zone is signed, and the DNS traffic will triple, including one round in which TCP state must be maintained between the server and the resolver. There are of course ways around this problem, the most apparent ones being to configure the firewall correctly, or to configure the resolver to not ask for DNSSEC records.

Effect of IPv6 on Priming Queries

The basic DNS protocol specifies that clients, resolvers, and servers be capable of handling message sizes of at least 512 bytes. They may support larger message sizes, but are not required to do so.

The 512-byte "minimal maximum" was the original reason for having only nine root servers. In 1996 Bill Manning, Mark Kosters, and Paul Vixie presented a plan to Jon Postel to change the naming of the root name servers to take advantage of DNS label compression and allow the creation of four more authoritative name servers for the root zone. The outcome was the root name server convention as it stands today.

The use of 13 "letters" left a few unused bytes in the priming response, which were left there to allow for changes—which soon arrived. With the advent of IPv6 addressing for the root servers, it was no longer possible to include both an IPv4 "A" record and an IPv6 "AAAA" record for every root server in the priming response without truncation; AAAA records for only two servers could be included without exceeding the 512-byte limit. Fortunately the root system was able to rely on the practical circumstance that any node asking for IPv6 address information also supported *Extension Mechanisms for DNS* (EDNS0)[4].

DNSSEC also increases the size of the priming response, particularly because there are now more records in the Resource Record set and those records are larger. In [5] the authors make the following observation: "The resolver MAY choose to use DNSSEC OK[6], in which case it MUST announce and handle a message size of at least 1220 octets."

EDNS and MTU Considerations

The changes described will also affect other parts of the Internet, including (for example) end-system applications such as web browsers; intermediary "middleboxes" that perform traffic shaping, firewall, and caching functions; and *Internet Service Providers* (ISPs) that "manage" the DNS services provided to customers.

Although modern DNS server software defaults to using EDNS0, current measurement[7] collected from several of the RFC 1918[11] servers suggests that EDNS0 usage has not yet reached generally accepted levels of usefulness. Over the 12-month study, the ratio of ENDS0 queries received at these nodes remained at roughly 65 percent of the total queries received, with about 33 percent being non-EDNS queries. In the "other" camp are queries that set EDNS0 but then restrict packet sizes to 512 bytes. These queries cannot use the larger, negotiable *Maximum Transmission Unit* (MTU) sizes for larger UDP responses and therefore must use TCP to support larger responses. Some evidence suggests that with signed data, there is a pattern of retransmission of queries when responses larger than 512 bytes are generated and blocked. Such retransmissions can take as long as 7 seconds before timing out.

Lack of EDNS0 support in DNS caches suggests that many parts of the Internet will be constrained to using the traditional UDP sizes or will fall back to using TCP. Even where EDNS0 is indicated as being available, there are increased difficulties in knowing or negotiating a consistent *Path Maximum Transmission Unit* (Path MTU)[8].

The data supports an argument that the expectation of a useful UDP "jumbogram" or enough resources to manage hundreds of thousands or millions of TCP connections is unfounded because of historical expectations on "normal" DNS packet profiles. Clean, clear Internet paths that will allow larger packet sizes are rare, particularly when crossing the Internet. Locally, it is much more likely that larger packet sizes will be found and supported, raising the question for wide-scale deployment of IPv6 or DNSSEC because both attributes require larger packet sizes regardless of transport. If neither larger UDP packets nor TCP will be viable, what other choices are there?

Recent work inside the *Internet Engineering Task Force* (IETF) is exploring the use of the *Hypertext Transfer Protocol* (HTTP) as an alternative transport protocol for DNS messages.[9] It might be possible to augment the deployed DNS base to understand the addition of a third transport protocol.

The augmentation of the DNS protocol to support multiple transport protocols will require additional logic on the part of the servers to keep track of which transport a query was received on and select that transport when sending back the response. It will also require more complex logic to determine failover selection from one transport to another.

With the efforts going into making the infrastructure of the Internet IPv6-capable, it is possible that the underlying MTU problems may be corrected faster than adoption of a new transport protocol for the DNS. Certainly MTU problems have been considered for many years and for slightly different reasons[8] principally related to faster signaling rates and changes in the types of data being moved through the Internet. Regardless, this transition will take considerably more time than a simple DNS code refresh. Full support for larger packet sizes in the DNS will require changes in the equipment and code that comprise the baseline Internet infrastructure—and such changes may take decades.

Networking @ Home

by Geoff Huston, APNIC

One of the more interesting sessions at the *Internet Engineering Task Force* (IETF) meeting in Quebec City in July 2011 was the first meeting of the recently established *Homenet Working Group*[1]. What is so interesting about networking the home? Well, if you regard challenges as "interesting," then just about everything is interesting when you look at networking in the home!

It has been a very long time since the state of the art in home Internet involved plugging the serial port of the PC into the dialup modem. The *Asymmetric Digital Subscriber Line* (ADSL) modem, even when combined with some form of Wi-Fi base station, is looking distinctly passé these days. Today, the home network is seeing the intersection of a whole set of interests, including phone service, television service, home security services, energy management, utility service metering, other forms of home device monitoring, and, of course, connecting laptops and mobile devices to the net. The home network is not just a wired *Local-Area Network* (LAN), Wi-Fi home networks are commonplace, and there are also various Bluetooth devices. Maybe sometime soon it will be common for the home network to host some form of *Third-Generation* (3G) femtocell mobile cell phone repeater as well. But these days even that level of network complexity is not enough. Increasingly, the home office is part of the work office, and if numerous residents are at home, then the home network may be an endpoint for several corporate and institutional *Virtual Private Networks* (VPNs)[2].

Within the home network we want sophisticated security. This security involves not just protecting the network from the neighbors; the security requirements include the ability for individuals to partition off their work-VPN part of the home network from other home users. For resiliency we might want a second network provider, so we might want to add site-based multihoming to the mix. And we need to make all this work for both IPv4 and IPv6.

That set of requirements represents a massive agenda. But to make this situation truly challenging, we cannot expect every home to come with an IT Operational Service Manager to ensure that all the various devices you bring into the home and connect to the network function as required for the particular requirements of the home. Indeed, we cannot expect any home to be so lavishly supported, nor can we afford to support home networking with a bevy of specialized call centers with on-demand support specialists, expert in the panoply of consumer devices that are being sold today.

With today's home networks, consumers are effectively on their own; and all this equipment better just work straight out of the box. No configuration, no buttons, it just has to work!

Routing @ Home

The evolution of networking at home has progressed from a single computer to a basic LAN, and from there to an Ethernet-bridged network with numerous Wi-Fi and wired LAN segments. All these environments have a single common architecture with a single "boundary" unit that acts as a point of demarcation between the *Internet Service Provider* (ISP) and the home network. This unit is generally called *Customer Premises Equipment* (CPE), and typically encompasses the functions of a modem; an IPv4 *Network Address Translator* (NAT); a *Dynamic Host Configuration Protocol* (DHCP) server for both IPv4 and IPv6; as well as security firewall, bridge, and rudimentary router functions.

But it is unrealistic to assume that home networks will continue to use a centralized model that places all of the management functions of the home network in a single unit. So how should we view home networks? Should home networks be a single bridged LAN, or are we seeing the evolution of home networks into multiple distinct domains with a routing fabric to glue them together? And if that is the case, what routing protocol should be used?

I have noticed in the low end of the CPE market it is not uncommon to see a rudimentary routing function supported by the *Routing Information Protocol* (RIP)[3]. Thankfully, it is RIP Version 2, so the routing protocol can be configured with variable-length subnet masks, but even so, RIP is a very basic and simple routing protocol. But perhaps in this environment, that might be a positive factor rather than a liability in so far as RIP is simple enough to be autoconfigurable. On the other hand, if there is an emergent need for more complex functions, then maybe we need to look a little harder at the available options.

One of these more complex functions is *subnet management*. In IPv6, the CPE will collect an IPv6 address prefix. This process differs from the conventional IPv4 environment where the CPE is typically assigned a single IPv4 address. So the ensuing question is: Is it possible to automate the distribution of IPv6 subnets across the entire home network? What form of management protocol is appropriate for this role?

Of course the situation gets much more complicated if the home network has two (or more) service providers. In the IPv6 environment, this task becomes a challenging one, not only with the distribution of multiple subnets across the home network, but also in the matter of exit path selection. If the home network is exercising due diligence to prevent source address spoofing, it is also necessary for the home routing infrastructure to deliver an outgoing packet to the "right" exit ISP, where the source address of the outgoing packet needs to match the address prefix provided by the corresponding ISP service. In other words, there is a requirement for source address routing in the home.

This challenge was not really addressed by the *Site Multi-Homing by IPv6 Intermediation Working Group* (SHIM6)[4], despite the best of intentions, and it represents an even greater challenge if the intent is to provide mechanisms that can achieve such routing in an unmanaged home network environment.

I must admit to some concern here. We have managed to keep Internet routing working by using two principles. The first is to try to keep the routing task as simple as possible. Routing propagates a single "best" path to a destination. It does not necessarily do this propagation quickly, nor necessarily does it carry around with it a whole set of alternatives. It does just one job. The second principle is to admit that we have never really succeeded with the first principle of functional simplicity and we have always had expertise at hand to oversee the routing function and apply manual patches as required. The specialized requirements for the home network appear to be breaking both principles. The requirements are certainly not simple, and I see a mix of routing techniques—including various forms of policy-based routing requirements—entering the discussion. Secondly, there is no assurance that if things fail expertise is at hand to mend the failure. Indeed, the more complex the routing environment, the greater the potential for complex forms of failure. As we contemplate ever more complex requirements in the home network, we face a greater risk of encountering failure "by design," where it is just not possible to design products for this environment that will "just work."

Names @ Home

What should I call my printer? More to the point, how should I identify my Wi-Fi printer to all those devices at home that want to use it to print? I am sure that I would not like to use a proprietary naming scheme that requires me to add additional name resolution software to every device at home that wants to print something, nor do I want to transcribe IP addresses into everything. I would like my printer to get dynamically assigned IPv4 and IPv6 addresses when the device is plugged in and switched on, and have the name of the printer published via a generic name resolution mechanism, namely the *Domain Name System* (DNS).

But most of the time the rest of the world has no need to know the name of my printer at home, and I am not sure that it is a good move, securitywise, to gratuitously publish information in the public DNS. So what I would like for my printer is some form of "local" or "scoped" DNS, where I can name my printers, my disk servers, and other devices that I have at home in the context of my home and not have this information leak further afield. Is this scoped form of name resolution, split horizon DNS, or split views, possible in the context of the DNS without invoking further elements of configuration management?

Multicast DNS (mDNS) is perhaps one of the strongest candidates for this role. In essence, mDNS replaces the explicit client-server structure of the DNS with a scoped name subdomain of `.local` that is inherently scoped to the associated multicast domain.

This setup allows a client to perform DNS-like name resolution functions on a local network without the need to configure a conventional DNS server environment, and without the need to obtain global delegation of a site name in the global DNS.

An alternative approach is to use a conventional DNS delegation and conventional unicast DNS queries and responses. Clients are able to use DNS *Dynamic Updates*[5] to provide the local DNS server with their details as they come online. This approach requires either open access from anyone to the nameserver or a security mechanism such as *Transaction SIGnature* (TSIG)[6]. TSIG generally requires manual configuration, and alternatives are either little used—such as *Transaction KEY* (TKEY)[7]—or involve further intricacies, such as Microsoft's *Active Directory,* which uses other user authentication mechanisms to bootstrap the TSIG part using the *Generic Security Service Algorithm for Secret Key Transaction* (GSS-TSIG)[8]. The DNS server itself can be advertised to all clients via the *Simple Service Discovery Protocol* (SSDP), as part of the larger *Universal Plug and Play* (UPnP) framework.

Sensing and Serving @ Home

Where to go from here? It is certainly the case that electronics has managed to pervade just about every device at home. Electricity meters are morphing into household energy-management systems, and many other household appliances are now controlled by internal processors. But individually configuring each of these devices is a forbidding task. Even adding an interface to allow manual configuration can often be a challenging objective.

The objective here is to define a standard mechanism to allow sensors to sense their local environment when powered up, obtain an IP address, advertise their existence and capabilities to the network, and, as appropriate, rendezvous with the sensor controller or controllers across the home network.

This example is another instance of a more generic class of automating the installation and use of services in "lightly" managed or even unmanaged networks, and it intersects significantly with the objectives encompassed with SSDP and UPnP. The potential volume of such devices places this example more squarely into a class of IPv6-only services, I suspect, which is a significant extension to the existing IPv4-centric UPnP frameworks.

What is needed is a bootstrap protocol that can provide a connecting device with:

- Address configuration
- Routing setup
- Name management and name server discovery
- Discovery of other services and controllers
- Security capabilities

Security @ Home

One of the most significant concerns with home networks lies in the area of security management. Host computers in a home network often want to place a very high level of implicit trust in their immediate network neighbors at the same home. It is not unusual for hosts in a home network to share printers, file servers, data, and even user profiles. Indeed, it is probably commonplace. But beyond this local security domain a host should become paranoid and treat all connection attempts with suspicion. But where does the local trust domain start and stop? What is the "local" security boundary?

This question is difficult to answer in an automated fashion. It is no longer the local LAN, particularly as home networks transition into routed networks. The security boundary is related to the local multicast scope, but this supposition assumes that it is possible to define a multicast scope that encompasses the local trust domain of the home network, and this assumption brings us back to the same question.

Even if you thought you might have a clean answer to the boundary question, you need to remind yourself about telecommuting. With telecommuting, there is a requirement to partition out an entire local network segment from the rest of the home environment and the home security domain and transplant it into the work security domain.

Everything @ Home

Home is certainly the new field of engagement for networked goods and services. However, it is one of the most challenging places to operate in from the perspective of attempting to deliver coherent services in a reliable and secure manner. The components are sourced from various vendors, and constructed incrementally over extended periods of time. It is an environment where older components need to coexist with new devices, and the overall engineering of the environment is at best piecemeal, and perhaps more often not engineered at all. In this environment out-of-the-box interoperability is of paramount importance, and therefore it is an environment where good standards really matter. Perhaps unsurprisingly, given these constraints, networking in the home is one of the environments that appear to raise the most challenges. It is an unforgiving environment where there is no real substitute for simplicity and reliability in a "plug-and-play" world.

The IETF Homenet Working Group has a lot of work to do. The Working Group will have to examine the diverse set of approaches in use today, add IPv6 functions, and produce a coherent set of outcomes in the form of standards that support robust, capable home networks that work in an unmanaged environment.

Ahhh home! There really is no place quite like it!

IETF Tools—Making It Easier to Make the Internet Work Better

by Robert Sparks

Many activities are associated with defining and refining an *Internet Engineering Task Force* (IETF) protocol, and all of them are detail-oriented. As IETF Working Groups are formed, mailing list discussions proceed, documents are written and reviewed, and interoperability is evaluated, participants encounter tasks that can be significantly simplified with the help of software tools. Fortunately, those participants frequently are also skilled software developers, and they create and share these tools as the need arises. A new paradigm has evolved recently: When a pressing need for a tool is identified—particularly one that has a large scope—the *IETF Administrative Oversight Committee* (IAOC) accelerates the creation of the tool by working with the community to gather requirements and financing the development of a solution. Comprehensive lists of available tools are maintained at [1] and at [2]. This article introduces a few important tools and discusses how you can help improve them or develop new ones.

Document Tools

The *Extensible Markup Language to Request For Comments* (XML2RFC)[0] tool was developed to assist with Internet-Draft composition. Marshall Rose created and maintained the initial versions, capturing its input language and operation instructions in RFC 2629[18]. This tool simplifies draft creation and maintenance by automatically producing documents that satisfy the RFC Editor's layout requirements, and assists in including the appropriate boilerplate as defined by the *IETF Trust*. It also simplifies the task of the *RFC Production Center*[19, 20]. Starting with XML input rather than a draft in text form reduces the work required to create the RFC. The IAOC is currently funding a reimplementation of XML2RFC to reflect many years of user feedback, simplify maintenance—particularly of boilerplate handling—and make it easier for volunteers to contribute improvements. This reimplementation is currently available at [3]. Tony Hansen has been very active in gathering the requirements for and evaluating the reimplemented version. Julian Reschke also maintains *Extensible Stylesheet Language Transformations* (XSLT) code at [4] that translates RFC 2629-based input into several output formats.

After a new draft is prepared, Henrik Levkowetz' *Internet-Draft Nit Checker* (idnits) tool at [5] can scan it for any problems with the RFC Editor's checklist and guidelines and for other problems that drafts frequently encounter later in review. There are also tools for verifying sections of the document containing formal languages such as *Augmented Backus-Naur Form* (ABNF) or XML.

When an editor is satisfied that the document is ready to place in the repository, the automated *ID Submission tool*[6] assists with an easy upload. At any point two versions of a draft can be compared with *rfcdiff*[7], a flexible comparison program created by Henrik Levkowetz.

As a draft progresses, its history and current status can be tracked using the *Internet-Drafts Tracker* (ID Tracker) tool[8]. This tool provides powerful search capabilities into the entire Internet-Draft repository, and a comprehensive view into the lifecycle of each Internet-Draft. With its roots in a tool to help the *Internet Engineering Steering Group* (IESG) keep track of drafts in IESG evaluation, the ID Tracker has evolved into a portal touching almost all aspects of IETF work. Each step of that evolution has improved efficiency and transparency, and has simplified access to the history of the development of each document.

Recent additions to the tracker allow for an easier capture of the details of Working Group processing. *Work in progress* will provide more visibility into the Working Group chartering and rechartering processes. The tracker is also used by other document streams. Many of the enhancements to the tracker are informed by the views into documents and Working Groups maintained by Henrik Levkowetz at [2]. The tracker continues to evolve through both IAOC-funded development efforts and volunteer contributions. An extension in progress will add visibility into the RFC Editor and *Internet Assigned Numbers Authority* (IANA) actions. When this extension is done the entire lifecycle of a Draft, from -00 submission to RFC publication, can be viewed in a single place.

Working Group and Meeting Tools

At each IETF meeting, a participant can build a custom view of the agenda using the tools at the datatracker and the tools sites. For example, [9] renders an interactive JavaScript-based calendar contributed by Adam Roach showing the *Real-Time Applications and Infrastructure* (RAI) meetings at IETF82. The pages at [10] provide a quick reference to the jabber rooms and audio streams of each Working Group meeting. The meeting materials tool facilitates uploading of agendas, slides, and minutes, which become available immediately through the agenda views.

Each Working Group has a Subversion Repository and an integrated instance of Trac[21] at its disposal. The Subversion Repository can be used to maintain Working Group draft source, versioned instances of test documents, and even implementation code. IETF-specific customizations of the Trac system are described at [11]. Many Working Groups are already taking advantage of what the wiki Trac provides, and are using its ticketing feature to effectively track major Working Group document problems.

Notable examples are the problem tracking integrated into the *Hypertext Transfer Protocol Bis* (HTTPBIS) document status page at [12], and the summary of DISPATCH activity at [13]. The Trac wiki capability is also used by the Working Group Chairs at [14] and the IESG at [15].

IETF News

Keeping up with all of the activity across the IETF can be a challenge. One of the better tools for seeing what is happening is *The Daily Dose of the IETF*, created by Pasi Eronen, available at [16].

Again, this article is an introduction to just a few important tools. Comprehensive lists of available tools are maintained at [1] and [2].

Many of these tools were created because a person who needed them coded an initial version and contributed it to the community. Volunteers (and when needed, IAOC-funded efforts) then improve these tools over time. For several years, a group of volunteers have been meeting the Saturday before each IETF meeting for a day-long *Code Sprint*. If the existing tools need a minor tweak to make things work much better for you, or if you have an idea for a new tool you would like to start, please consider participating at the next Code Sprint. Between sprints, you can still help with the code. Refer to the sprint pages for an upcoming or recent sprint such as [17] and for information about getting started.

Whether or not you can contribute to the code, please discuss your ideas on the **tools-discuss@ietf.org** mailing list.

Several tool contributers have already been mentioned. Henrik Levkowetz deserves to be mentioned again. His herculean efforts maintaining **tools.ietf.org** and creating many of the tools there are of great benefit to the community.

Professor Kilnam Chon Receives 2011 Postel Service Award

The *Internet Society* (ISOC) recently announced that its prestigious *Jonathan B. Postel Service Award* was presented to leading technologist Professor Kilnam Chon for his significant contributions in the development and advancement of the Internet in Asia.

Professor Chon contributed to the Internet's growth in Asia through his extensive work in advancing Internet initiatives, research, and development. In addition, his pioneering work inspired many others to promote the Internet's further growth in the region. The international award committee, comprised of former Jonathan B. Postel award winners, noted that Professor Chon was active in connecting Asia, and that his efforts continue today in the advancement of the Internet in other regions.

The Postel Award was established by the Internet Society to honour individuals or organisations that, like Jon Postel, have made outstanding contributions in service to the data communications community.

Lynn St. Amour, President and CEO of ISOC, commented, "I met Professor Chon nearly fifteen years ago. He has long been a pioneer in the advancement of the Internet, striving to ensure its robust development. Beyond the amazing breadth of Professor Chon's work, perhaps his most remarkable achievement is his ability to inspire others. As a result of his work and the efforts of those he has motivated, Kilnam Chon has helped to ensure the global Internet is truly for everyone."

ISOC presented the award, including a US$20,000 honorarium and a crystal engraved globe, during the 82nd meeting of the *Internet Engineering Task Force* (IETF) in Taipei, November 13–18, 2011.

The Internet Society is the world's trusted independent source of leadership for Internet policy, technology standards and future development. Based on its principled vision and substantial technological foundation, ISOC works with its members and Chapters around the world to promote the continued evolution and growth of the open Internet through dialog among companies, governments, and other organizations around the world. For more information about the Postel Service Award see: `http://www.isoc.org/postel/`

Alexandre Cassen and Rémi Després Receives 2011 Itojun Service Award

The third *Itojun Service Award* was presented to Alexandre Cassen and Rémi Després at the *Internet Engineering Task Force* (IETF) meeting held in Taipei, Taiwan in November 2011. The awardees were recognized for their design and implementation of "6rd," an IETF protocol that aims to speed the transition to global deployment of IPv6, which is critical to ensuring the continued growth and evolution of the Internet.

The 6rd protocol has been implemented by several *Internet Service Providers* (ISPs) around the world, including *Free Telecom*—the second largest ISP in France—as part of their efforts to deploy IPv6.

First awarded in 2009, the Itojun Service Award honors the memory of Dr. Jun-ichiro "Itojun" Hagino, who passed away in 2007 at the age of 37. The award, established by the friends of Itojun and administered by the *Internet Society* (ISOC), recognizes and commemorates the extraordinary dedication exercised by Itojun over the course of IPv6 development.

"Alexandre and Rémi's efforts have helped to quickly bring a real IPv6 experience to hundreds of thousands of Internet users, demonstrating that IPv6 deployment can be effectively implemented on a large scale by commercial network providers," said Jun Murai of the Itojun Service Award committee and founder of the WIDE Project. "On behalf of the Itojun Service Award committee, I am extremely pleased to present this award to Alexandre and Rémi for the significant work they have done to advance IPv6 development and deployment."

The Itojun Service Award is focused on pragmatic contributions to developing and deploying IPv6 in the spirit of serving the Internet. The award, presented annually, includes a presentation crystal, a US$3,000 honorarium and a travel grant.

Alexandre Cassen said, "It is truly an honor to have been selected to receive the Itojun Service Award. As a software developer myself, It is particularly touching to receive an award created in the memory of a coding legend such as Itojun. I would also like to thank the entire team at Free Telecom who, in 2007, implemented and deployed 6rd, allowing any subscriber who asked for IPv6 to have it with a single click. As I write this, Free Telecom has more than 1,500,000 subscribers using IPv6 every day, and all new subscribers have IPv6 enabled by default. IPv6 is happening Itojun!"

Rémi Després said, "The Itojun Award is the best possible recognition that long efforts to make IPv6 deployment practicable have been useful to the Internet community. Latecomer in IPv6 standardization, I was about to send my first email to Itojun on a technical issue when I heard of his death. I was even sadder since we undoubtedly would have otherwise enjoyed sharing our ideas and our enthusiasm. Sharing the honor of this award with Alexandre Cassen perfectly illustrates the great progress possible when a dynamic network operator with a pioneer spirit and talented engineers adopts an innovative and simple design. Making IPv6 operational on a large scale in only five weeks will be remembered as a milestone of both of our professional lives."

More information on the Itojun Service Award is available at:
http://www.isoc.org/itojun

Internet Society Joins Opposition to Stop Online Piracy Act

The Internet Society Board of Trustees has expressed concern with a number of U.S. legislative proposals that would mandate *Domain Name System* (DNS) blocking and filtering by *Internet Service Providers* (ISPs) to protect the interests of copyright holders. While the Internet Society agrees that combating illicit online activity is an important public policy objective, these critical issues must be addressed in ways that do not undermine the viability of the Internet as a platform for innovation across all industries by compromising its global architecture. The Internet Society Board of Trustees does not believe that the *Protect-IP Act* (PIPA) and *Stop Online Piracy Act* (SOPA) are consistent with these basic principles.

Specifically, the Internet Society is concerned with provisions in both bills regarding DNS filtering. DNS filtering is often proposed as a way to block illegal content consumption by end users. Yet policies to mandate DNS filtering will be ineffective for that purpose and will interfere with cross-border data flows and services undermining innovation and social development across the globe.

Filtering DNS or blocking domain names does not remove the illegal content—it simply makes the content harder to find. Those who are determined to download filtered content can easily use a number of widely available, legitimately-purposed tools to circumvent DNS filtering regimes. As a result, DNS filtering encourages the creation of alternative, non-standard DNS systems.

From a security perspective, DNS filtering is incompatible with an important security technology called *Domain Name System Security Extensions* (DNSSEC). In fact, DNSSEC would be weakened by these proposals. This means that the DNS filtering proposals in SOPA and PIPA could ultimately reduce global Internet security, introduce new vulnerabilities, and put individual users at risk.

Most worrisome, DNS filtering and blocking raises human rights and freedom of expression concerns, and often curtails international principles of rule of law and due process. Some countries have used DNS filtering and blocking as a way to restrict access to the global Internet and to curb free expression.

The United States has been a strong proponent of online Internet freedoms and therefore has an important responsibility to balance local responsibilities and global impact, especially with respect to Internet policy. Given this commitment to global Internet freedom, it would be harmful to the global Internet if the United States were to implement such an approach.

"The Internet Society Board of Trustees is deeply concerned about the ramifications of the PIPA and SOPA bills on the overall stability and interoperability of the Internet," said Raul Echeberria, Chairman of the Internet Society Board of Trustees.

"The Board recognizes that there can be misuses of the Internet; however, these are greatly outweighed by the positive uses and benefits of the Internet. We believe the negative impact of using solutions such as DNS blocking and filtering to address these misuses, far outweighs any short-term legal or business benefits."

"The Internet Society believes that sustained, global collaboration amongst all parties is needed to find ways that protect the global architecture of the Internet while combating illicit online activities," said Internet Society President and CEO Lynn St. Amour. "Mandating DNS blocking and filtering is simply not a viable option for the future of the Internet. We must all work together to support the principles of innovation and freedom of expression upon which the Internet was founded."

For more details on DNS Filtering, visit:
`http://www.isoc.org/internet/issues/dns.shtml`

APNIC and JPRS Collaborate to Translate DNSSEC Technology Experiment Report

The *Asia Pacific Network Information Centre* (APNIC) has collaborated with *Japan Registry Services* (JPRS) to translate from Japanese into English the documents "DNSSEC Technology Experiment Report – Verification of Functionality and Performance" and "DNSSEC Technology Experiment Report – Operational Design."

These documents contain the latest information on *Domain Name System Security Extensions* (DNSSEC) implementation, and provides information to those interested in implementing it. These reports are designed to introduce case studies to share knowledge and results gained through experiments conducted in 2010 that JPRS carried out in cooperation with Japanese ISPs, equipment vendors, and hosting providers.

APNIC would like to thank JPRS's great initiative and all those involved in the process for making such an important contribution to DNSSEC awareness. APNIC also appreciates JPRS for making the documents available in English for wider distribution. The reports are available for download from:

`http://jprs.jp/dnssec/doc/DNSSEC-testbed-report-fpv1.0-E.pdf`

and

`http://jprs.jp/dnssec/doc/DNSSEC-testbed-report-odv1.0-E.pdf`

RFC Series Editor Appointment

The *Internet Architecture Board* (IAB) is pleased to announce the appointment of Heather Flanagan as the *Request For Comments Series Editor* (RSE). Ms. Flanagan will assume the responsibilities from the Acting RSE, Olaf Kolkman, and begin her tenure on January 1, 2012. The contract negotiated by the *IETF Administrative Oversight Committee* (IAOC) includes an initial term of two years and a presumptive renewal of two years.

Ms. Flanagan was selected by the *RFC Series Oversight Committee* (RSOC) based upon her experience, education, skills and energy she will bring to the position.

Ms. Flanagan is currently the Project Coordinator for the *COmanage* project, an effort funded by a grant from the *National Science Foundation* (NSF) and Internet2 to create a collaboration management platform, prior to that she was Director of Systems Administration, IT Services at Stanford University in Palo Alto, California. Her technical background is complemented by a Masters of Science of Library Science from the University of North Carolina, Chapel Hill that will prove invaluable in the accessing and indexing of RFCs.

Ms. Flanagan brings a high degree of energy and enthusiasm to the position. Her interpersonal skills as a facilitator and good listener will enable her to work well with the capable staff at the RFC Production Center and with the community in reaching consensus on a variety of issues facing the RFC Series.

The RSOC selection followed a lengthy process that included announcing the position inside and outside the community, several rounds of interviews, reference checks, and face-to-face interviews in Taipei at IETF 82. More than thirty-five applications were received, two-thirds of which were from outside the community.

We express our congratulations to Ms. Flanagan. We also want to extend our thanks to Ray Pelletier and the RSOC chaired by Fred Baker for their role in bringing the RSE selection process to a successful conclusion; to Olaf Kolkman for his service to the community as Acting RSE; to Joel Halpern for his ongoing work as editor of the "RFC Editor Model v2" document; and to the RFC Production Center for its customary diligence in the editing and publishing of RFCs this year, likely the second most productive in RFC publication history.

We look forward to working with the new RSE; we wish her well; and know that the community will work with Heather for the betterment of the RFC Series.

—For the IAB
Bernard Aboba, IAB Chair

2011 Global IPv6 Survey Results

On October 20, 2011 the *Number Resource Organization* (NRO) announced the publication of the "Global IPv6 Deployment Monitoring Survey 2011 Results," initially previewed at the *Internet Governance Forum* (IGF) in Nairobi, Kenya, in September.

The findings from the survey drew on data supplied by around 1,600 international respondents, over 350 of which were from the *American Registry for Internet Numbers* (ARIN) region. On behalf of ARIN and GNKS Consulting, we would like to thank all who participated in the survey. Your feedback is crucial to expanding the understanding of where this community is moving, and what can be done to ensure readiness for the widespread adoption of IPv6. We hope you will take this opportunity to review the results at: **http://www.nro.net/wp-content/uploads/ipv6_deployment_survey.pdf**

The Public Switched Telephone Network in Transition

The United States *Federal Communications Commission* (FCC) recently held two workshops to examine the transition from the *Public Switched Telephone Network* (PSTN) to new technologies. Circuit-switched wireline voice technology has created a high standard for reliability, accessibility, and ubiquity. Consumers will continue to expect and demand these qualities, even as they shift from PSTN services to services provided over different networks. The transition away from the PSTN is already occurring, and is likely to accelerate. Through these workshops, the Commission will seek input on the technical, economic, and policy issues that must be addressed to minimize disruption during this transition, and to protect consumers, public safety, competition, and other important interests. For more information, visit: **http://www.fcc.gov/events/public-switched-telephone-network-transition-0**

Upcoming Events

The *North American Network Operators' Group* (NANOG) will meet in San Diegeo, California, February 5–8, 2012. For more information see: **http://nanog.org**

The *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT) will meet in New Delhi, India, February 21–March 2, 2012. For more information see:
http://www.apricot2012.net/

The *Internet Engineering Task Force* (IETF) will meet in Paris, France, March 25–30, 2012. For more information see:
http://www.ietf.org/meeting/

The *Internet Corporation for Assigned Names and Numbers* (ICANN) will meet in San Jose, Costa Rica, March 11–16, 2012 and in Prague, Czech Republic, June 24–29, 2012. For more information, see: **http://icann.org/**

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ contains standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

ISSN 1944-1134

From The Editor

Internet security continues to receive much attention both in the media and within the *Internet Engineering Task Force* (IETF) and similar organizations that develop technical solutions and standards. Last September, someone managed to break into a trusted *Certification Authority*'s system and subsequently produced numerous fake *digital certificates,* files that comprise part of the architecture for what is generally referred to as "browser security." In our first article, Geoff Huston describes what happened, the implications of this form of attack on the security of web-based services on the Internet, and what can be done to prevent similar attacks in the future.

In our second article, Richard Barnes describes the work of the *DNS-based Authentication of Named Entities* (DANE) working group in the IETF and explains how DANE, when deployed, can help prevent the sort of attack that is described in our first article.

This year I am celebrating 25 years in Internet technical publishing. Prior to launching *The Internet Protocol Journal* (IPJ), I was the editor of *ConneXions—The Interoperability Report,* published from 1987 until 1997 by Interop Company. With the generous support of *The Charles Babbage Institute* at the University of Minnesota, *ConneXions,* which was a paper-only publication, has been scanned and made available online. To mark the 25 combined years of *ConneXions* and IPJ, we asked Geoff Huston to examine the state of computer communications 25 years ago and give us his thoughts on where we have been and where we might be going in this rapidly developing technology landscape.

Please remember to check your subscription expiration date and take the necessary steps if you wish to continue receiving this journal. You will need your subscription ID and the e-mail address you used when you subscribed in order to access your record and renew online. Visit the IPJ website at **www.cisco.com/ipj** and click on the "Subscriber Services" link to get to the login page. The system will send you a URL that allows direct access to your record. If you no longer have access to the e-mail you used when you subscribed or you have forgotten your subscription ID, just send a message to **ipj@cisco.com** and we will make the necessary changes for you.

Hacking Away at Internet Security

by Geoff Huston, APNIC

The front page story of the September 13, 2011, issue of the *International Herald Tribune* said it all: "Iranian activists feel the chill as hacker taps into e-mails." The news story relates how a hacker has "... sneaked into the computer systems of a security firm on the outskirts of Amsterdam" and then "... created credentials that could allow someone to spy on Internet connections that appeared to be secure." According to this news report, the incident punched a hole in an online security mechanism that is trusted by hundreds of millions of Internet users all over the network.

Other news stories took this hyperbole about digital crime and tapping into e-mail conversations on the Internet to new heights, such as *The Guardian's* report on September 5, 2011, which claimed that the "... DigiNotar SSL certificate hack amounts to cyberwar, says expert."[1]

If application-level security is so vulnerable to attack, then this incident surely calls into question the basic mechanisms of trust and security upon which the entire global Internet has been constructed. By implication it also calls into question the trustworthiness of services operated by the major global Internet brands such as Google and Facebook, as much as it raises doubts about the levels of vulnerability for the use of online services such as banking and commercial transactions.

Just how serious is this problem? Are we now at the end of civilization as we know it?

Well, hardly!

Is digital cryptography now broken? Has someone finally managed to devise a computationally viable algorithm to perform prime factorization of massively large numbers, which lies at the heart of much of the cryptography used in the Internet today?

I really don't think so. (At the very least, if someone has managed to achieve this goal, then that person is staying very quiet about it.).

Does this situation represent a systematic failure of security? Do we need to rethink the entire framework of cryptography and security in the Internet?

Not this time.

As far as I can tell, there has been no dramatic failure in the integrity of the digital technology used for security in the Internet today. Yes, some were surprised by this failure, including the Netherlands government, which uses certificates issued by the compromised certification authority, DigiNotar (`http://www.diginotar.com`) as part of its online service infrastructure. But the hacking incident was not based on a successful direct attack on the technology of cryptography by itself, and there is no reason to suppose that the strength of today's encryption algorithms is any weaker today than yesterday.

But in observing that the basic technology tools of the Internet security framework are still operating within acceptable bounds of integrity, and observing that this hacking attack did not create a gaping hole in our commitment to digital cryptography, what cannot be claimed is that the use of these cryptographic tools in today's Internet service environment is similarly trustworthy. The hacking attempt apparently was successful in so far as it provided the capability for third parties to impersonate trusted services and thereby capture users' private data, and evidently some people did indeed do precisely that, and that is not good at all.

Let's look a little more closely at this hacking episode and examine the way in which security is applied to the world of web browsing and the manner in which the vulnerabilities in this security framework were evidently exploited.

Securing a Connection

When I point my browser at my online banking service—or at any other secure website for that matter—a part of the browser navigation bar probably glows a reassuring green, and when I click it I get the message that I am connected to a website run by the Acme Banking corporation, and that my connection to this website has been encrypted to prevent eavesdropping. However, the website *certificate* was issued by some company that I have never even heard of. When I ask for more information, I am told the domain name, the company to whom the certificate for this domain name was issued, the identity of the certificate issuer, and the public key value. I am also reassuringly informed that the message I am viewing was encrypted before being transmitted over the Internet, and that this encryption makes it very difficult for unauthorized people to view information travelling between computers, and it is therefore very unlikely that anyone could read this page as it passes through the network. All very reassuring, and for the most part true, to the extent that we understand the strength of cryptographic algorithms in use today. The connection is using a *Transport-Layer Security* (TLS)[2] connection and the traffic is encrypted using a private session key that should be impenetrable to all potential eavesdroppers.

But that is not the entire truth, unfortunately.

It may well be that your conversation is secure against eavesdropping, but it is only as secure as the ability of the other party to keep its private key a secret. If the other side of the conversation were to openly broadcast the value of its private key, then the entire encryption exercise is somewhat useless. So, obviously, my local bank will go to great lengths to keep its private key value a secret, and I rely on its efforts in order to protect my conversations with the bank.

But even then it is not quite the full story.

Am I really talking to my bank? Or in more general terms, am I really talking to the party with whom I wanted to talk?

The critical weakness in this entire framework of security is that the binding of certificates and keys to *Domain Name System* (DNS) names is not an intrinsic part of the DNS itself. It is not an extension of *Domain Name System Security Extensions* (DNSSEC)[3, 4]. It has been implemented as an add-on module where third parties generate certificates that attest that someone has a particular domain name. Oddly enough, these *Certification Authorities* (CAs) may never have actually issued that particular domain name, because they are often disconnected from the DNS name registration business. Their business is a separate business activity where, after you have paid your money to a domain name registrar and secured your domain name, you then head to a domain name Certification Authority and pay them money (commonly they charge more money than the name registration itself) and receive a domain name certificate.

Certification Authorities

Who gets to be a Certification Authority? Who gets to say who has which domain name and what keys should be associated with that domain name?

Oddly enough the answer is, at a first level of approximation, just about anyone who wants to! I could issue a certificate to state that you have the domain name **`www.example.com`** and that your public key value is some number. The certificate I issue to that effect would not be much different from the certificates issued by everyone else. Yes, my name would be listed as the certificate issuer, but that is about all in terms of the difference between this certificate and the set of certificates you already trust through your browser.

So what is stopping everyone from being a Certification Authority? What is preventing this system from descending into a chaotic environment with thousands of certificate issuers?

For this situation the browser software folks (and other application developers of secure services) have developed a solution. In practice it requires a lot of effort, capability, diligence, and needless to say, some money, to convince a browser to add your Certification Authority public key to its list of trusted Certification Authorities.

You have to convince the browser developers that you are consistently diligent in ensuring that you issue certificates only to the "correct" holders of domain names and that you undertake certificate management practices to the specified level of integrity and trust. In other words, you have to demonstrate that you are trustworthy and perform your role with consistent integrity at all times. You then get listed with all the other trusted Certification Authorities in the browser, and users will implicitly trust the certificates you issue as part of the security framework of the Internet.

How many trusted Certification Authorities are there? How many entities have managed to convince browser manufacturers that they are eminently trustable people? If you are thinking that this role is a special one that only a very select and suitably *small* number of folks who merit such absolute levels of trust should undertake for the global Internet—maybe two or three such people—then, sadly, you are very much mistaken.

Look at your browser in the preferences area for your list of trusted Certification Authorities, and keep your finger near the scroll button, because you will have to scroll through numerous such entities. My browser contains around 80 such entities, including one government ("Japanese Government"), a PC manufacturer ("Dell Inc"), numerous telcos, and a few dedicated certificate issuers, including DigiNotar.

Do I know all these folks that I am meant to trust? Of course not! Can I tell if any of these organizations are issuing rogue certificates, deliberately—or far more likely—inadvertently? Of course not!

The structural weakness in this system is that a client does not know *which* Certification Authority—or even which duly delegated subordinate entity of a Certification Authority—was used to issue the "genuine" DNS certificate. When a client receives a certificate as part of the TLS initialization process, then as long as any one of the listed trusted Certification Authorities is able to validate the presented certificate, even if it is the "wrong" Certification Authority, then the client will proceed with the session with the assumption that the session is being set up with the genuine destination.

In other words the entire certification setup is only as strong—or as weak—as the weakest of the certification authorities. It really does not matter to the system as a whole if any single Certification Authority is "better" at its task than the others, because every certified domain name is protected only to the extent that the "weakest" or most vulnerable trusted Certification Authority is capable of resisting malicious attack and subversion of its function. Indeed, one could argue that there is scant motivation for any trusted Certification Authority to spend significantly more money to be "better" than the others, given that its clients are still as vulnerable as all the other clients of all the other Certification Authorities.

In other words, there is no overt motivation for market differentiation based on functional excellence, so all certificates are only as strong as the weakest of all the Certification Authorities. And therein lies the seed of this particular hacking episode.

The Hack

The hack itself now appears to have been just another instance of an online break-in to a web server. The web server in question was evidently running the service platform for DigiNotar, and the hacker was able to mint some 344 fraudulent certificates, where the subject of the certificate was valid, but the public key was created by the hacker. A full report of the hacking incident was published by Fox-IT[5].

To use these fraudulent certificates in an attack requires a little more than just minting fraudulent certificates. It requires traffic to be redirected to a rogue website that impersonates the webpage that is under attack. This redirection requires collusion with a service provider to redirect client traffic to the rogue site, or a second attack, this time on the Internet routing system, in order to perform the traffic redirection.

So minting the fraudulent certificates is just one part of the attack. Were these fake certificates used to lure victims to fake websites and eavesdrop on conversations between web servers and their clients? Let's look at the client's validation process to see if we can answer this question.

When starting a TLS session, the server presents the client with a certificate that contains the server public key. The client is expected to validate this certificate against the client's locally held set of public keys that are associated with trusted certification authorities. Here is the first vulnerability. The client is looking for any locally cached trusted key to validate this certificate. The client is not looking as to whether a particular public key validates this certificate. Let's say that I have a valid certificate issued by the Trusted Certification Authority Inc. for my domain name, **`www.example.com`**. Let's also say that the server belonging to another Certification Authority, Acme Inc, is compromised, and a fake certificate is minted. If a user is misdirected to a fake instance of **`www.example.com`** and the bad server passes the client this fake certificate, the client will accept this fake certificate as valid because the client has no *presumptive* knowledge that the only key that should validate a certificate for **`www.example.com`** belongs to the Trusted Certification Authority Inc. When the key belonging to Acme Inc validates this certificate and ACME is a trusted entity according to my browser, then that is good enough to proceed.

Actually that is not the full story. What if I wanted to cancel a certificate? How do certificates get removed from the system and how do clients know to discard them as invalid?

A diligent client (and one who may need to check a box in the browser preference pane to include this function) uses a second test for validity of a presented certificate, namely the *Online Certificate Status Protocol* (OCSP)[6]. Clients use this protocol to see if an issued certificate has been subsequently revoked. So after the certificate has been validated against the locally held public key, a diligent application will then establish a secure connection to the certification authority OCSP server and query the status of the certificate.

This secure connection allows for prompt removal of fraudulent certificates from circulation. It assumes of course that clients use OCSP diligently and that the Certification Authority OCSP server has not also been compromised in an attack, but in an imperfect world this step constitutes at least another measure of relative defence.

The OCSP server logs can also provide an indication of whether the fraudulent certificates have been used by impersonating servers, because if the certificate was presented to the client and the client passed it to an OCSP server for validation, then there is a record of use of the certificate. The Fox-IT report contains an interesting graphic that shows the geolocation of the source addresses of clients who passed a bad `*.google.com` certificate to OCSP for validation. The source addresses have a strong correlation to a national geolocation of Iran.

Obviously this attack requires some considerable sophistication and capability, hence the suspicion that the attack may have had some form of state or quasi-state sponsorship, and hence the headlines from *The Guardian,* quoted at the start of this article, that described this attack as an incident of cyberwarfare of one form or another. Whether this incident was a cyber attack launched by one nation state upon another, or whether this was an attack by a national agency on its own citizens is not completely clear, but the available evidence points strongly to the latter supposition.

Plugging the Hole?

This incident is not the first such incident that has created a hole in the security framework of the Internet, and it is my confident guess that it will not be the last. It is also a reasonable guess that the evolution of the sophistication and capability that lie behind these attacks points to a level of resourcing that leads some to the view that various state-sponsored entities may be getting involved in these activities in one way or another.

Can we fix this?

It seems to me that the critical weakness that was exploited here was the level of disconnection between domain name registration and certificate issuance. The holders of the domain names were unaware that fraudulent certificates had been minted and were being presented to users as if they were the real thing. And the users had no additional way of checking the validity of the certificate by referring back to information contained in the DNS that was placed there by the domain name holder.

The end user was unable to refine the search for a trusted Certification Authority that would validate the presented certificate from all locally cached trusted Certification Authorities to the one certification authority that was actually used by the domain name holder to certify the public key value. So is it possible to communicate this additional information to the user in a reliable and robust manner?

The last few years have seen the effort to secure the DNS gather momentum. The root of the DNS is now DNSSEC-signed, and attention is now being focused on extending the interlocking signature chains downward through the DNS hierarchy. The objective is a domain name framework where the end client can validate that the results returned from a DNS query contain authentic information that was entered into the DNS by the delegated authority for that particular DNS zone.

What if we were able to place certificates—or references to certificates—into the DNS and protect them with DNSSEC? The *DNS-based Authentication of Named Entities* (DANE) Working Group of the IETF[0, 7] is considering this area of study. They are considering numerous scenarios at present, and the one of interest here does not replace the framework of Certification Authorities and domain name certificates, but it adds another phase of verification of the presented certificate.

The "Use Cases"[8] document from the DANE working group illustrates the proposed approach. I will quote a few paragraphs from this document. The first paragraph describes the form of attack that was perpetrated in June and July this year on the DigiNotar CA. It is not clear to me if the text predates this attack or not, but they are closely aligned in time:

> "Today, an attacker can successfully authenticate as a given application service domain if he can obtain a 'mis-issued' certificate from one of the widely-used CAs—a certificate containing the victim application service's domain name and a public key whose corresponding private key is held by the attacker. If the attacker can additionally insert himself as a man in the middle between a client and server (for example, through DNS cache poisoning of an A or AAAA record), then the attacker can convince the client that a server of the attacker's choice legitimately represents the victim's application service."[8]

So how can DNSSEC help here?

> "With the advent of DNSSEC [RFC 4033], it is now possible for DNS name resolution to provide its information securely, in the sense that clients can verify that DNS information was provided by the domain holder and not tampered with in transit.

> The goal of technologies for *DNS-based Authentication of Named Entities* (DANE) is to use the DNS and DNSSEC to provide additional information about the cryptographic credentials associated with a domain, so that clients can use this information to increase the level of assurance they receive from the TLS handshake process.
>
> This document describes a set of use cases that capture specific goals for using the DNS in this way, and a set of requirements that the ultimate DANE mechanism should satisfy. Finally, it should be noted that although this document will frequently use HTTPS as an example application service, DANE is intended to apply equally to all applications that make use of TLS to connect to application services named by domain names."[8]

Does DANE represent a comprehensive solution to this security vulnerability?

I would hesitate to be that definitive. As usual with many aspects of security, the objective of the defender is to expend a smaller amount of effort in order to force an attack to spend a far larger amount of effort. From this perspective, the DANE approach appears to offer significant promise because it interlocks numerous security measures and forces a potential attacker to compromise numerous independent systems simultaneously. Within the DANE framework the attacker cannot attack any certification authority, but must compromise a particular certification authority, and the attacker must also attack DNSSEC and compromise the information contained in signed DNS responses for that domain in order to reproduce the effects of the attack described here. This scenario seems to fit the requirement of a small amount of additional defensive effort by the server and the client, creating a significantly larger challenge to the attacker.

But many preconditions must be met here for this approach to be effective:

- DNSSEC needs to be ubiquitously deployed and maintained.
- Issued DNS certificates need to be published in the secure DNS zone using the DANE framework.
- Client DNS resolvers need not only to be DNSSEC-aware, but also to enforce DNSSEC outcomes.
- Applications, including browsers, need to validate the certificate that is being used to form the TLS connection against the information provided by a validated DNS response for the DANE credentials for that DNS zone.

It is probably not perfect, but it is a large step forward along a path of providing more effective security in the Internet.

Unfortunately, this solution does not constitute an instant solution ready for widespread use today—or even tomorrow. We could possibly see this solution in widespread use in a couple of years, but, sadly, it is more likely that securing the DNS for use in the Internet will not receive adequate levels of attention and associated financial resourcing in the coming years. It may take upward of 5 years before we see ubiquitous adoption of DNSSEC and any significant levels of its use by a DANE framework for certificates in the DNS. Until then there is the somewhat worrisome prospect of little change in the framework of Internet security from that used today, and the equally concerning prospect that this particular hacking event will not be the last.

Acknowledgement

I am indebted to Olaf Kolkman of NLnet Labs for a stimulating conversation about this attack and the implications for securing the Internet. NLnet Labs is one of a small number of innovative and highly productive research groups that has developed considerable levels of expertise in this area of security and the DNS.[9]

Postscript

When you lose that essential element of trust, your continued existence as a trusted Certification Authority is evidently a very limited one. On Tuesday September 20, 2011, the Dutch company DigiNotar was officially declared bankrupt in a Haarlem court.

Let the Names Speak for Themselves: Improving Domain Name Authentication with DNSSEC and DANE

by Richard L. Barnes, BBN Technologies

Authentication of domain names is a fundamental function for Internet security. In order for applications to protect information from unauthorized disclosure, they need to make sure that the entity on the far end of a secure connection actually represents the domain that the user intended to connect to. For many years, authentication of domain names has been accomplished by having third-party *Certification Authorities* attest to which entities could represent a domain name. This system of external authorities, however, has recently come under heavy attack, and there have been several high-profile compromises[0]. The *Domain Name System Security Extensions* (DNSSEC) offer an alternative channel for distributing secure information about domain names, through the *Domain Name System* (DNS) itself. The *DNS-based Authentication of Named Entities* (DANE) working group in the *Internet Engineering Task Force* (IETF) has developed a new type of DNS record that allows a domain itself to sign statements about which entities are authorized to represent it. End users' applications can use these records either to augment the existing system of Certification Authorities or to create a new chain of trust, rooted in the DNS.

Authentication

Without authentication, other security services are moot. There is little point in Alice's encrypting information en route to Bob if she has not first verified that she is talking to Bob and not an attacker Eve. In the context of Internet applications, authentication is about ensuring that users know whom they are talking to, and in most cases, that "whom," is represented by a domain name. For example, in the *Hypertext Transfer Protocol* (HTTP), the "authority" section of a *Uniform Resource Identifier* (URI) indicates the domain name of the server that will fulfill requests for that URI. So when an HTTP user agent starts a TCP connection to a remote server, it needs to verify that the server is actually authorized to represent that domain name[1].

The most common security protocol used by Internet applications is the *Transport Layer Security* (TLS) protocol[2]. TLS provides a layer above TCP that facilitates authentication of the remote side of the connection as well as encryption and integrity protection for data. TLS underlies *Secure HTTP* (HTTPS) and secure e-mail[1, 3, 4], and provides hop-by-hop security in real-time multimedia and instant-messaging protocols[5, 6]. In all of these applications, the server that the user ultimately wants to connect to is identified by a DNS domain name[7, 8]. A user might enter `https://example.com` into a web browser or send an e-mail to `alice@example.com`.

One of the main purposes of using TLS in these cases is thus to assure the user that the entity on the other end of the connection actually represents `example.com`; in other words, to authenticate the server as a legitimate representative of the domain name. Note that these comments apply to *Datagram Transport Layer Security* (DTLS) as well, because it provides the same functions as TLS for *User Datagram Protocol* (UDP) packet flows[9].

Today, a server asserts its right to represent a domain by presenting a *Public Key Infrastructure* (PKIX) digital certificate containing that domain[8, 10]. A certificate is an attestation by a Certification Authority of a binding between a public key and a name—the entity holding the corresponding private key is authorized to represent that name. TLS ensures that only the holder of a given private key can read the encrypted data; the certificate ensures that the holder of the key represents the desired name.

Current TLS-based applications maintain a list of Certification Authorities whose certificates they will accept. Unfortunately, over time, these lists have grown very long, with major web browsers trusting nearly 200 Certification Authorities, representing a diverse range of organizations. Because any of these Certification Authorities can vouch for any domain name, a long list creates many points of vulnerability; a compromise at any point allows the attacker to issue certificates for any domain. Several recent attacks have taken advantage of this fact by targeting smaller Certification Authorities as a way to obtain certificates for major domains. For example, an attack through DigiNotar against Google is discussed in this issue[0].

DNSSEC offers an alternative to Certification Authorities. In the DNSSEC system, each domain holder can act as an authority for subordinate domains. The IETF DANE working group has developed a DNS record format for "certificate associations," so that domain holders can sign statements about which certificates can be used to authenticate as that domain. In effect, this scenario allows a domain to speak for itself, instead of through a third-party Certification Authority. DANE associations can be used either as a check on the current model (for example, to limit which Certification Authorities may vouch for a domain) or as an alternative trust path, rooting trust in a DNSSEC authority instead of a Certification Authority. Work on the protocol document is drawing to a close, and several prototype implementations are already in progress.

Background: PKIX and DNSSEC

At one level, the choice of which authentication technology to use is a choice of authorities and scoping. As mentioned previously, authentication is fundamental for security, but it is also very hard to accomplish scalably. For example, a web browser needs to be able to authenticate any website the user chooses to visit. It would clearly not work for each browser vendor to send a human representative to meet every website owner in order to find out what public key should be used for that website.

So instead of relying on having preestablished relationships with every entity we want to authenticate, we rely on centralized authorities to do identity checking. The authorities then create credentials that anyone else can check, so that if the credential is valid and you believe the authority is trustworthy, then the entity holding the credential has the indicated identity.

In a technical sense, an entity holds a credential if it holds the private key corresponding to the public key in the credential. The credential encodes a *binding* between the public key and the identity, asserted by the authority.

Authority is of course not a purely digital concept. If we want to know a person's name in real life we do not just ask them directly, because the person could lie. Instead we look to a credential issued by an authority, such as a driver's license or birth certificate. So the technology question here is how to manage authorities, and how to encode these credentials.

The IETF has defined two major cryptographic authority systems: PKIX, based on digital certificates[10]; and DNSSEC, based on the DNS[11]. Both of these systems allow authorities to associate public keys with identities, and both arrange these authorities hierarchically.

The hierarchy is important because it allows a *relying party* (someone who is verifying identities) to choose whom to trust. In these hierarchical systems, an authority's identity can itself be attested by a credential issued by another authority. When a relying party wants to verify a credential issued by an authority A, he then has to verify that A's credential is valid (under an authority B), and so on until he reaches an authority that he trusts. This sequence of credentials constitutes a logical path through the hierarchy, known as a "certification path" in PKIX terminology (Figure 1).

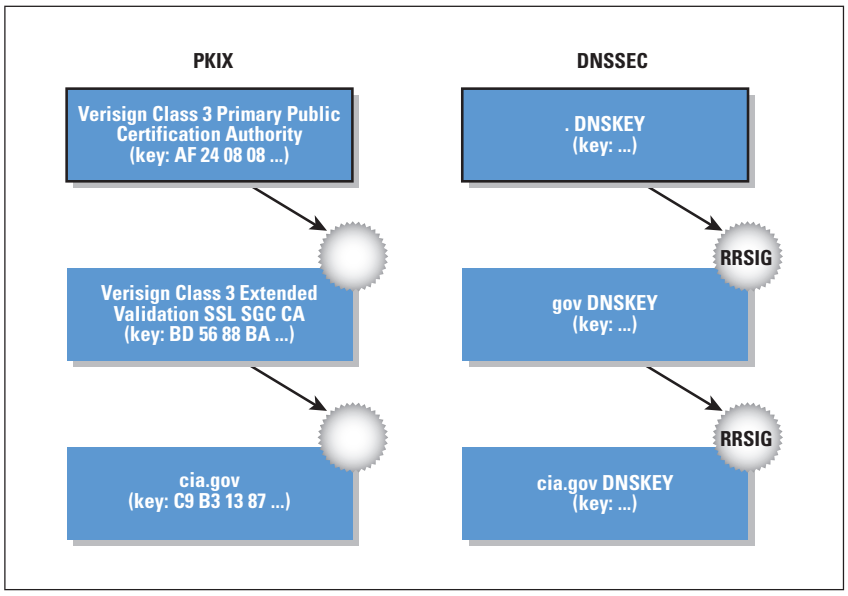

Figure 1: PKIX and DNSSEC Trust Hierarchies

In order to be useful as a given relying party to authenticate someone, a certification path has to end in a *trust anchor,* that is, an authority that the relying party trusts to make assertions. In the DNSSEC context, relying parties can in principle have only one trust anchor, namely the DNS root, although alternatives to the root have been proposed[12]. The PKIX system, on the other hand, does not represent a single globally consistent hierarchy, so in order to be able to validate many certificates, relying parties often have to choose many trust anchors.

Crossing the Streams

Current TLS-based applications rely on PKIX for authentication of domain names, which has facilitated fairly broad deployment, but also created some vulnerabilities. PKIX is based on a very general digital certificate system called X.509, and because of this generality, it has no inherent binding to the DNS. This situation creates two problems when it comes to authenticating domain names.

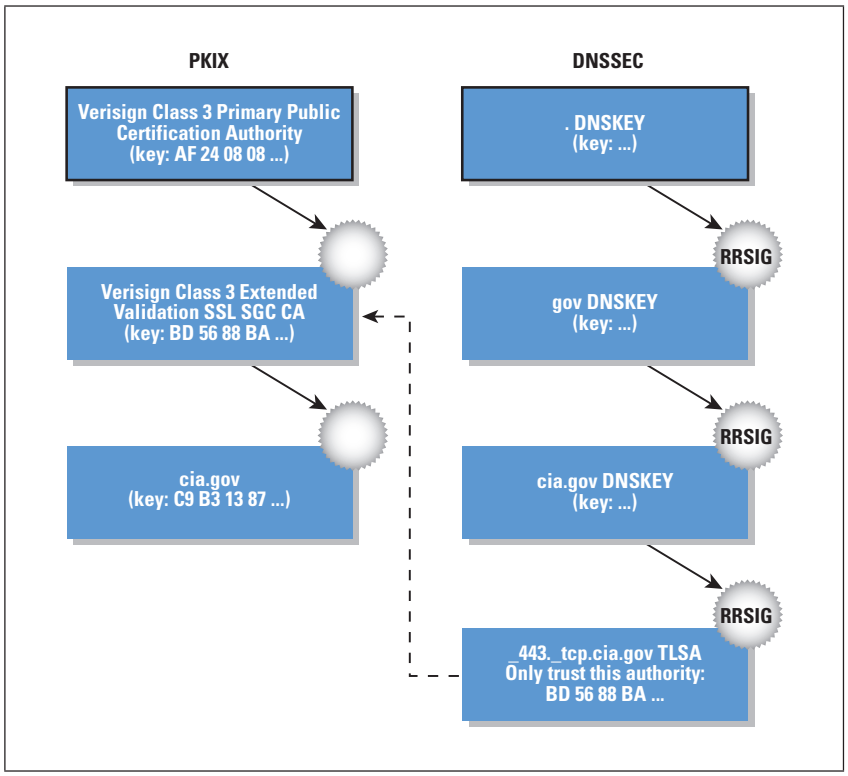
First, unlike the DNS, which has a single global root, there is no single authority under which all PKIX certificates can be verified. Indeed, there is an open marketplace of authorities, where each entity can choose which authority will sign its certificate, leaving relying parties with a choice: Either they must trust every authority that has signed a certificate for an entity it wants to authenticate, or they will be unable to validate the identities of some entities. In general, current software has preferred the former approach of trusting many authorities, to the extent that modern browsers and operating systems will trust up to 200 authorities by default. Users can add to this list, for example, using the "Accept this certificate?" dialogs in their browsers, but it can be very difficult to remove trust anchors from the default list[13].

Second, PKIX authorities today are not constrained in the scope, so they can issue credentials for any name—even those for whom they have no real information (in contrast to the DNS—where each zone can vouch only for sub-domains; only the root can act with impunity). Conversely, there is no real way for a relying party to know what authority should be vouching for a site, so if a rogue authority were to issue a certificate to an unauthorized party, relying parties would have no way to detect it.

Given these vulnerabilities, any of the many authorities trusted within the PKIX system can attack any domain by issuing a false certificate from that domain. This false certificate can then be used to masquerade as the victim domain, for example, to perform a man-in-the-middle attack. Note that the authority itself is not necessarily the bad actor in this attack—it could be an external attacker that can obtain illicit access to the systems that issue certificates. The risks of having broadly trusted Certificatation Authorities have recently become clear, because attackers were able to break into two small Certification Authorities and create fraudulent certificates for Google and Facebook, among others[14, 15].

The goal of DANE is to address some of the vulnerabilities of the current PKIX ecosystem by allowing DNSSEC—to "cross the streams" to allow domains to publish information secured with DNSSEC that can add additional security to PKIX certificates used for TLS. For example, a domain might use DANE to inform relying parties of which authorities can be trusted, as illustrated in Figure 2.

Figure 2: Using a DANE TLS Associations (TLSA) Record to Indicate Which PKIX Authority Should Be Trusted



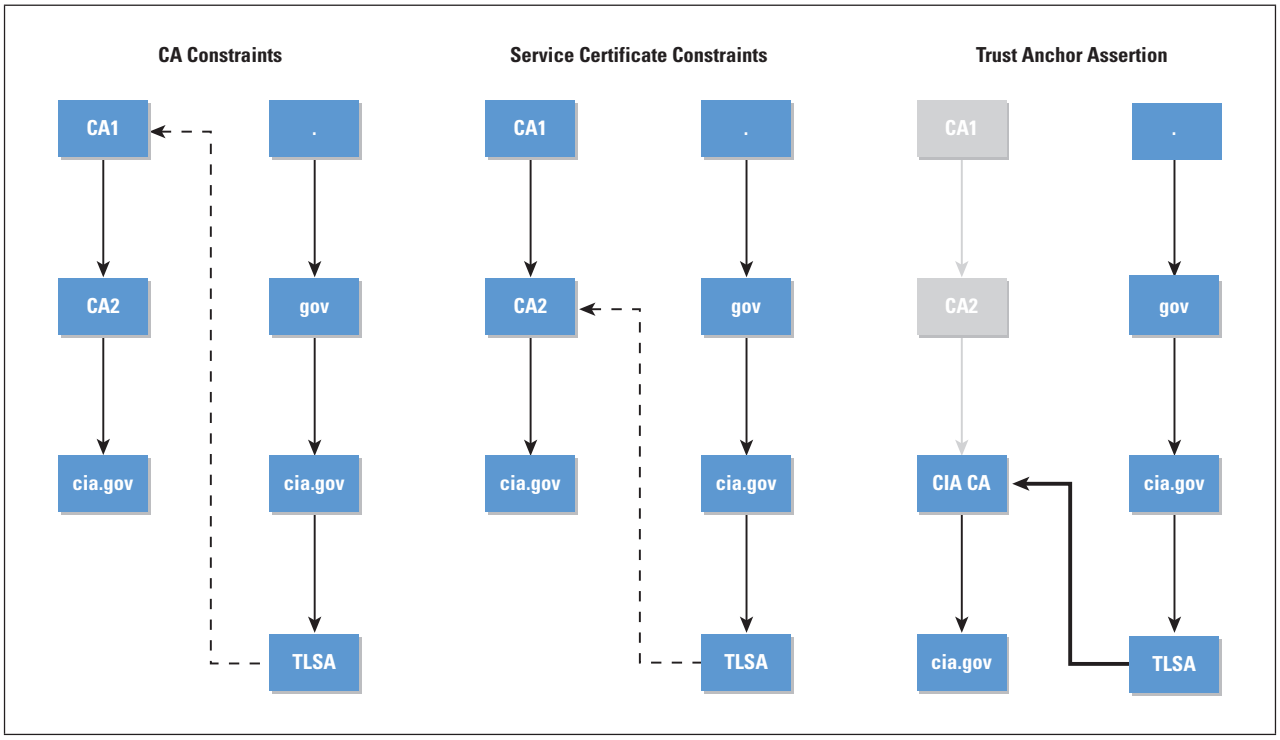
DANE Records

If the goal of DANE is to allow domain operators to make statements about how clients should judge TLS certificates for their domains, then what sorts of statements should DANE allow them to make? The DANE use cases document[16] lays out three major types of statements (Figure 3):

1. *CA Constraints:* The client should accept only certificates issued under a specific Certificatation Authority.
2. *Service Certificate Constraints:* The client should accept only a specific certificate.
3. *Trust Anchor Assertion:* The client should use a domain-provided trust anchor to validate certificates for that domain.

All three of these statements can be viewed as constraining the scope of trust anchors. The first two types limit the scope of existing trust anchors, whereas the third provides the client with a new trust anchor (still within a limited scope). More on these anchors in a moment.

Figure 3: DANE Use Cases



The current draft DANE protocol defines a DNS Resource Record type TLSA for describing *"TLS Associations"*—statements about what certificates are "associated" to a domain[17]. Each TLSA record has three basic fields:

- *Usage:* Which type of statement this record is making
- *Selector/Matching:* How a TLS certificate chain should be matched against this record (for example, by exact match, by public key, or by SHA-1 digest)
- *Certificate for Association:* The actual data against which the TLS certificate chain should be matched

These records are stored under the target domain with a prefix that indicates the transport and port number for the TLS server. So for example, if Alice runs a secure web service at **`example.com`** and wants to tell clients that they should accept only certificates from the Charlie's CA, she could provision a TLSA record under **`_443._tcp.example.com`** with the following contents:

- *Usage:* CA constraint
- *Selector/Matching:* SHA-1 digest
- *Certificate for Association:* SHA-1 digest of Charlie's certificate

When a client Bob wants to connect to **`https://example.com`**, he can find these TLSA records and apply Alice's constraints when he validates the server certificate.

Adding Constraints to PKIX

The major objective of the CA constraints and service certificate constraints is to guard against "mis-issue" of certificates. A certificate is "mis-issued" when a CA issues a certificate to an entity that does not actually represent the domain name in the certificate. Mis-issue can come about in many ways, including through malicious Certification Authorities, compromised Certification Authorities (as in the Comodo and DigiNotar example discussed previously), or Certification Authorities that are simply misled as to the attacker's identity through fraud or other means. Today, mis-issue can be difficult to detect, because there is no standard way for clients to figure out which Certification Authorities are supposed to be issuing certificates for a domain. When an attacker issued false certificates for the Google Gmail service under the DigiNotar Certification Authority, it was noticed only because a vigilant user posted to a Gmail help forum.[18]

By contrast, domain operators know exactly which Certification Authorities they have requested certificates from, and, of course, which specific certificates they have received. With DANE, the domain operator can convey this information to the client. For example, to guard against the DigiNotar attack, Google could have provisioned a TLSA record expressing a Certification Authority constraint with its real Certification Authority (which is not DigiNotar) or a certificate constraint with its actual certificate. Then DANE-aware clients would have been able to immediately see that the DigiNotar certificates were improperly issued and possibly indicative of a man-in-the-middle attack.

Empowering Domain Operators

According to data from the EFF SSL Observatory, which scans the whole IPv4 address space for HTTPS servers and collects their certificates, around 48 percent of all HTTPS servers present self-signed certificates[19]. An unknown number of other servers present certificates issued under Certification Authorities that are not in the major default trust anchor lists. For example, the United States Air Force web portal uses a certificate issued under a Department of Defense Certification Authority that is not trusted by Firefox[20]. In the current environment, most clients cannot authenticate these servers at all; they have to rely on users manually checking certificates, hopefully with some out-of-band information. As a result, these servers and their users are highly vulnerable to man-in-the-middle attacks against their supposedly secure sessions.

DANE Trust Anchor Assertions enable the operators of a domain to advertise a new trust anchor, under which certificates for that domain will be issued. Using these records, clients can dynamically discover what trust anchors they should accept for a given domain, instead of relying on a static list provided by a browser or operating system.

It may seem odd to talk about a domain supplying a client with trust anchors, because trust anchor provisioning is typically a very sensitive activity. If an attacker is able to install a trust anchor into a victim's trust anchor store, then the attacker can masquerade under any name he wants by issuing certificates under that name. The PKIX working group even defined a whole protocol for managing trust anchors[21].

DANE ensures that this trust anchor provisioning is secure by applying scoping and verifying that scoping using DNSSEC. DANE trust anchor assertions are scoped to a particular domain name, so even if an attacker can introduce a false trust anchor, he can use it to spoof only a single name. Furthermore, trust anchor assertions must be DNSSEC-signed, so clients can verify that the entity providing the trust anchor represents the domain in question. Ultimately, the client still has to have a list of trust anchors configured—but they are DNSSEC trust anchors instead of PKIX trust anchors.

Of course, in principle, a client needs only one trust anchor for DNSSEC, the root zone trust anchor. Because control of the DNS root does not change very often, it makes sense for this trust anchor to be statically configured!

The ability of a domain operator to explicitly indicate a trust anchor for a domain is obviously very powerful. It may be tempting to ask whether this case is really the only use case that DANE needs, that is, whether the constraint cases mentioned previously are needed at all. The answer is that the constraint cases are useful as a way to fold in PKIX validation with external Certification Authorities in addition to domain-asserted trust anchors. Most obviously, this feature is useful in transition, when not all clients will be DANE-aware. But even in the longer term, it is possible that Certification Authorities will be able to provide added value over DANE. For example, while DANE is made to bind certificates to domain names, Certification Authorities can vouch for bindings of certificates to other things, such as the legal identity and physical location attested in Extended Validation certificates[22].

Transition Challenges

As described previously, DANE offers some valuable new security properties for TLS authentication. But as with most IETF technologies—especially security technologies—there are some challenges to be overcome and some new potential pitfalls.

The most significant constraint for DANE deployment is DNSSEC deployment. On the server side, this problem is not a significant one because DNSSEC support is spreading fairly rapidly. On the client side, it may be more difficult. Although there are DNS libraries with robust DNSSEC support, many of the major DNS *Application Programming Interfaces* (APIs) that applications use do not provide any information about the DNSSEC status of the results returned.

So in order to implement DANE, application developers may have to re-factor their DNS support in addition to querying for some new record types. If more sites come to rely on DANE, then this process could also draw increasing attention to the various types of intermediaries that cause DNSSEC breakage (for example, home gateways that set DNS flags improperly).

Adding DNSSEC to the TLS connection process can also add significant latency to the TLS connection process. In addition to completing the TLS handshake and certificate validation, the client has to wait for several DNS round trips and then validate the chain of DNSSEC signatures. These combined delays can add up to multiple seconds of latency in connection establishment. Especially for real-time protocols such as HTTPS, *Session Initiation Protocol* (SIP), or *Extensible Messaging and Presence Protocol* (XMPP), such delay is clearly undesirable.

One mechanism proposed to mitigate these delays is to have the server pre-fetch all of the relevant DNSSEC records, namely all of the DS, DNSKEY, and RRSIG records chaining back to the root[27]. Then the server can provide a serialized version of the DNSSEC records in the TLS handshake, saving the client the latency of the required DNS queries. The details of this mechanism, however, are still being worked out among the DANE, TLS, and PKIX working groups[23]. A prototype version is now available in the Google Chrome web browser[24].

Security Considerations

From a security perspective, the major effect of DANE is the new role that DNS operators will play in securing Internet applications. Although DNSSEC has always meant that DNS operators would have more security functions, DANE deployment will give them an explicit effect on application security, acting as arbiters of who can authenticate under a given name in TLS. Especially if services use trust anchor assertions, DNS operators will play an analogous role to the one Certification Authorities play today—a compromise in a DNS operator will allow an attacker to masquerade as a victim domain (albeit for a more limited set of domains because of DANE constraints on names). So DNS operators are likely to inherit many of the security troubles that Certification Authorities experience today and will need to strengthen their security posture accordingly.

Another more subtle risk arises from the fact that the operator of a DNS zone is not always the same as the entity that is authorized to control the contents of the zone, which we will call the "domain holder." We used the phrase "domain operator" previously because DNSSEC protects DNS information only between the operator's name server and the client—it does not say that what is provisioned in the name server is authorized by the domain holder.

When a domain is operated by a third party, that third party is a point of vulnerability between the client and the holder of the domain. If the domain operator provides false DANE information through malice or compromise, then a client will not be able to distinguish it from genuine DANE information. To some extent, this risk is not really new; because many current Certification Authorities authenticate requests for domain certificates based on information that is under the control of the domain operator, domain operators can already influence the credentialing process. With DANE, however, the vulnerability is much easier to exploit, for example, because the DNS operator does not have to trick a third party. This vulnerability is also fundamental to protocols that rely on DNSSEC for security, and the implications for DANE are discussed in detail in the DANE use cases document[16]. The main mitigation is simply increased care on the part of domain holders to ensure that domain operators are not behaving badly.

Conclusions

For many years now, Internet applications have relied on assertions by third-party PKIX Certification Authorities to ensure that a server holding a particular private key was authorized to represent a domain. The promise of DANE is a more direct interaction between clients and the domains they interact with, secured by DNSSEC. In the short run, DANE can be deployed as an adjunct to the current system of certificates and authorities, adding constraints to better protect domains. In the long run, DANE will also allow domain operators to vouch for their own names.

The transition and security problems that face DANE are largely the growing pains of DNSSEC. It is not that DANE is causing these problems itself; rather, the problems arise because DANE is the first real application of DNSSEC that is expected to be widely deployed. So although it may be difficult to mitigate some of the security problems that DANE raises, and to enable more robust DNSSEC support in applications and gateways, these changes will ultimately make it simpler for applications to use DNSSEC for other purposes.

The DANE working group is making consistent progress on its deliverables, and there are already some prototype deployment tools. Their use cases document has been published as RFC 6394[16], and the corresponding document defining the TLSA record type is starting to mature[17]. As of this writing, it is in Working Group Last Call. On the client side, a variant of DANE has already been implemented in Google Chrome; on the server side, prototype tools are available to generate DANE records and to generate "DNSSEC-stapled" certificates based on DANE records[24, 25]. There is also an early-stage command-line tool for generating and verifying TLSA records[26].

A Retrospective: Twenty-Five Years Ago

by Geoff Huston, APNIC

The Information Technology business is one that rarely pauses for breath. Gordon Moore noted in 1965 that the number of components in integrated circuits had doubled every year from 1958 to 1965, and confidently predicted that this doubling would continue "for at least 10 years." This feature has been a continuing feature of the silicon industry for the past 50 years now, and its constancy has transformed this prediction into *Moore's Law*. The implications of this constant impetus for innovation in this industry have resulted in an industry that is incapable of remaining in stasis, and what we have instead is an industry that completely reinvents itself in cycles as short as a decade.

Looking back over the past 25 years, we have traversed an enormous distance in terms of technical capability. The leading silicon innovations of the late 1980s were in the Intel 80486 chip, which contained 1 million transistors on a single silicon chip with a clock speed of 50 MHz, and a similarly capable Motorola 68040 processor. Twenty-five years later the state of the art is a multicore processor chip that contains just under 3 billion individual transistors and clock speeds approaching 4 GHz. And where has all that processing power gone? In the same period we have managed to build extremely sophisticated programmed environments that have produced such products as Apple's *Siri* iPhone application, which combines voice recognition with a powerful information manipulation system, and we have packaged all of this computing capability into a device that fits comfortably in your pocket with room to spare!

Given that the last 25 years in IT has been so active, to look back over this period and contemplate all that has happened is a daunting task, and I am pretty sure that any effort to identify the innovative highlights in that period would necessarily be highly idiosyncratic. So instead of trying to plot the entire story that took us from then to now, I would like instead just to look at "then." In this article, to celebrate 25 combined years of *The Internet Protocol Journal* (IPJ)[2, 3] and its predecessor *ConneXions—The Interoperability Report*[0], I would like to look at the networking environment of the late 1980s and see what, if anything, was around then that was formative in shaping what we are doing today, and how it might influence our tomorrow.

The Computing Landscape of the Late 1980s

The computing environment of the late 1980s now seems to be quite an alien environment. Obviously there were no pocket-sized computers then. Indeed there were no pocket-sized mobile phones then. (I recall a visit from a salesman at the time who sported the very latest in mobile telephony—a radio setup that was the size of a briefcase!)

In 1987 the IT world was still fixated with the mainframe computer, which was basking in its last couple of years of viability in the market. IBM enjoyed the dominant position in this marketplace, and *Digital Equipment Corporation* (DEC) was competing with IBM with its VAX/VMS systems. These systems were intended to take the place of the earlier DEC-10 architectures, as well as offering an upgrade path for the hugely successful PDP-11 minicomputer line. The typical architecture of the computing environment was still highly centralized, with a large multiuser system at its core, and an attendant network or peripheral devices. These peripheral devices were traditionally video terminals, which were a simple ASCII keyboard and screen, and the interaction with the mainframe was through simple serial line character-based protocols.

Although it may not have been universally accepted at the time, this period at the end of the 1980s marked the end of the custom-designed mainframe environment, where large-scale computer systems were designed as a set of component subsystems, placed into a rack of some sort and interconnected through a bus or blackplane. Like many other human efforts, as far as the mainframe computer sector was concerned its final achievements were its greatest.

While the mainframe sector was inexorably winding down, at the other end of the market things were moving very quickly. The Zylogics Z80 processor of the mid-1970s had been displaced by the Intel 8080 chip, which evolved rapidly into 16-bit, then 32-bit processor versions. By 1987 the latest chip was the Intel 80386, which could operate with a clock speed up to 33 MHz. The bus was 32 bits wide, and the chip supported a 32-bit address field. This chip contained some 275,000 transistors, and was perhaps the transformative chip that shifted the personal computer from the periphery of the IT environment to the mainstream. This chip took on the mainframe computer and won. The evolving architecture of the late 1980s was shifting from a central processing center and a cluster of basic peripheral devices to one of a cluster of personal desktop computers.

The desktop personal computer environment enabled computing power to be treated as an abundant commodity, and with the desktop computer came numerous interface systems that allowed users to treat their computer screens in a manner that was analogous to a desktop. Information was organized in ways that had a visual counterpart, and applications interacted with the users in ways that were strongly visual. The approach pioneered by the Xerox Star workstation in the late 1970s and brought to the consumer market through the Apple Lisa and Macintosh systems were then carried across into the emerging "mainstream" of the desktop environment with Windows 2.0 in the late 1980s.

The state of the art of portability was still in the category of "luggable" rather than truly portable, and the best example of what was around at the time is the ill-fated Macintosh Portable, which like its counterpart in the portable phone space was the size of a briefcase and incredibly heavy.

Oddly enough, while the industry press was in raptures when it was released in 1989, it was a complete failure in the consumer market. The age of the laptop was yet to come.

One major by-product in this shift in the computing environment to a distributed architecture was a major shift in the attention to networking, and at the same time as there was a large-scale shift in the industry from mainframes to personal computers, there were also numerous major changes in the networked environment.

The Networking Environment of the Late 1980s

A networking engineer in the late 1980s was probably highly conversant in how to network serial terminals to mainframes. The pin-outs in the DB-25 plug used by the RS-232 protocol was probably one of the basic ABCs of computer networking. At that time much of the conventional networked environment was concerned with connecting these terminal devices to mainframes, statistical multiplexors, and terminal switches, and serial switch suppliers such as Gandalf and Micom were still important in many large-scale computing environments.

At the same time, another networking technology was emerging—initially fostered by the need to couple high-end workstations with mainframes—and that was *Ethernet*. Compared to the kilobits per second typically obtained by running serial line protocols over twisted pairs of copper wires, the 10-Mbps throughput of Ethernet was blisteringly fast. In addition, Ethernet could span environments with a diameter of around 1500 meters, and with a certain amount of tweaking or with the judicious use of Ethernet bridges and fibre-optic repeaters this distance could be stretched out to 10 km or more.

Ethernet heralded a major change in the networked environment. No longer were networks hub-and-spoke affairs with the mainframe system at the center. Ethernet supplied a common bus architecture that supported any-to-any communications. Ethernet was also an open standard, and many vendors were producing equipment with Ethernet interfaces. In theory, these interfaces all interoperated, at least at the level of passing Ethernet frames across the network (aside from a rather nasty incompatibility between this original Digital-Intel-Xerox specification and the IEEE 802.3 "standardized" specification!).

However, above the basic data framing protocol the networked environment was still somewhat chaotic. I recall the early versions of the multiprotocol routers produced by Proteon and Cisco supported more than 20 networking protocols! There was *DECnet,* a proprietary network protocol suite from the Digital Equipment Corporation, which at around 1987 had just released Phase IV, and was looking toward a Phase V release that was to interoperate with the International Organization for Standardization's *Open Systems Interconnection* (OSI) protocol suite[1] (more on this subject a bit later).

There was IBM's *Systems Network Architecture* (SNA), which was a hierarchical network that supported a generic architecture of remote job entry systems clustered around a central service mainframe. There was the *Xerox Network Services* (XNS) protocol used by Xerox workstations. Then there were Apollo's *Network Computing Architecture* (NCA) and Apple's *AppleTalk*. And also in this protocol mix was the *Transmission Control Protocol/Internet Protocol* (TCP/IP) protocol suite, used at that time predominately on UNIX systems, although implementations of TCP/IP for Digital's VAX/VMS system were very popular at the time. A campus Ethernet network of the late 1980s would probably see all of these protocols, and more, being used concurrently.

And there was the ISO-OSI protocol suite, which existed more as a future protocol suite than as a working reality at the time.

The ISO-OSI and TCP/IP protocol suites were somewhat different from the others that were around at the time because both were deliberate efforts to answer a growing need for a vendor-independent networking solution. At the time the IT environment was undergoing a transition from the monoculture of a single vendor's comprehensive IT environment—which bundled the hardware of the mainframe, network, peripherals, terminals, and the software of the operating system, applications, and network all into the one bundle—into a piecemeal environment that included a diverse collection of personal workstations, desktop computers, peripherals, and various larger minicomputers and mainframe computers in one environment. What was needed was a networking technology that was universally supported on all these various IT assets. What we had instead was a more piecemeal environment. Yes, it was possible to connect most of these systems into a common Ethernet substrate, but making A talk to B was still a challenge, and various forms of protocol translation units were also quite commonplace at the time. What the industry needed was a vendor-independent networking protocol, and there were two major contenders for this role.

ISO-OSI and TCP/IP

The ISO-OSI protocol suite was first aired in 1980. It was intended to be an all-embracing protocol suite that embraced both the IEEE 802.3 Ethernet protocols and the X.25 packet switching protocols that were favoured by many telephony operators as their preferred wide-area data services solution. The ISO-OSI network layer included many approaches, including the telephony sector's *Integrated Service Digital Network* (ISDN), a *Connection-Oriented Network Service* (CONS), a virtual circuit function based largely on X.75 that was essentially the "call-connection" function for X.25, and a *Connectionless Network Service* (CLNS), based loosely on the IP protocol with the use of the *End System-to-Intermediate System Routing Exchange Protocol* (ES-IS) routing protocol.

Above the network layer were numerous end-to-end transport protocols, notably *Transport Protocol Class 4* (TP4), a reliable connection-oriented transport service, and *Transport Protocol Class 0* (TP0), a connectionless packet datagram service. Above this layer was a Session Layer, X.215, used by the TP4 CONS services, and a Presentation Layer, defined using the *Abstract Syntax Notation One* (ASN.1) syntax.

ISO-OSI included numerous application-level services, including *Virtual Terminal Protocol* (VTP) for virtual terminal support, *File Transfer Access And Management* (FTAM) for file transfer, *Job Transfer And Management* (JTAM) for batch job submission, *Message Handling System* (MHS, also known as X.400) for electronic mail, and the X.500 Directory service. ISO-OSI also included a *Common Management Information Protocol* (CMIP). ISO-OSI attempted to be everything to everybody, as evidenced by the "kitchen sink" approach adopted by many of the OSI standardization committees at the time.

When confronted by many technology choices, the committees apparently avoided making a critical decision by incorporating both approaches into the standard. The most critical decision in this protocol suite was the inclusion of both connection-oriented and connectionless networking protocols. They also used session and presentation layer protocols, whose precise role was a mystery to many! ISO-OSI was a work-in-progress at the time, and the backing of the telephone sector, coupled with the support of numerous major IT vendors, gave this protocol an aura of inevitability within the industry. Whatever else was going to happen, there was the confident expectation that the 1990s would see all computer networks move inevitably to use the ISO-OSI protocol suite as a common, open, vendor-neutral network substrate.

If the ISO-OSI had a mantra of inevitably, the other open protocol suite of the day, the TCP/IP protocol suite, actively disclaimed any such future ambitions. TCP/IP was thought of at the time as an experiment in networking protocol design and architecture that ultimately would go the way of all other experiments, and be discarded in favor of a larger and more deliberately engineered approach. Compared to the ISO-OSI protocols, TCP/IP was extremely "minimalist" in its approach. Perhaps the most radical element in its design was to eschew the conventional approach at the time of building the network upon a reliable data link protocol. For example, in DECnet Phase IV, the data link protocol, *Digital Data Communications Message Protocol* (DDCMP), performed packet integrity checks and flow control at the data link level. TCP/IP gracefully avoided this problem by allowing packets to be silently dropped by intermediate data switches, or corrupted while in flight. It did not even stipulate that successive packets within the same end-to-end conversation follow identical paths through the network.

Thus the packet switching role was radically simplified because now the packet switch did not need to hold a copy of transmitted packets, nor did it need to operate a complex data link protocol to track packet transmission integrity and packet flow control. When a switch received a packet, it forwarded the packet based on a simple lookup of the destination address contained in the packet into a locally managed forwarding table. Or it discarded the packet.

The second radical simplification in TCP/IP was the use of real-time packet *fragmentation*. Previously, digital networks were constructed in a "vertically integrated" manner, where the properties of the lower layers were crafted to meet the intended application of the network. Little wonder that the telephone industry put its support behind X.25, which was a reliable unsynchronized digital stream protocol. If you wanted low levels of jitter, you used a network with smaller packet sizes, whereas higher packet sizes improved the carriage efficiency. Ethernet attempted to meet this wide variance in an agnostic fashion by allowing packets of between 64 and 1500 octets, but even so there were critics who said that for remote terminal access the smallest packets were too large, and for large-scale bulk data movement the largest packets were too small. *Fiber Distributed Data Interface* (FDDI), the 100-Mbps packet ring that was emerging at the time as the "next thing" as commodity high-speed networking used a maximum size of 4000 octets packets in an effort to improve carriage efficiency, whereas the *Asynchronous Transfer Mode* (ATM) committee tried to throw a single-packet-size dart at the design board and managed to get the rather odd value of 53 octets!

IP addressed this problem by trying to avoid it completely. Packets could be up to 64,000 octets long, and if a packet switch attempted to force a large packet through an interface that could not accept it, the switch was allowed to divide the packet into appropriately sized autonomous fragments. The fragments were not reassembled in real time: that was the role of the ultimate receiver of the packets.

As an exercise in protocol design, IP certainly showed the elegance of restraint. IP assumed so little in terms of the transmission properties of the underlying networks that every packet was indeed an adventure! But IP was not meant to be the protocol to support the prolific world of communicating silicon in the coming years. This protocol and the IP networks that were emerging in the late 1980s were intended to be experiments in networking. There was a common view that the lessons learned with experience of operating high-speed local networks and wide-area networks using the TCP/IP protocol suite would inform the larger industry efforts. The inclusion of IP-based technologies in the ISO-OSI protocol suite[4] was a visible instantiation of this proposed evolutionary approach.

While these two protocol suites vied with each other for industry attention at the time, there was one critical difference: It was a popular story at the time that the ISO-OSI protocol suite was a stack of paper some 6 feet high, which cost many hundreds of dollars to obtain, with no fully functional implementations, whereas the TCP/IP protocol suite was an open-sourced and openly available free software suite without any documentation at all. Many a jibe at the time characterized the ponderous approach of the ISO-OSI approach as "vapourware about paperware," while the IP effort, which was forming around the newly formed *Internet Engineering Task Force* (IETF), proclaimed itself to work on the principle of "rough consensus and running code."

Local- and Wide-Area Networking

The rise of Ethernet networks on campuses and in the corporate world in the late 1980s also brought into stark visibility the distinction between local- and wide-area networking.

In the local-area network, Ethernet created a new environment of "seamless connectivity." Any device on the network could provide services to any other device, and the common asset of a 10-Mbps network opened up a whole new set of computing possibilities. Data storage could be thought of as a networked resource, so desktop computers could access a common storage area and complement it with local storage, and do so in a way that the distinction between local resources and shared networkwide resources was generally invisible. The rich computing environment of visualizing the application, popularized by both the Macintosh and Windows 2.0, complemented a rich networked environment where rather than bringing a user into the location that had both the data and the computing resources, the model was invested, and the user was able to exclusively use the local environment and access the remote shared resources through networking capabilities integrated into the application environment. Local-area networking was now an abundant resource, and the industry wasted no time on exploiting this new-found capability.

But as soon as you wanted to venture further than your *Local-Area Network* (LAN), the picture changed dramatically. The wide-area networking world was provisioned on the margins of oversupply of the voice industry, and the services offered reflected the underlying substrate of a digital voice circuit. The basic unit of a voice circuit was a 64-kbps channel, which was "groomed" into a digital circuit of either 56 or 48 kbps, depending on the particular technology approach used by the voice carrier. Higher capacities (such as 256 or 512 kbps) were obtained by multiplexing individual circuits together. Even high-capacity circuits were obtained by using a voice trunk circuit, which was either 1.5 (T1) or 2.048 Mbps (E1), again depending on the digital technology used by the voice carrier. Whereas the LANs were now supporting an any-to-any mode of connection, these *Wide-Area Networks* (WANs) were constructed using point-to-point technologies that were either statically provisioned or implemented as a form of "on-demand" virtual circuit (X.25).

In the late 1980s users' patience was running thin over having to use an entirely different protocol suite for the wide area as distinct from the local area. Often the wide area required the use of different applications with different naming and addressing conventions. One approach used by many Ethernet switch vendors was to introduce the concept of an *Ethernet Serial Bridge*. This technology allowed a logical IEEE 802.3 Ethernet to encompass much larger geographic domains, but at the same time protocols that worked extremely efficiently in the local area encountered significant problems when passed through such supposedly "transparent" Ethernet serial bridges.

However, these bridge units allowed significantly larger and more complex networks to be built using Ethernet as the substrate. The Ethernet *Spanning Tree Algorithm* gained traction in order to allow arbitrary topologies of interconnected LANs to self-organize into coherent topologies that eliminated loops and allowed for failover resilience in the network.

What has changed, and what has stayed the same?

So what have we learned from this time?

In the intervening period ISO-OSI waned and eventually disappeared, without ever having enjoyed widespread deployment and use. Its legacy exists in numerous technologies, including the X.500 Directory Service, which is the substrate for today's *Lightweight Directory Access Protocol* (LDAP) Directory Services. Perhaps the most enduring legacy of the ISO-OSI work is the use of the "layered stack" conceptual model of network architectures. These days we refer to "Layer 2 Virtual LANs (VLANs)" and "Layer 3 Virtual Private Networks (VPNs)" perhaps without appreciating the innate reference to this layered stack model.

Of course the ISO-OSI protocol suite was not the only casualty of time. DECnet is now effectively an historic protocol, and Novell's *NetWare* has also shifted out of the mainstream of networking protocols. Perhaps it may be more instructive to look at those technologies that existed at the time that have persisted and flourished so that they now sit in the mainstream of today's networked world.

Ethernet has persisted, but today's Ethernet networks share little with the technology of the original IEEE 802.3 *Carrier Sense Multiple Access with Collision Detection* (CSMA/CD) 10-Mbps common bus network. The entire common bus architecture has been replaced by switched networks, and the notion of self-clocking packets was discarded when we moved into supporting Gbps Ethernets. What has persisted is the IEEE 802.3 packet frame format, and the persistence of the 1500-octet packet as the now universal lowest common factor for packet quantization on today's network. Why did Ethernet survive while other framing formats, such as *High-Level Data Link Control* (HDLC), did not?

I could suggest that it was a triumph of open standards, but HDLC was also an open standard. I would like to think that the use of a massive address space in the Ethernet frame, the 48-bit *Media Access Control* (MAC) address, and the use since its inception of a MAC address registry that attempted to ensure the uniqueness of each Ethernet device were the most critical elements of the longevity of Ethernet.

Indeed not only has UNIX persisted, it has proliferated to the extent that it is ubiquitous, because it now forms the foundation of the Apple and Android products. Of the plethora of operating systems that still existed in the late 1980s, it appears that all that have survived are UNIX and Windows, although it is unclear how much of Windows 2.0 still exists in today's Windows 7, if anything.

And perhaps surprisingly TCP/IP has persisted. For a protocol that was designed in the late 1970s, in a world where megabits per second was considered to be extremely high speed, and for a protocol that was ostensibly experimental, TCP/IP has proved to be extremely persistent. Why? One clue is in the restrained design of the protocol, where, as we have noted, TCP/IP did not attempt to solve every problem or attempt to be all things for all possible applications. I suspect that there are two other aspects of TCP/IP design that contributed to its longevity.

The first was a deliberate approach of modularity in design. TCP/IP deliberately pushed large modules of functions into distinct subsystems, which evolved along distinct paths. The routing protocols we use today have evolved along their own paths. Also the name space and the mapping system to support name resolution has evolved along its own path. Perhaps even more surprisingly, we have had the rate control algorithms used by TCP, the workhorse of the protocol suite, evolve along its own path.

The second aspect is use of what was at the time a massively sized 32-bit address space, and an associated address registry that allowed each network to use its own unique address space. Like the Ethernet 48-bit MAC address registry, the IP address registry was, in my view, a critical and unique aspect of the TCP/IP protocol suite.

Failures

What can we learn from the various failures and misadventures we have experienced along the way?

Asynchronous Transfer Mode (ATM) was a technology that despite considerable interest from the telephone operators proved to be too little too late, and was ultimately swept aside in the quest for ever larger and ever cheaper network transmission systems. ATM appeared to me to be perhaps the last significant effort to invest value into the network through allowing the network to adapt to the various differing characteristics of applications.

The underlying assumption behind this form of adaptive networking is that attached devices are simply incapable of understanding and adapting to the current state of the network, and it is up to the network to contain sufficient richness of capability to present consistent characteristics to each application. However, our experience has been quite the opposite, where the attached devices are increasingly capable of undertaking the entire role of service management, and complex adaptive networks are increasingly seen as at best meaningless duplication of functions, and at worst as an anomalous network behavior that the end device needs to work around. So ATM failed to resonate with the world of data networking, and as a technology it has waned. In the same way subsequent efforts to equip IP networks with *Quality of Service* (QoS) responses, or the much-hyped more recent *Next-Generation Networking* (NGN) networking efforts have been failures, for much the same basic reasons.

Fiber Distributed Data Interface (FDDI) also came and went. Rings are notoriously difficult to engineer, particularly in terms of managing a coherent clock across all attached devices that preserves the circumference of the ring, as measured in bits on the wire. From its earlier lower-speed antecedents in the 4-Mbps token, the 100-Mbps FDDI ring attracted considerable interest in the early 1990s. However, it was in effect a dead end in terms of longer-term evolution—the efforts to increase the clock speed required either the physical diameter of the ring to shrink to unusable small diameters or the clock signal to be locked at extraordinarily high levels of stability that made the cost of the network prohibitive. This industry appears to have a strong desire for absolute simplicity in its networks, and even rings have proved to be a case of making the networks too complex.

Interestingly, and despite all the evidence in their favor, the industry is still undecided about open technologies. TCP/IP, UNIX, and the Apache web platform are all in their own way significant and highly persuasive testaments to the power of open-source technologies in this industry, and a wide panoply of open technologies forms the entire foundation of today's networked environment. Yet, in spite of all this accumulated experience, we still see major efforts to promote closed, vendor-specific technologies into the marketplace. Skype is a case in point, and it is possible to see the iPhone and the Kindle in a similar light, where critical parts of the technology are deliberately obscured and aspects of the device behavior are deliberately sealed up or occluded from third-party interception.

The Next Twenty-Five Years

In wondering about the next 25 years, it may be interesting to look back ever further, to the early 1960s, and see what, if anything, has proved to be enduring from the perspective of the past 50 years. Interestingly, it appears that very little of that time, except for the annoying persistence of Fortran, and the ASCII keyboard as the ubiquitous input device, is still a part of today's networked environment. So over a 50-year time period much has changed in our environment.

But, interestingly, when we par down the period to the past 25 years, there is still much that has survived in the computing and networking environment. A Macintosh computer of the late 1980s looks eerily familiar, and although today's systems are faster, lighter, and a lot less clunky, there is actually very little that has changed in terms of the basic interface with the user. A Macintosh of that time could be connected to an Ethernet network, and it supported TCP/IP, and I suspect that if one were to resurrect a Mac system from 1988 loaded with *MacTCP* and connect it to the Internet today it would be frustratingly, achingly slow, but I would like to think that it would still work! And the applications that ran on that device have counterparts today that continue to use the same mechanisms of interaction with the user.

So if much of today's world was visible 25 years ago, then where are the aspects of change? Are we just touching up the fine-point details of a collection of very well established technologies? Or are there some basic and quite fundamental shifts underway in our environment?

It seems to me that the biggest change is typified in today's tablet and mobile phone computers, and in these devices it is evident that the metaphors of computing and interaction with applications are changing. The promise from 1968 in the film *2001: A Space Odyssey* of a computer that was able to converse with humans is now, finally, within reach of commodity computing and consumer products. But it is more than merely the novelty of a computer that can "talk." The constant search for computing devices that are smaller and more ubiquitous now means that the old paradigm of a computer as a "clever" but ultimately bulky typewriter is fading away. Today we are seeing modes of interaction that use gestures and voice, so that the form factor of a computer can become smaller while still supporting a functional and efficient form of interaction with the human user.

It is also evident that the pendulum of distribution and centralization of computing capability is swinging back, and the rise of the heavily hyped *Cloud*[5, 6] with its attendant collection of data centers and content distribution networks, and the simultaneous shrinking of the end device back to a "terminal" that allows the user to interact with views into a larger centrally managed data store held in this cloud, appears to be back in vogue once more.

It is an open question whether these aspects of today's environment will be a powerful and persistent theme for the next 25 years, or whether we will see other aspects of our environment seize industry momentum, so they are very much just a couple of personal guesses. Moore's Law has proved to be truly prodigious over the past 50 years. It has allowed us to pack what was a truly unbelievable computing capability and storage into astonishingly small packages and then launch them into the consumer market with pricing each year that appears to be consistently lower than the previous year.

If this property of packaging ever greater numbers of transistors into silicon chips continues for the next 25 years at the same rate, then it is likely that whatever happens in the next 25 years, the only limitation may well be our imagination rather than any intrinsic limitations of the technology itself.

Letter to the Editor

Dear Editor,

Who knew? Twenty-five years ago I started a tiny company that grew into Interop to spread the technical word about this funny thing we called *The Internet* and this really obscure thing called "TCP/IP." Back in the '70s, when the basic protocols were being created and experimented with, you were a high school kid in Norway and I was running a tiny group at SRI International and I let you use my machine across the ocean by using the ARPANET, the precursor to the Internet, because you seemed both smart and polite. Fifteen years later I decided to hire you to start a newsletter, *ConneXions—The Interoperability Report,* about the burgeoning Internet because of those properties and the perceived need to communicate monthly about the ins and outs of these simple but far-reaching technical protocols. You had the technical knowledge and good sense to enlist the brains of the real engineers in the field with real experience to further the knowledge of "all things Internet."

Who knew this would be still going on 25 years later? Your combination of passion and patience has produced an amazing record of ongoing expertise for the whole world to enjoy.

Thank you for being Ole!

—Dan Lynch
Founder of Interop
dan@lynch.com

Thank you, Dan!

I appreciate your very kind words. I also want to take this opportunity to thank all of the contributors to this journal. We could not do this without you!

CONNEXIONS
The Interoperability Report
January 1990 Volume 4, No. 1
ConneXions—
The Interoperability Report tracks current and emerging standards and technologies within the computer and communications industry.
In this issue:
Components of OSI: The Application Layer Structure 2
Kerberos 10
New Publication 14
Book Review 15
From the Editor
We begin 1990 and Volume 4 of ConneXions with yet another installment in our series Components of OSI. As you will have discovered by now, the articles have been presented in no particular order. Maybe some day when all the pieces are in, we can assemble them all into a special issue, which would actually be a small book on OSI. Meanwhile, this month's topic is the OSI Application Layer Structure (ALS), presented here by Marshall Rose and largely taken from his book The Open Book: A Practical Perspective on OSI.
Security continues to be an important topic for today's computer networks. The MIT Project Athena has developed the Kerberos authentication system. The system, which is rapidly gaining popularity in the Internet community, is described by one of its designers, Jeff Schiller, in an article on page 10.
Security, or perhaps lack thereof, was also what sent Clifford Stoll on a spy-chasing mission through a maze of computer networks around the world a couple of years ago. The story is told in his recently published book entitled The Cuckoo's Egg, and is highly recommended for anyone involved with network or system administration. We asked Jon Postel to review the book. See page 15.
We are pleased to announce that Richard desJardins has joined Advanced Computing Environments as Vice President of program development. Dick has been involved in the OSI standardization process from the very beginning. Prior to joining ACE, he spent six years with Computer Technology Associates as chief engineer and a senior technical consultant in areas of distributed computing, network and protocol design, and space data systems. He has taught several courses on OSI, and will continue to do so for our Internetworking Tutorial series. As our certified in-house OSI expert, Dick will undoubtedly be called upon by yours truly to contribute to ConneXions from time to time.
Advanced Computing Environments will be offering an extensive set of courses in our 1990 Internetworking Tutorials program. There are over 20 tutorials to choose from, and courses will be offered at four different locations and dates throughout 1990. The first set of tutorials will take place in Los Angeles, California from January 29 through February 1, 1990. For a complete course program, call Advanced Computing Environments at 415-941-3399 or Fax us at 415-949-1779.
ConneXions is published monthly by Advanced Computing Environments, 480 San Antonio Road, Suite 100, Mountain View, California 94040, USA. Phone: 415-941-3399. Fax: 415-949-1779.

Call for Papers 31
From The Editor
Depletion of the IPv4 address space and the transition to IPv6 has been a "hot topic" for several years. In 2011, interest in this topic grew considerably when the Asia Pacific Network Information Centre (APNIC) became the first Regional Internet Registry (RIR) to start allocating addresses from its final /8 IPv4 address pool. Although depletion dates are difficult to predict accurately, there is no question that the day will come when it will no longer be possible to obtain IPv4 space from the RIRs. News stories about IP addresses being sold for considerable sums of money are becoming more common.
Numerous organizations have been working diligently to promote, test, and deploy IPv6 through efforts such as the World IPv6 Day, while the Internet Engineering Task Force (IETF) continues to develop solutions to aid in the transition. One such effort, the Port Control Protocol (PCP), is described in our first article by Dan Wing.
The Internet Corporation for Assigned Names and Numbers (ICANN) will soon begin accepting applications for new Top-Level Domains (TLDs). It is not yet known how many new TLDs will eventually be deployed, but the plans have prompted several studies focused on the resiliency and scalability of the Domain Name System (DNS). Bill Manning discusses some of the technical challenges associated with a vastly expanded TLD space.
The IETF Homenet Working Group "...focuses on the evolving networking technology within and among relatively small 'residential home' networks. For example, an obvious trend in home networking is the proliferation of networking technology in an increasingly broad range and number of devices. This evolution in scale and diversity sets some requirements on IETF protocols." Geoff Huston gives an overview of some of the challenges facing this Working Group.
The product of the IETF is a set of documents, mainly protocol specifications and related material. These documents start life as Internet Drafts and proceed through a series of iterative refinements toward eventual publication as Request For Comments (RFCs). Over time, several tools have been developed to aid in the document development process, and they are now organized at the IETF Tools webpage. We asked Robert Sparks to give us an overview of some of the most important tools and the process involved in their development.

Fragments

NIXI to Run New NIR in India

March saw the launch of a new *National Internet Registry* (NIR) for India, following the successful conclusion of talks between the *Asia Pacific Network Information Centre* (APNIC) and the Government of India.

The *Indian Registry For Internet Names And Numbers* (IRINN) will be run by the *National Internet Exchange of India* (NIXI) and serve ISPs within the country that wish to sign up. It is the result of a long collaboration between APNIC and NIXI, with APNIC staff sharing their expertise with NIXI, and NIXI officials putting together an impressive technical installation in preparation for the launch. The new registry was announced on the final day of APNIC 33, a technical conference conducted in conjunction with the *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT 2012).

APNIC Executive Council Chairman, Akinori Maemura said of the announcement, "We are extremely happy that this process is heading towards a positive conclusion; which, on the other hand, is also a commencement of a new relationship. I would like to thank the NIXI team for their support and the hard work they have demonstrated in making this a reality."

Director General of APNIC, Paul Wilson commented, "We welcome the new National Internet Registry in India to the APNIC community. The Internet is a global community and IRINN, as the NIR is being called, should be part of that. I hope that many new Internet Services Providers will be formed in India, and they will always be able to choose between IRINN and APNIC for IP addresses. The market here is big enough and that kind of diversity will ensure better services and lower prices for all Indians."

APNIC has over 300 members locally, mostly Internet Services Providers and Telecommunication Communications companies, and over 6 million *Internet Protocol version 4* (IPv4) addresses were allocated in 2011. There are already 6 National Internet Registries in Asia in South Korea: (KISA KRNIC), Japan (JPNIC), China (CNNIC), Indonesia (IDNIC), Vietnam (VNNIC) and Taiwan (TWINIC). This is out of 56 economies in the Asia Pacific region.

"It's really about what is a better fit for the individual organizations. Typically we tend to see larger organizations prefer a regional service, especially those who operate in multiple economies to maintain an account with APNIC," said Paul Wilson.

NIXI is a not-for-profit organization, set up for peering of ISPs among themselves for the purpose of routing domestic traffic within India, instead of routing it through international peering points, thereby resulting in reduced latency and reduced bandwidth charges for ISPs. NIXI is managed and operated on a neutral basis, in line with the best practices for such initiatives globally.

Internet Hall of Fame Advisory Board Named

The *Internet Society* (ISOC) recently announced that in conjunction with its 20th anniversary celebration, it is establishing an annual *Internet Hall of Fame* program to honor leaders and luminaries who have made significant contributions to the development and advancement of the global Internet.

Inaugural inductees will be announced at an Awards Gala during the ISOC's *Global INET 2012* conference in Geneva, Switzerland, April 22–24, 2012, **www.internetsociety.org/globalinet**

"There are extraordinary people around the world who have helped to make the Internet a global platform for innovation and communication, spurring economic development and social progress," noted ISOC CEO Lynn St. Amour. "This program will honor individuals who have pushed the boundaries to bring the benefits of a global Internet to life and to make it an essential resource used by billions of people. We look forward to recognizing the achievements of these outstanding leaders."

ISOC has convened an Advisory Board to vote on the inductees for the 2012 Internet Hall of Fame inauguration. The Advisory Board is a highly-qualified, diverse, international committee that spans multiple industry segments and backgrounds. This year's Advisory Board members include:

- Dr. Lishan Adam, ICT Development Researcher, Ethiopia
- Chris Anderson, Editor-in-Chief, *WIRED Magazine*
- Alex Corenthin, Directeur des Systemes d'Information, University Cheikh Anta Diop of Dakar/Chair, Internet Society Senegal Chapter
- William Dutton, Professor of Internet Studies, Oxford Internet Institute
- Joichi Ito, Director, MIT Media Lab
- Mike Jensen, Independent ICT Consultant, South Africa
- Aleks Krotoski, Technology Academic/Journalist/Author
- Loic Le Meur, Founder & CEO, LeWeb
- Mark Mahaney, Internet Analyst, Citigroup
- Dr. Alejandro Pisanty, Professor at National University of Mexico/ Chair of Internet Society Mexico Chapter
- Lee Rainie, Director, Pew Research Center's Internet & American Life Project
- Jimmy Wales, Co-founder, Wikipedia

"We are extremely grateful to our distinguished Advisory Board members who have donated their time, energy, and expertise to this program," St. Amour added. "The breadth of their experiences and the diversity of their perspectives are invaluable, and we truly appreciate their participation."

The Internet Society is the trusted independent source for Internet information and thought leadership from around the world. With its principled vision and substantial technological foundation, the Internet Society promotes open dialogue on Internet policy, technology, and future development among users, companies, governments, and foundations. Working with its members and Chapters around the world, the Internet Society enables the continued evolution and growth of the Internet for everyone.

From The Editor

Deployment of IPv6 took another step forward on June 6, 2012, when numerous website operators, *Internet Service Providers* (ISPs), and home router vendors participated in the *World IPv6 Launch*. Organized by the Internet Society, the event attracted significant media attention as the participants enabled IPv6 permanently and rendered it "on by default." More information about the event is available from www.worldipv6launch.org

Migration to IPv6 is not a simple task, as outlined in many previous editions of this journal. Various tools and techniques have been developed, one being the use of so-called *Carrier-Grade NATs* whereby the end customers connect to the Internet using private (RFC 1918) addresses and the ISP provides translation for both public IPv4 and IPv6 addresses. In April of this year, the *Internet Engineering Task Force* (IETF) approved and the *Internet Assigned Numbers Authority* (IANA) allocated a new IPv4 address block (100.64.0.0/10), designated for use as "Shared Transition Space" in support of the IPv6 transition. We asked Wesley George to describe the rationale behind the use of this additional private address space and discuss the debate that resulted from this allocation.

The world of telecommunications has changed dramatically as a result of the rapid expansion of the Internet. Traditional telephone lines are being replaced by *Voice over IP* (VoIP) systems for both private and business use. These changes represent big challenges for traditional telephone carriers, and even for some countries whose income used to depend largely on telephone "settlement charges" for international phone calls. The *World Conference on International Telecommunications* (WCIT) will take place this coming December in Dubai. Geoff Huston discusses some of the proposed changes to the *International Telecommunication Regulations* that could affect the Internet in various ways and will be discussed at WCIT.

The IETF is concerned not only with IPv4-to-IPv6 migration, but also with recovery upon router or link failure. In our final article, Russ White describes *IP Fast Reroute,* a technique for providing fast traffic recovery when these failures occur.

As always, your feedback about anything you read in this journal is most appreciated. Please contact us at ipj@cisco.com and don't forget to renew your subscription and provide us with any postal or e-mail changes.

Shared Transition Space: Is it necessary?

by Wesley George, Time Warner Cable

Recently, the *Internet Engineering Task Force* (IETF) approved[1] and the *Internet Assigned Numbers Authority* (IANA) allocated[2] a new IPv4 address block (`100.64.0.0/10`) designated for use as "Shared Transition Space" in support of the IPv6 transition. This decision was highly controversial within the different standards and policy bodies that discussed the idea. The author would like to note that people have been debating this topic for years, and nearly everyone within the broad stakeholder community seems to have a strong opinion on the matter, including me. Despite the best of intentions, some of my opinions and biases may appear within the article. I did not intend this article to be a definitive conclusion on the matter, but rather a summary of the recent discussion. Whether the standards bodies involved came to the "right" or "wrong" conclusion—as well as the veracity of the arguments on both sides—is an exercise for you, the reader.

Internet Service Providers (ISPs) and users have significant investments in equipment and applications that must be updated to support IPv6. Progress is accelerating with regard to IPv6 availability in hardware, software, and access, though broad availability remains a long-term problem. In the interim, IPv4 will continue to be an important capability for providing users with access to Internet resources. As a consequence, considerable effort has been expended in conserving the increasingly scarce IPv4 resources while maintaining "business as usual." This conservation has taken the form of policies for address allocation and management[3], as well as new protocols and technologies. It is likewise important to note that ISPs must manage IPv4 exhaustion in a way that is least disruptive to users while undertaking full IPv6 deployment—two completely different and parallel activities. Any business that relies entirely on efforts to extend the useful life of IPv4 without executing on an IPv6 deployment plan is merely delaying the inevitable effects on their customers and ultimately their profitability.

IPv4 "life extension" is an area that remains controversial. Some believe that any effort to extend the useful life of IPv4 and allow the IPv4 Internet to keep growing beyond its original design limitations will seriously affect the timeliness of reaching critical mass with IPv6. The idea that many opponents of the "life-extensions" methods are supporting is that IPv4 exhaustion and the resulting transition from IPv4 to IPv6 is going to be disruptive to customers and operations no matter when it actually occurs. From this perspective it is preferable to have a brief—but significant—disruption and transition completely to IPv6. This plan is akin to the idea that it is better to just rip the bandage off and have a moment of pain than removing it slowly in an attempt to reduce the pain.

The counterpoint to this argument is that we must look at the situation pragmatically with the goal of maintaining business continuity, growth, and customer satisfaction.

IPv4 Exhaustion

The impending IPv4 address exhaustion[4] and the problems it will create has been the topic of much discussion in many different areas of the Internet community. The need to deploy IPv6 has figured prominently in the discussion, because it is the proper long-term solution. However, the unfortunate reality is that deploying IPv6 is a parallel activity to any work that provides continuity to the existing IPv4 network in order to keep it operational and able to grow to meet demand. As an Internet community, we are not where we need to be in terms of critical mass of our IPv6 deployments, in terms of either available, deployed equipment that supports IPv6 fully or applications that are able to use IPv6 when it is available.

IPv6 deployment is a requirement, but most ISPs do not have control over all variables affecting IPv6 deployment, and they have limited influence on progress outside of their network boundaries. This reality is especially true with residential services, where customers often purchase IP-enabled hardware directly from retailers to connect to their home networks. Consumers generally do not care about whether a device supports IPv4 or IPv6, so they do not make purchasing decisions based on such features. Customers should not be required to be technology experts in order to get their devices to work properly for their intended use. Customers generally are not interested in their ISP dictating the equipment that they may use in their home, and they do not like being told that they must replace "obsolete" gear, especially if they purchased it recently. The service provider sells "Internet" service, so customers expect their "Internet" devices to work—period. As a result, if an ISP wants to continue to grow, that ISP must continue to offer IPv4 services until the existing equipment without IPv6 support ages out of the network and is replaced.

The IETF recently released a *Best Current Practice* (BCP) document[5] that provides some guidance for implementers that support for IPv6 on "IP-capable" devices is going to be a necessity, and the *Consumer Electronics Association* (CEA) now has a working group on IPv6 Transition[6]. In conjunction with events like *World IPv6 Launch*[7], there are near-constant improvements in the availability of IPv6-capable hardware, software, access, and services. The result of this situation should be that critical mass of IPv6 deployment will happen soon and reduce reliance on IPv4 and IPv4 life-extension technologies.

Because of the costs, operational complexities, performance concerns, and effects on customers that most IPv4 life-extension technologies create, service providers should focus on reaching IPv6 critical mass in essential areas.

When IPv6 has become sufficiently ubiquitous, the need for IPv4 life-extension technologies will be reduced along with the scale of deployments. Because a lot of the costs of deploying IPv4 life-extension technologies are initial costs, there is some truth to the argument that after they are deployed they are unlikely to disappear anytime soon. Why would a carrier invest significant time and money in deploying something only to pull it back out a short time later? Therefore the best method to reduce the cost of *Carrier-Grade NAT* (CGN) deployment is to work to deploy less of it.

ISPs are different when it comes to their expectations for growth, and their IPv4 addressing reserves or consumption rates differ accordingly. Some have areas of their internal network where they can make changes and reclaim globally unique IPv4 addresses for reuse to support customers, some have addresses that can be reclaimed via auditing and improved efficiency of allocation, and still others have already undertaken many of these projects and do not have much address space left to reclaim. Further, new IPv4 address availability as a combination of policies and demand may be different for each *Regional Internet Registry* (RIR). To summarize, the need for IPv4 address life-extension technologies is different on each network. The costs of deploying, the complexity of supporting, and the growth rate all figure into how widely service providers will have to deploy one or more technologies to extend their remaining IPv4 resources.

NAT444

Network Address Translation (NAT)[28, 30] is already widely used for translating one IPv4 address to another, usually to provide separation or address sharing between a private network with multiple hosts and a public network or the Internet. In the context of IPv4 and IPv6 transition, these types of NAT are commonly referred to as *NAT44,* because they translate between IPv4 and IPv4 (vs. IPv4 to IPv6, IPv6 to IPv6, etc.). There is a proposed extension to NAT intended to preserve even more IPv4 resources. This proposal is called *Carrier-Grade NAT* (CGN)[8]. The "Carrier Grade" in the name originates from the position of the NAT within the topology. Instead of NAT between a private and public network at the edge of a single network such as a home or business office, CGN is implemented inside of an ISP's network and serves many customers simultaneously. These CGN implementations are typically scaled to handle thousands of simultaneous customer endpoints, often resulting in millions of simultaneous sessions. The RFC[8] does not advocate the use of CGN; it describes how an ISP forced to deploy CGN can use it during IPv6 transition.

This sort of implementation addresses the need for an individual, globally unique IPv4 address for each of the ISP's customers by allowing the ISPs to allocate each customer an IPv4 address that may not be globally unique and employ NAT to give them access to resources on the IPv4 Internet.

This sharing often allows ISPs to see oversubscription of public IPv4 addresses anywhere from 2:1 to more than 10,000:1 based on the type of applications behind the NAT and their simultaneous application layer port allocations and session counts. Most commonly, a CGN is used in conjunction with a local NAT on the customer's home network, creating two layers of NAT to traverse between the home network and the Internet. This model is commonly referred to as *NAT444,* because there is a translation layer between three sets of IPv4 addresses end to end.

A known problem with NAT is that it makes end-to-end communication and visibility between hosts more difficult, because it essentially hides hosts behind address translation. Because NAT is so common (nearly every home network and many commercial networks use NAT), networking applications have adapted so that they can discover the presence of a NAT and then change their behavior in order to maintain communications in the presence of NATs. However, the addition of this second layer of NAT often interferes with those workarounds, and undesirable or unpredictable results may occur[9].

Over time it is likely that applications will again adapt to the impediments created by multiple layers of NAT, but it is not possible to anticipate and correct every potential problem that may be generated by adding this second layer of NAT. This reality should serve as a warning to those who provide services over an Internet connection: IPv6 support is extremely important. IPv6 is important because CGN means that ISP-controlled equipment will be actively involved in the path between content or application providers and their end users, making that relationship reliant on the service provider and the service provider's CGN vendor to an extent that was not necessary in the past. If the CGN implementation breaks something, it not only reflects on the CGN vendor and the service provider, it also reflects poorly on the relationship between the end customer and the service that that customer is using—and may cause that customer to form a negative opinion of the brand itself.

In other words, if a consumer uses an Internet-enabled application on a new Brand X smart TV and it does not work well, regardless of whether it is a problem with the CGN, the service provider, or something else entirely, the consumer may form the opinion and share via an online review that, "Brand X's TVs are ok, unless you try to use any of their fancy new features. I would not buy one if I were you, because Company X clearly does not know what it is doing." CGN represents a potentially significant increase in the amount of testing that must be done, especially in implementations that are uncommon, such as small, corner-case deployments, and closed architectures. Although using IPv6 is dependent on support at the client, the content or application provider, and the ISPs in between, if this support is present, it allows the content or application provider and client to bypass the service provider's CGN machinery—as well as any IPv4 NAT that may be present—and have a true end-to-end connection. This scenario restores control over the user experience back to the brand, and allows the ISP to resume supplying bit carriage.

IPv4 Addressing Requirements

Independent of the potential connectivity problems that NAT444 may create, it generates additional problems for the implementing ISP because of its need for IPv4 addresses. Because the CGN requires two sets of addresses—one for the inside (private) network and one for the outside (public) network—the ISP must identify address ranges to use for both. In order for its customers to be able to reach the Internet, the external pool must use globally unique IPv4 addresses. The number of addresses required will depend on the implementation of CGN, its scale profile, the topology of the network (how many hosts are behind each CGN instance), and the usage profile of the customer traffic. If the service provider has few or no available globally unique IPv4 addresses, it will have to either make changes in its network in order to reclaim addresses from elsewhere or make a request for a new allocation from its RIR[29].

However, depending on the number of addresses that the RIR has available and its policies for justification, it may not be possible to obtain sufficient address space with this method. For example, in the Asia-Pacific region, the austerity policies in place mean that no matter how many IPv4 addresses they might have been able to justify using previous rules, most requesters are eligible for only a few hundred IPv4 addresses as their final allocation ever[10]. This situation then requires the ISP to source IPv4 addresses via the IPv4 address transfer market[11], adding additional cost to an already expensive deployment. In fact, if the service provider must source addresses via the transfer market, it may be more cost-effective to simply obtain more addresses and continue with business as usual without deploying CGN at all.

Internal Pool: Private Addressing Alternatives

When addresses are sourced for the public address pool, the service provider must also identify a pool of private addresses that is large enough for the provider to allocate one to each customer behind the CGN. Depending on the size and scale of the CGN, and how much the service provider is willing to segment and separate different sections of its network, this number could be a large block of addresses, perhaps even a `/8` or more.

The most obvious choice might be to simply use address ranges reserved for private network use[12], because there is a `/8`, a `/12`, and a `/16` available for this purpose. However, this address space has some drawbacks. First, because of the prevalence of RFC 1918 addressing within most enterprise networks, there is a significant chance that the chosen address blocks may conflict with existing use of RFC 1918 space for management systems and other internal resources. Depending on the size of the CGN implementation, it may be necessary to instantiate multiple segments of the network where the entirety of RFC 1918 space is used, and in order for those segments to talk to one another or to talk to devices with conflicting numbering, significant additional complexity is required.

On the customer side, remote workers could experience problems where the address that they have been assigned is in a block that is already in use on their company's enterprise network, meaning that it may cause problems connecting to those hosts via a *Virtual Private Network* (VPN), or problems accessing some of the resources from the remote network. It may be possible to change the address assigned to the end user in an attempt to eliminate this conflict, but this approach is not necessarily scalable because it likely requires manual intervention in an automated address-assignment system, and there are limits to the number of times that a change of address can "fix" this problem without creating a problem for another user.

The other problem with the use of RFC 1918 space in the CGN is that it may conflict with the address space used by the customer's local network and NAT. For example, if a customer has a local network numbered out of `192.168.1.0/24` and the customer's router is allocated the external address of `192.168.1.85`, the router may fail to function properly because it has the same address range on both the internal and external interface. It may be possible through analysis to identify and carefully allocate addresses so that the portions of RFC 1918 commonly used by default in home gateway devices are not allocated. However, anecdotal evidence[13] suggests that because of the wide variety of devices and implementations available—plus the fact that many users reconfigure their networks to use a different IP address range than the default configuration of the device—there simply may not be enough RFC 1918 addresses not in use to make this option viable.

"Squat" Space

Another alternative is to unofficially reuse one or more portions of the existing range of allocated globally unique IPv4 addresses as private addresses. In a network that does not talk directly to the Internet, such as a private network or VPN, the existing allocations of IPv4 space do not have any meaning, and so it is not strictly necessary to stick to RFC 1918 address space for numbering resources that are only internally accessible. Reuse of allocated IPv4 addresses has the benefit of not conflicting with in-use RFC 1918 addresses, but comes with its own set of problems. If the provider's own space is reused, the provider must carefully separate the private use from the public use to avoid conflicts, and managing this overlap may require additional complexity such as the use of VPNs as a method to separate the networks. The more common method is to reuse a block of addresses that is not currently allocated to the network using them; in other words, squatting on "someone else's" address space. Usually providers select space to use in this manner based on a low likelihood that either the owner will begin announcing the space on the global Internet or the users behind that network will need to connect to the users behind the ISP's NAT.

This method requires extreme care. The service provider must ensure that the routes for those prefixes are not inadvertently leaked to the global Internet, because such a leak could potentially cause a route-hijack denial-of-service attack, albeit an unintentional one. This method is even more risky if the ISP has one or more partners who have connections into the private portion of its network, because it may not have complete control of the announcement boundaries. Certainly there are safeguards such as tagging the announcements with *Border Gateway Protocol* (BGP) communities such as no-advertise or no-export[14], but these solutions are not always practical, and they are not completely fail-safe. Depending on the chosen address space, the effects could be significant based on the true owner of that space—no service provider really wants to risk a public relations nightmare because it inadvertently caused an outage affecting the critical infrastructure of a large government agency or multinational corporation whose space it "borrowed" and then leaked to the Internet.

As a result of the IPv4 transfer market, it is quite likely that some of the address blocks that are not visible on the global Internet today and that some consider "safer" to squat on may end up being transferred to another party who plans to begin using them on the public Internet, and potentially requiring those squatting on the space to renumber to a different address block. ISPs can mitigate this risk somewhat by selecting multiple candidate blocks that are all preconfigured in the network such that it is relatively straightforward to make a rapid change from one block to another if the current block in use suddenly becomes unacceptable. Many ISPs use this method today, but because of the risks, it cannot be considered a real solution to the problem. Further, because it essentially encourages large service providers to violate the spirit—if not the letter—of the very policies that govern IP address allocation and use, standards bodies such as the IETF or policy organizations like RIRs cannot officially recommend such a solution.

Class E Addresses

A final alternative is to repurpose the reserved space in `240/4`[2] and make it available for this use. There have been several failed attempts to repurpose this reserved space within the IETF in the past few years[15, 16]. The primary challenge with this alternative is that because the Class E space has been reserved for many years, many networking implementations are explicitly configured to reject this address space as invalid. Getting this problem fixed in software, and more importantly, getting those software upgrades deployed widely, may require a similar level of effort to that which is required to deploy IPv6, and deploying IPv6 would be a more effective use of the resources required to implement software and hardware changes.

Even in situations like a CGN where more of the implementation is under central control, this solution would be attractive only to a service provider that owns and operates the *Customer Premises Equipment* (CPE) routers for all of its customers such that it could work with a small number of vendors to get software patches to enable use of this space. Therefore this solution is also too limited in applicability to be seen as a general solution that a body like the IETF could recommend.

Shared Addresses

Although the solutions previously discussed may be acceptable in some applications, the risks and deficiencies make it necessary for other applications to find another source for the IP address blocks to be used on the private side of a CGN. It is possible to use "public" (globally unique) IPv4 addresses on the private side as well, but the challenges to obtaining additional public IPv4 addresses that were discussed previously are exacerbated by the even larger number of addresses required, so this solution is far from practical. Additionally, expecting each service provider that implements CGN to obtain its own address space for its inside pools would end up using a significant amount of the remaining IPv4 resources in a way that does not necessarily require globally unique addresses. However, because each service provider has different needs, growth rates, and applications, it is unclear that simply expecting each service provider to request space from the RIRs for its internal CGN pools would create a doomsday scenario where a few networks would use up all of the remaining available IPv4 space in a short time. Because CGN creates additional costs and complexity to implement and support, and could be viewed as "second-class" IPv4 service, most service providers are not likely to implement it across the entire network and all tiers of customers, instead preferring to implement it only as widely as absolutely necessary.

Service providers could choose to implement it only for net new customers (that is, growth above turnover); they could choose to implement it only in certain markets or for certain types of service where it is less likely to cause support problems and adversely affect the service. All of these things reduce the number of addresses that may be needed for the interior CGN address pool. Nevertheless, using globally unique addresses in an application that does not require unique addresses is not a good use of a very limited resource. That is why the idea of having a shared and reserved block of addresses specifically for use as an interior (private) pool on a CGN keeps resurfacing.

One alternative to formally reserving a shared transition space was to have a third party request a block of sufficient size from one or more of the RIRs and then make it available for use as a shared block by anyone who wishes to do so.

Given the "last /8" policies in effect at each of the RIRs, it would likely be quite difficult to justify sufficient space to be useful, and the cost involved in receiving and maintaining such a delegation would likely be prohibitive. There would also be challenges addressing potential abuse concerns.

Reserving a block via the standard IETF/IANA process meant that IETF would have a chance to document the problems and recommend best practices that must be considered when implementing something that uses this shared space. This policy would help to ensure that service providers and implementers are aware of these guidelines and recommendations. For example, many implementations make certain assumptions about address scope based on the address itself, such as assuming that RFC 1918 addresses are locally scoped, and then adapt their behavior accordingly. With things like squat space or an unofficially shared CGN space, implementers would not know that this space should be treated in a specific way, and the result may be more network breakage. The officially declared shared space must still wait for implementers to make changes to their products, and that may not always happen, but the chances are still better than if it had been done in an unofficial manner.

As you can probably see, this problem does not have a clear-cut and straightforward solution, and this situation has led to vigorous discussion within the standards and policy bodies that have discussed it. The next section gives a brief history of the activity in those bodies that ultimately led to the space being allocated.

Some History

Shared transition space proposals have been controversial each time a variant of the idea has come up for discussion. As IPv4 exhaustion became a reality and IPv6 deployment continued to lag, more people realized that IPv4 life-extension technologies such as CGN may be a necessary evil. When people saw CGN as a likely response to the gap between IPv4 exhaustion and wide IPv6 support, they began to understand the need for the shared transition space, and thus support for allocating that space has gradually grown.

Although variants of this discussion may be much older than the items discussed in the following paragraphs, this article focuses specifically on the history of the idea to allocate shared address space specifically for CGN. There was an unsuccessful proposal in 2005[17] to update RFC 1918 with an additional three /8s, but this proposal was not specifically focused on CGNs, unlike some of the other proposals. The most recent set of proposals regarding shared CGN space first came up in the APNIC Policy *Special Interest Group* (SIG) in early 2008, where Policy Proposal 058 was discussed. APNIC members abandoned the proposal and recommended that the authors take the idea to the IETF, because that is the body that typically directs IANA to reserve IP address blocks for special uses such as this one[18].

This recommendation resulted in a pair of Internet drafts[19, 20], hereafter referred to as **shirasaki** in late 2008. The draft originally requested four /8s, with a minimum size of a /12, but subsequent revisions of the draft revised the request to only one /10. The draft never gained much traction within the IETF, but the authors continued to update it to keep the discussion going. In mid-2010, a second IETF draft[21] was published, requesting that a full /8 be reserved for this purpose. It contained references to the **shirasaki** drafts, but provided additional justification and noted that a /10 may not be enough addresses for many of the large service providers.

The draft went through several revisions in the following months, eventually being replaced by a different draft[22], hereafter referred to as **draft-weil**, which reduced the /8 requested down to a /10. Attendees of the IETF 79 meeting in Beijing, China, discussed the draft across two different working groups. People expressed strong opinions both in support of and in opposition to the idea, but the draft did not achieve clear consensus. With the future of the draft unclear, one of its authors submitted policy proposal 127 to the *American Registry for Internet Numbers* (ARIN)[23]. The ARIN *Advisory Council* (AC) accepted this policy proposal as draft policy 2011-5[24] in early 2011, and vigorously discussed it with participants at the ARIN XXVII public policy meeting and with members of the mailing list. At the conclusion of the discussion, the ARIN AC recommended the policy to the ARIN board for adoption.

This discussion took on additional urgency because during this time the IANA officially announced that it had exhausted the free pool of IPv4 addresses and delegated the last of the /8s to the RIRs in accordance with policy[4]. The side effect of this exhaustion meant that it was no longer possible for IETF to direct IANA to reserve space unless IANA was directed to repurpose an existing reservation, because it had no unreserved address blocks of sufficient size to meet the request. Therefore, the IETF and one or more of the RIRs would have to work in concert to make a suitable IPv4 address block available, instead of it being solely under IETF's purview. ARIN staff reached out to the IETF's *Internet Architecture Board* (IAB) for guidance, because by strict interpretation[25], ARIN was not authorized to make this allocation by itself. IAB reaffirmed this interpretation, and recommended that the matter be brought back to the IETF for (re)consideration[26]. With this guidance, the authors revised **draft-weil-shared-transition-space-request** and reintroduced it for discussion. For a period of time, the document was split into two, with most of the long-form discussion of pros and cons being moved to a second draft[27].

As of the publication date of this article, the secondary draft has expired without progressing, but most of the important information contained there was incorporated back into **draft-weil**. The document was not adopted by any IETF Working Group. Instead, an IETF Area Director sponsored it as an individual submission.

It went through its first IETF "Last Call" to gauge consensus and receive comments in August 2011. The subsequent discussion, revisions, and secondary last calls (October 2011 and January 2012) generated hundreds of messages on the IETF discussion list and a total of 12 versions of the document before it was approved for publication in February 2012.

The reason why the debate on this shared transition space was so spirited can be traced to a few critical concerns. First, although consensus-based RFCs documenting CGN[8] were already approved, this draft allocating space specifically to facilitate its deployment became a referendum within the IETF on whether NAT444/CGN should even be used. If you believed that NAT444 and CGN were bad ideas, it was likely that you would also be against a shared transition space. From that perspective, shared transition address space provided a more complete solution to a problem that had been created by a "Bad Idea" that should not have been allowed to proceed in the first place. There was also resistance to what was deemed "waste" of the limited remaining blocks of IPv4 addresses to solve a problem that not everyone agreed was a real or important problem. Also, although IETF participants do not speak for their companies per se, this proposal had consistent support from numerous individuals employed by large residential broadband providers. As a result, some saw it as those service providers looking for a way to bail themselves out of a problem that they created by not deploying IPv6 rapidly enough to avoid having to use CGN. On the converse side of the argument, those in favor saw CGN as a largely foregone conclusion, and saw this proposal as simply a practical solution to a real problem.

The *Internet Engineering Steering Group* (IESG) ultimately sent a note to the IETF discussion list acknowledging the difficulty of coming to a decision on this matter and noting that some explanatory text would be added to RFC 6598:

> "Colleagues,
>
> The IESG has observed very rough consensus in favor of the allocation proposed in **`draft-weil-shared-transition-space-request`**. Therefore, the IESG will approve the draft. In order to acknowledge dissenting opinions and clarify the IETF position regarding IPv6, the IESG will attach the following note:
>
> > "A number of operators have expressed a need for the special purpose IPv4 address allocation described by this document. During deliberations, the IETF community demonstrated very rough consensus in favor of the allocation.
> >
> > While operational expedients, including the special purpose address allocation described in this document, may help solve a short-term operational problem, the IESG and the IETF remain committed to the deployment of IPv6."

In many ways, the final decision came down to the difference between theory and practice in the IETF's desire to make the Internet work better. Theoretically, making a CGN easier to implement has the potential to make the Internet work much more poorly, and could be seen as rewarding bad behavior (failing to deploy and support IPv6 in a timely fashion). However, in practice, making CGN harder to implement causes unnecessary pain and effort for operators and potentially for users, while having little or no effect on IPv6 deployment. Approving this shared transition space avoids the appearance that IETF is trying to punish operators or users for perceived past "sins" and helps to reinforce the idea that IETF is responsive to operational concerns and therefore still relevant to the operator community. It is unlikely that the result of this decision will have much bearing on an operator's plan for how widely, when, where, or even if it will deploy CGNs, and this article makes no such recommendations. However, I will reiterate that IPv6 is the long-term solution, and that the smallest CGN deployment possible will make for a less complex and less expensive network for the continued support of traditional IPv4 devices.

Acknowledgements

Special thanks to Ole Jacobsen for suggesting that I write this article, to Kirk Erichsen and Jason Weil for their review and comments, and to all involved in the discussion of the referenced IETF drafts and ARIN policy for giving me plenty to write about!

December in Dubai: Number Misuse, WCIT, and ITRs

by Geoff Huston, APNIC

In November 1988, telephone companies from 178 nations sent their respective government representatives to the *World Administrative Telegraph and Telephone Conference* (WATTC) in Melbourne, Australia. At the time the generally cosy relationships between governments and their monopoly telephone companies often made it extremely difficult to see the difference between the government's representatives and those of the telephone company. The group resolved to agree to the rather grandly titled *International Telecommunication Regulations* (ITRs)[1].

At this meeting the companies' national representatives agreed to a set of additional regulations that supplemented the binding regulations of the *International Telecommunication Convention*. The goals of these regulations were rather grand; they aspired to promote the "harmonious development and efficient operation of technical facilities, as well as the efficiency, usefulness and availability to the public of international telecommunication services." More practically, these ITRs defined the general principles for the provision and operation of international telephony services among signatories to the ITRs.

At that time the Internet was little more than a somewhat obscure experiment in advanced data communication protocols undertaken by a small number of researchers in North America and to a far smaller extent in Europe. However, since 1988 the Internet—and the world in which the Internet has flourished—has changed dramatically. If we view the rise of the Internet over the past 25 years as a product of an appropriately liberalized international regulatory regime as much as it was a product of the titanic shifts in computing and communications technologies that also occurred over this period, then we can make the case that the Internet of today is a product of these ITRs. And what a prodigious product it has been!

In Dubai, between the 3rd and 14th of December 2012, the nations of the world will convene at the 2012 *World Conference on International Telecommunications* (WCIT)[2], and they intend to use this conference to review these 25-year-old ITRs and consider some proposed changes to this regulatory framework that underlie international telecommunications.

At the moment the international meeting cycle is ramping up to consider what aspects of the ITRs should be altered, what should stay the same, and what should be dropped. After all, much has happened in the past 25 years, and an argument could be made that the ITRs should be amended to better reflect today's world.

But the world is not exactly aligned at the moment about what should and what should not be folded into a new set of international regulatory obligations.

Some countries appear to be advocating for some quite specific measures to be added to the ITR to address what for them are characterized as otherwise unresolvable operational problems. Others are advocating a more general approach to have the ITRs explicitly embrace the Internet and fold references to the Internet in every place where specific carriage and service delivery technologies are referenced in the ITRs. It is when these two approaches intersect that the situation gets interesting.

In order to illustrate some of the underlying tensions that exist in this activity, I would like to take a specific example of a proposed amendment to the ITRs and consider in in terms of the broader context of telephony and the Internet.

The proposal I want to examine here concerns the topic that has been called "number misuse." In telephony this term referred to an operating practice where a call to a dialled number is not routed to the destination subscriber who is located at that called number, but instead the call is re-routed to a different destination.

What we see in the "Number Misuse" proposal for a revision of the ITRs is an attempt to fold the concepts of "number misuse" and the Internet together, with a result that some countries want the ITRs to explicitly take on the concept of "IP Address and Routing Misuse" within the framework of national obligations through common regulatory action within the same scope as the telephony called number misuse. If successful, this effort would result in a regulatory obligation for governments to take necessary actions to investigate and prosecute such instances of so-called "number misuse." The intended scope of such enforcement of such obligations would encompass not only the telephone network but also the Internet. Surely we all desire a global public communications network that operates with integrity, and surely we would want to see countries take the necessary actions to ensure that it happens. So why is this idea not exactly the best idea to appear in the ITR negotiation process so far?

Let's look at the motivations behind number misuse in the world of telephone carriers and telephone services, and then look at how it could conceivably map in to the world of the Internet.

To understand the telephone world and where this problem of number misuse is coming from, it may be useful to understand a little of how money circulates in the phone world.

Telephony: Sender Pays

In many ways the telephone leaned heavily on the telegraph service for its service model, which, in turn, leaned on the postal service, establishing a provenance for the telephone service model that stretched back over some centuries to at least the 1680s and London's Penny Post, if not earlier.

The postal service model that gained ascendency over the preceding centuries was one in which the original sender of the letter paid for the entire service of letter delivery. If the postal service that received the letter in the first place needed to use the services of a different postal service to complete the delivery, neither the sender nor the intended recipient were aware of it. The postal services were meant to divide the money received from the sender to deliver the letter, and apportion it between themselves to compensate each service provider for undertaking its part in the delivery of the letter.

The telephone service, for the most part, operates in a very similar fashion. The caller pays for the entire cost of the call, and the called party pays nothing.

When both the caller and the called party are connected to the same carrier, the process is straightforward. The carrier charges the caller for the cost of the call and, presumably, some small (often not so small) margin for profit.

However, when we apply the same model to, say, international phone calls, the model is not so simple. The common desire on the part of the telephone operators was to preserve the same simple model: the caller pays. Now in this case the caller pays the presumably higher price of establishing a voice circuit from a carrier in one country in one part of the world to another carrier in another country in another part of the world. But now the caller's carrier should not keep all the revenue associated with the call. The other end, the *terminating carrier,* has also incurred costs in servicing this call. The arrangement that the telephone industry developed was the concept of "intercarrier call accounting financial settlements."

To explain this concept it may be useful to introduce the unit of a *call minute,* which is commonly used as a means of measuring a telephone call. What carriers establish between themselves on a bilateral basis is the intercarrier settlement cost per call minute of a telephone call that originates in one carrier and is terminated by the other carrier.

Now if both carriers can establish a value of a call-minute settlement rate where in both directions the call-minute termination costs roughly equate to the call-minute settlement rate, then in theory, at any rate, neither party is relatively advantaged over the other, irrespective of whether the callers are predominately located in one carrier or in the other carrier. In theory, such an arrangement should be financially neutral to both carriers.

However, although in theory practice and theory should align, in practice it rarely happens. What happened in the telephone case was that we saw some carriers set a call-minute call-termination settlement rate that was well above cost, while at the same time set its international call tariffs such that outbound calls were prohibitively expensive for local subscribers.

The result was that the local customers of these carriers found it cheaper to request that the other party call them—the desired outcome. The local carrier then generated income not by charging local subscribers but by revenue generated as an outcome of the call accounting settlement payments that were generated by the net imbalance of called versus calling call minutes.

Carriers all over the world played this game. For example, in France in the early 1990s it was some 5–10 times more expensive to call a U.S. number from France than it was to make a call between the same two numbers in the other direction. If you add in a further consideration, namely that in the 1980s many carriers were part of the public administration and were in effect government-operated national monopolies whose profits contributed to national revenue, then you get an outcome that is described in *Opinion No. 1* of the 1989 ITRs, under the heading "Special Telecommunication Arrangements," namely: "...considering further that, for many Members, revenues from international telecommunications are vital for their administrations."

Telephony Special Services and Number Misuse

It is often said that the only really major innovation in more than a century of the telephone service was the fax. Perhaps that is a little too unkind, but innovations in the delivered services industry were few and far between. However, there were many innovations that are important to this story, and the ones that are relevant here are *number redirect* and the so-called *premium* services.

The premium services attracted a higher call cost, and the carrier conventionally split the revenue from the service with the called service. These services traditionally included weather forecasts, sports results, new headlines (until the Internet became all but completely ubiquitous and decimated these services!), and so on. They also attracted the sex industry. However, in many countries such services were not permitted, so a conventional premium service was not an option for this industry.

As ever, we are naturally inventive, and some folks came up with a clever solution to use number redirect to redirect the call to this otherwise not-permitted premium service to another country. As part of this redirection, the premium service provider needed to reach an agreement with the new home carrier of the call-termination point to divide the international call accounting revenue provided by callers to this service between the carrier and the service provider. Not only did this arrangement effectively circumvent local regulations relating to locally provided premium services, it also leveraged off the international call accounting arrangements to the benefit of the premium service provider as well as the terminating carrier.

We may be inventive, but all too often we are greedy as well. The next step was to circumvent any arrangement with the destination carrier and redirect the call to an entirely different carrier.

One of the side effects of deregulation of the telephone industry in many countries was that in place of a single carrier that would receive all incoming international calls for a given country code there were numerous carriers that were ostensibly competing for the these incoming calls. Instead of routing calls based solely on the dialled country code, carriers now could route calls based on number blocks within the country code, and use different transit routes based on number-block rules. What if a premium service provider took a number block from a country code and specified that all incoming calls were to be routed by a third-party carrier? That all sounds innocent enough, but what if this third party did not actually route the calls through to the country in question, but instead terminated the calls and still charged the calling carrier the international call accounting settlement rate? No doubt the service provider has gotten a better deal, so the service provider is happy, and the carrier that terminates the call is receiving a portion of the call settlement rate, so the terminating carrier is happy. But happiness is not universal here. The carrier in the called country code is getting nothing from this arrangement, even though its country call code is being used for these premium service calls. From the carrier's perspective it is being defrauded of what it might claim is legitimate international call accounting revenue through the "misuse" of the number block drawn from its country code.

If the country-code carrier could discover this unauthorized number-block diversion, then presumably it could withdraw the number block and stop the international call diversion. Unfortunately it does not always work. The carrier can withdraw the number block, but at times—and under perhaps somewhat shady circumstances—the premium service provider, and potentially the transit carriers, might still be able to convince local carriers that the number-block diversion is still legitimate. Although the country-code carrier might see the problem, the carrier's ability to enforce carriers in other countries to respect its authority regarding the use of number blocks drawn from its country code is not always clear. At times the carrier is effectively powerless to enforce a remedy.

And the scheme can be further refined. Why even enter into any form of discussion with the international carrier for a number block? Why not pick one or more of the more obscure national country codes, generate some number blocks from these codes, and then get a cooperative transit carrier to enter a number-block diversion request into the local carrier? The number block is perhaps drawn from a country code that already makes extensive use of third-party transit arrangements, the local carrier may not question the request, and the carriers in the countries from which the number blocks have been drawn may not have the resources to even detect that this event has occurred.

At this point we have arrived at the situation that is motivating some of the proposals to augment the ITRs in this round of negotiation. The position of the nations that have been highlighting this problem as being an important problem in the world of international telephony is that the unauthorized use of phone numbers drawn from their E.164[3] telephone number block is, in their eyes, a case of "number misuse."

The reason why they want to identify this situation and write it into the ITRs at this time is that they would like to involve governments in the role of enforcers of conformance with the conventions of management of telephone country codes. It appears that they would like to obligate governments to adopt a policy, as a common convention, that calls made to a country's country code be directed such that the call request is sent to an authorized carrier located in the country, and to ensure that all authorized carriers essentially honor the integrity of the country codes of all other countries that use the E.164 country-code number plan.

It is also reasonable to ascribe the motivation for this measure as one that is intended to ameliorate the inexorable revenue leakage of the former rich money tap of international call accounting settlement payments. I am not sure that the various antics of the international premium service market are the true intended target of this measure. I suspect that the intended targets of this proposed regulatory measure are those carriers that have devised other methods to honor the intentions of their callers when they make an international phone call, and make the phone of the dialled number ring, yet at the same time bypass the traditional call accounting arrangements. Already *Voice over IP* (VoIP) trunking is commonplace, where the call is mapped into a VoIP call, and one way to bypass the conventional call accounting measures is to use a VoIP trunk to enter the dialled country, and then pass the call back into the *Public Switched Telephone Network* (PSTN) as a locally originated call, terminating it on the originally dialled number. The call is then subject to domestic intercarrier call-termination tariffs, which are generally far lower than their international counterparts.

The Internet and services such as Skype are exerting massive downward pressure on what carriers can charge for conventional phone services without encouraging all remaining customers to use Internet-based services. In an effort to retain some level of market share, it is now evidently more commonplace for carriers themselves to embrace IP-based approaches and bypass these imposed intercarrier international settlement charges. For many countries in the developing world, however, this shift represents a twofold financial blow. Not only are they seeing their foreign-sourced revenue stream disappear at the same rate as the call-termination minutes of conventional telephony vaporise, but they are also seeing this revenue stream being replaced by growing IP traffic volumes that represent a net cost to the national economy.

It should come as no surprise to see some countries attempt to advocate an international regulatory response that is intended to reverse this development, and restore the role of the international telephone network as a means of structural flow of monies from the business sector from the richer economies to the consolidated revenue stream of those poorer economies.

Internet Number Misuse

In and of itself, the previous discussion is by no means a novel discussion for the telephone world, and the tensions exposed by the continual erosion of the traditional telephone business through the onslaught of new technology is not at all surprising.

What is perhaps a bit surprising are the recent moves within the ITR preparatory activities that see numerous national delegations advocating pulling Internet addressing and routing into the same category of telephone-number regulation and also fold these factors into this matter of number misuse in a manner that would apply to both E.164 numbers and IP addresses.

Now some things do not readily translate from telephony to the Internet: there is no "National IP Address Plan" as a counterpart to the E.164 number plan, because the IP address plan is aligned to networks, as distinct from countries. However, you could take a broad view and find some form of mapping from the proposed recommendations regarding the use of E.164 networks to IP addresses. It would appear that the application of the proposals regarding number misuse would see a regulation to the effect that IP packets should be routed to the destination address specified in the packet, and not rerouted and terminated elsewhere. Surely this scenario describes part of the way the Internet works in any case. For the network to actually function, packets need to be passed to their addressed destination. Or so you would think.

And that is indeed what happens much of the time within the Internet. But by no means all of the time. As part of the normal course of operation of IP networks, many operators deploy equipment that intercepts packets and forms a synthetic response using the address of the intended destination. And many national administrations either operate—or mandate the operation of—equipment that inspects packets in transit and discards packets addressed to certain number blocks.

What is going on? Why do network operators regularly "misuse" IP addresses by deliberately intercepting packets and generating a synthetic response?

Packet Diversion

The most prevalent reason is the use of proxies, and, in particular, web proxies. These devices sit "on the wire" and intercept web fetches and cache the downloaded data.

When another user requests the same URL, the proxy uses the cached version of the content rather than forwarding the request on to the original site. This caching is by no means unusual: it is typical for web browsers to cache the most recently visited webpages and when the user returns to the page, the local cached copy is used rather than re-performing the download. For the browser and the network operator the rationale for this form of "address misuse" is the same: it is both a desire to improve performance for the end user and a desire to increase the efficiency of the network by reducing the data volumes being shifted across the transit links. So the outcomes are, on the whole, positive outcomes; users see improved performance and potentially lower costs for the service, using an interception technique that is generally transparent.

Is the deployment of a web proxy an instance of fraud?

Here is where another critical difference between the Internet and the telephone world comes into play. In the Internet the sender does not "pay all the way" to get a packet from its source to its intended destination. In general, every IP packet could be thought of as being partially funded by both the sender and the receiver.

The user who generated the packet pays for an *Internet Service Provider* (ISP) service, and the ISP may, in turn, purchase transit services from another ISP, and so on for sequenced transit services. However, at a peering exchange point, or within a provider network, the sender's money runs out. The packet is not unfunded, however, for at this point the receiver's services take over, and the packet transits a path that is funded by the receiver's ISP's transit services, and there to the receiver's ISP and there to the receiver.

If a packet is diverted to a proxy, then who wins and who loses? Can we make the case that a party in this situation is being cheated?

As long as the proxy is a faithful proxy, then the user wins, insofar as the user experiences improved performance and the benefits of a more efficient network while still seeing precisely the same content. And the content provider wins, insofar as the content is delivered to the user without the incremental cost of packet handling at the content site. And the network service providers win, in so far as the amount of network traffic is reduced while the revenue levels remain constant. In this case there is no end-to-end service payment on the part of the user that would trigger an intercarrier settlement payment, so it is difficult to make the case that this action necessarily damages any party involved in the network transaction.

Given the widespread deployment of these proxy caching devices across the entire Internet, the beneficial outcomes of improved performance and network efficiency, and the option for content providers to use techniques that in effect mark content as not cacheable, it is extremely challenging to sustain a case that the use of proxies is a case of address misuse.

So the use of traffic diversion and intercepting proxies in the Internet is not generally regarded as an example of intentional fraud or even an accepted case of address misuse. It is just what we do today in the Internet.

Packet Interception

What about the deliberate interception and discarding of packets in flight? Surely this case is one of "misuse" of IP addresses?

That is a very hard case to make when you consider that such actions are exactly how firewalls work, and almost every network uses firewalls in some manner or other. The action of a firewall is to intercept all packets, and discard those that match some predetermined set of rules relating to acceptable and unacceptable packets.

Many users run firewalls that deliberately block all incoming connection requests unless they match quite specific rules.

Many ISPs run firewalls that deliberately block access to ISPs' services from users who are not direct customers of the ISP.

Many countries have content regulations that block access to certain content, enforced either through government-operated facilities or through obligations imposed through the conditions associated with the carrier license within that country. The country I live in, Australia, imposes such constraints on its carriers for certain types of content, as does China through its much-reported national firewall facilities.

Users, service providers and carriers, and governments all use various forms of packet interception. Are we all guilty of number misuse? Should we support changes to the ITRs to obligate governments to stop this practice completely?

Aside from many other motivations for firewalls, security is a continuing concern in the Internet, and there is little doubt that although firewalls have not eradicated all forms of toxic traffic and associated abuse and attack, they are an important part of a larger story about securing the Internet. Irrespective of the various views that are expressed at a national level about censorship, intellectual property rights, and the position of common carriers and users, it seems counterintuitive to me that we would want to obligate governments to pull down our firewalls and filters as a necessary consequence of a revised set of ITRs.

Number "Misuse"

What this example illustrates is that the two networks—the traditional telephone network and the Internet—operate in very distinct and different ways. It not only encompasses differences between circuit and packet switching, but also reaches into the differences in the concepts of a network transaction, differences in the tariff structures, and, critically, differences in the way in which financial settlements are undertaken between service providers on the Internet.

Consider what could readily be acknowledged as an operating practice that defrauds operators in the world of telephony and negatively affects the services provided to telephone subscriber—that same practice in the Internet can result in positive outcomes used to enhance performance, reduce costs, and improve the operational efficiency of the service delivered to end users.

This case of attempting to regulate "number misuse" illustrates the fact that to take a stance of "one size fits all" when considering the topic of international regulation of telecommunications is a stance that has considerable risks of generating outcomes that are entirely inappropriate when translating a particular situation from telephony to the Internet.

WCIT and the ITRs—Where to Go from Here?

The international call accounting arrangements used by the telephone world, and the use of structurally embedded imbalances in call accounting settlement rates, are still major factors in the ITR discussions. This accounting imbalance is sanctioned in the resolutions of the 1988 World Administrative Telegraph and Telephone Conference, where *Resolution 3,* concerning the apportionment of revenue, provided for structural cross-subsidization of the developing world through asymmetric fixing of call accounting rates between the so-called developed and developing economies.

But in an increasing commercial world of telecommunications, where it is no longer a relatively exclusive collection of publicly funded monopolies that were an integral part of public utility service providers that in effect were an instrument of national governments, pushing the onus of an international developmental agenda onto an increasingly privatized commercial activity has been a less-than-comfortable fit. Private operators see this situation in a more dispassionate light as a business cost input, and seek to find ways to minimize this cost in order to improve the competitive positions of their businesses.

However, the changes in this industry over the past 25 years are so much larger than even this significant broad-scale shift in the onus of capital injection and operation from the public to the private sector. At the same time, we are seeing an even more fundamental shift in technology foundations, from circuits to packets with the introduction of the Internet into the picture. This shift has brought about profound shifts in the engineering of communications infrastructure and, as we have seen, it also has triggered profound shifts in the pricing of the consumer service, shifting from transactional pricing to a "connection rental" model where packet transit costs are bundled into the service. This bundling, in turn, has led to profound shifts in the manner in which money moves between the network operators themselves.

And perhaps of even greater and more lasting significance in this industry is the decoupling of carriage and content. We have now seen the rise of highly valuable content-centric enterprises that have business models that rely on a ubiquitous and abundant underlying communications infrastructure but are not financially beholden to the infrastructure operators. They have been able to forge direct relationships with consumers without having to deal with any form of mediation or brokerage imposed by carriage providers. The current values of these content enterprises dwarf the residual value of the carriage service sector, and the outlook for this sector is one of continuing shift in value away from carriage service providers and into the areas of content-based services.

Given the sheer scale of these changes in this industry over the past quarter century, it seems to me that the view that you can simply fold the Internet transparently into the current framework of the ITRs by the prolific insertion of "and the Internet" into the text of the regulations is simply not viable.

Packets are not circuits, and the mechanisms used to engineer packet networks are entirely different from those used with the circuit switches that supported traditional telephony services. This difference encompasses far more than engineering. The ways in which users pay for services differ, and this shift in the retail tariff structure of the Internet service implies a forced change in the way in which carriers interact to support a cohesive framework of network interconnection. The concept of a "call" really has no direct counterpart in the Internet. To extend this thought further into the area of "call accounting" and "caller pays" is again an extension that does not clearly map into the Internet. So when the existing ITRs refer to intercarrier call accounting financial settlements, there is no clear translation of such a concept into the Internet. When we extend this intercarrier interconnection framework into structural imbalances in call accounting settlement rates, and extend this framework further into the concepts of number misuse, all forms of connection between traditional telephony and the Internet are completely lost.

However, this conclusion should not imply that the ITRs are now an historic relic, completely overtaken by comprehensive shifts in both the technology and service models of today's global communications network. Irrespective of the fine level of detail in these 25-year-old documents, the ideals behind the ITRs are indeed worthy ideals, and they should not be discarded lightly.

Ultimately, what we are dealing with here is the role of individual nation states with respect to a public communications service for the entire world. In setting forth a framework for supporting an efficient, effective, and capable global communications system, the obligations stated in the current ITRs relating to the promotion of international telecommunications services, and the endeavours to make such services generally available to the public, all remain thoroughly worthwhile objectives.

The concept that widely respected technology standards are critical to worldwide technical interoperability of any telecommunications service is also an important aspect, and again the recognition of this factor in the ITRs is a worthwhile consideration.

But, as we both review the changes of the past quarter century and try to peer into what may emerge over the next quarter century, perhaps less is best in this area of regulatory measures.

Rather than seeking to explicitly add various regulations that attempt to address specific incidents of number misuse, and instead of making rather clumsy efforts to include the Internet into the already detailed provisions relating to intercarrier settlement models of the increasingly historic traditional telephone network, perhaps the best set of ITRs we could have for tomorrow's world are national obligations that support a lightweight common regulatory framework.

This framework should be both more minimal with respect to describing or relying on particular technologies and service frameworks and more encompassing in scope in stating the overall objectives and common aspirations all nations share in supporting this unique, incredibly valuable common resource of a common communications service that truly embraces the entire world.

Postscript: "It's All Just Telecoms"

I received a comment soon after I wrote an early draft article that I thought would provide some further insight to the WCIT process, so here is the comment and some further thoughts on the topic:

The comment was in the form of a report from a preparatory meeting for WCIT earlier in 2012. Evidently there is a mood within certain parts of the ITR drafting process to simply say: "The ITRs should apply to the Internet in full, because the Internet is nothing more than a telecom service and should be treated that way."

In one sense it is true that the Internet is nothing more than a telecommunications service, but in the same way that the post, radio, television, and of course the telephone are also all just telecommunications services. But the nature of the particular service has many consequences, and the attempt to lump telephony and the Internet into the same form of regulatory handling is at best a somewhat misguided effort.

I truly wonder if, more than a century ago, the counterparts of today's government delegates, in a meeting of that august body, the *Universal Postal Union* (UPU), would have argued that a telephone conversation was just an exchange of letters without the artifice of paper, and that the telephone was indeed just a part of the postal service, because it is just "a communications service."

Indeed I am pretty sure their counterparts did precisely that, and for the next 80 years or more in many countries the Postmaster General operated the telephone service, and operated the wireless spectrum administration and regulated radio and television broadcasts, as well as operating the national postal service, the telegraph service, and telex services, all because "it's all just communications."

But, ultimately we changed this paradigm. We created distinct entities to administer different communications media and services because it is actually not "all just communications"—nor is it "all just telecoms." Effective regulatory handling of these different communications mechanisms, using distinct forms of investment and finances, and at times entirely distinct regulatory frameworks and often distinct organizations and associated participatory arrangements, allows us to realize the true potential of these various services and do so efficiently and effectively. This recognition of a need for distinction in the regulatory frameworks for various services avoids the unfortunate situation of the stultifying dead hand of history misapplying one form of regulation on an entirely distinct and very different medium.

I suspect the best thing the postal folks, in the form of the UPU, ever did was to tell the telephone folks "hail and farewell" and let them get on with their role using an organization specifically designed to meet their collective needs in supporting telephony.

It may be well and truly time for the telephone folks, in the form of the *International Telecommunications Union* (ITU), to come to a similar arrangement in its dealings with the Internet!

Behind the Curtain: IP Fast Reroute

by Russ White, Verisign

The field of network and protocol engineering has three watchwords: *faster, bigger,* and *cheaper.* Although we all know the joke about choosing two out of the three, the reality of networking is that we have been doing all three for years—and it doesn't look like there is any time on the horizon when we will not be doing all three.

In that spirit, *IP Fast Reroute* addresses all three of these watchwords. Fast—you are probably thinking—is obvious, but what about bigger and cheaper? Fast Reroute provides the network designer with some trade-offs in the space of redundancy through additional backup links against deploying protocol changes, and network stretch against the size of a failure domain, so you can—in theory—build larger, less-redundant failure domains with Fast Reroute than without.

But to understand these effects, we need to go behind the curtain, understanding Fast Reroute as more than a few configuration options. This article first looks at the motivation behind IP Fast Reroute, and then discusses four different techniques, or stages, in the Fast Reroute story.

What Is Your Motivation?

To really discuss network speed, we need to be able to define how fast "fast" really is. In the 1980s, a network was fast if it could converge in 90 seconds or less (the longest time the *Routing Information Protocol* [RIP] could take to converge). As we moved into more advanced Distance-Vector and Link State protocols (*Enhanced Interior Gateway Routing Protocol* [EIGRP], *Open Shortest Path First* [OSPF], and *Intermediate System-to-Intermediate System* [IS-IS]), 5-second convergence became the norm. We learned to tweak timers to get to convergence times faster than 1 second.

But what if we need convergence that is faster than less than 1 second? What if we need to converge so fast that the only packets lost are either in flight or in a buffer waiting to be serialized onto the link? And what if we need to be able to handle a large number of prefixes with minimal network disruption due to link or device failures?

IP Fast Reroute techniques come into play in this situation.

Preinstalled Backup Paths

Although it is often sold as a Fast Reroute technique, *preinstalled backup paths* really are not; rather they support other Fast Reroute techniques at the protocol level. If the protocol has calculated a loop-free path that is an alternate to the current best path, this alternate path can be installed in the forwarding table so it is readily available for use in case the best path fails.

This solution does provide immediate failover at the hardware level, but the alternate path must be calculated to be installed. How is this alternate path computed?

Loop-Free Alternates

The first mechanism available for calculating an alternate path is with *Loop-Free Alternates*. To understand this mechanism, we must make a short detour into graph theory (or geometry, if you prefer). Use the following network as an example:

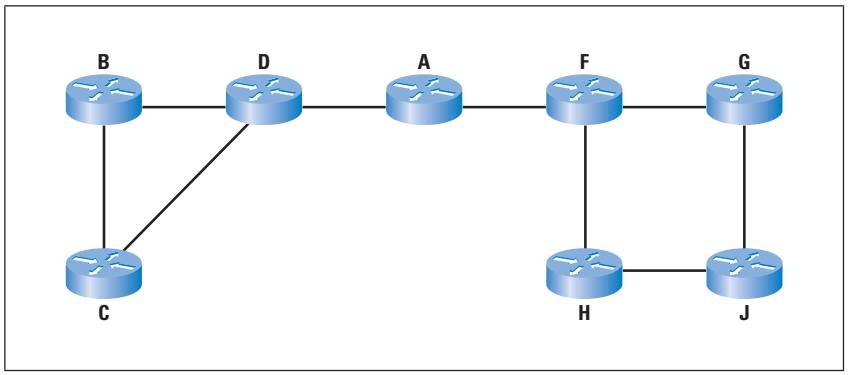

Figure 1: Network for Loop-Free Alternates

Assume:

- A is the destination.
- B's best path is through D to A.
- G's best path is through F to A.

What is the key to allowing B to forward traffic through C toward A if the B → D link fails? B must know the traffic it forwards to C (for A) will not be forwarded back to B itself. How can B know C will forward the traffic to D, rather than to B itself? By examining the metric at C toward A.

In EIGRP, B knows C's metric toward A because the routing protocol includes this information in the update. In a link state protocol (OSPF or IS-IS), B can calculate C's cost to A directly by running *Shortest Path First* from C's perspective (given B and C share the same link state database).

Loop-free alternates are simply calculating whether any given neighbor will forward traffic to any particular destination back to you, or on toward the destination. If a neighbor would forward the traffic on toward the destination, then it is a loop-free alternate.

Under what conditions would C forward traffic sent from B back to B? *If C is using B as its best path (or one of its best paths) toward A.*

What about G? If it forwards traffic to J toward A, will J return the traffic to G itself? In this four-hop ring, there are two possible configurations:

- J is using H as its best path. In this case, traffic forwarded by G to A through J will be correctly forwarded. Note, however, that in this case H cannot use J as an alternate path toward A, because any traffic H sends to A through A will loop back to H itself.
- J is using G as its best path. In this case, J can use G as a loop-free alternate, but G cannot use J as a loop-free alternate.

No matter how you work the metrics in the four-hop ring case, there will always be at least one device that does not have a loop-free alternate path to A.

Split Horizon and Loop-Free Alternates

If the concept of loop-free alternates is difficult to understand by considering the problem in this way, another useful way to look at the problem is through the distance-vector idea of *split horizon*. To review, the split horizon rule states:

> *Do not advertise a route to a destination toward a neighbor you are using to forward traffic to that same destination.*

If C is forwarding traffic toward A to B, then C will not advertise A to B, meaning B will not even know about this alternate path, preventing a loop even if B's best path to A fails. If you always consider where a distance-vector protocol will split horizon, you will always be able to see where loop-free alternates will fail to provide an alternate path to any given destination.

Getting Around the Loops

If we want to design a system that will find every possible alternate path toward a given destination, rather than just finding those that are not normally taken out by split horizon anyway, what must we do? We need to find a way to route through a neighbor to some distant next hop without that neighbor actually forwarding the traffic back to the originating router.

To put this concept in more concrete terms, examine the following network as an example:

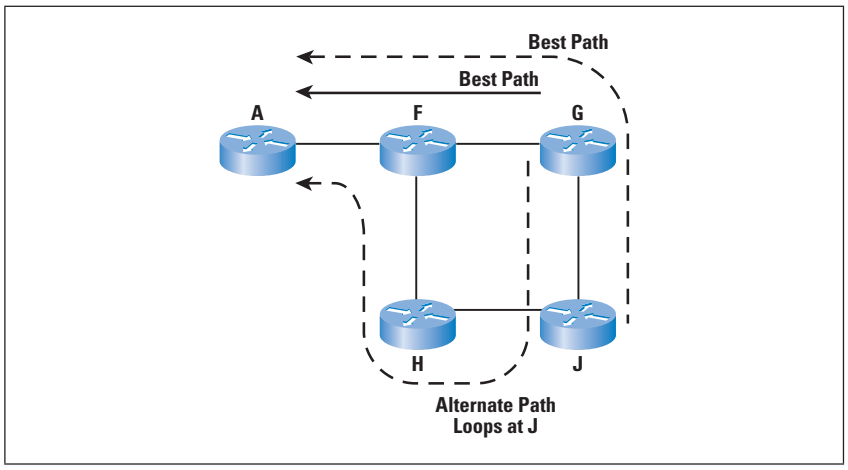

Figure 2: Alternate Path Loops

If G wants to use the path through J as an alternate path, then it must somehow figure out how to forward traffic to J without J returning the traffic to G itself. How can this process be done? G can tunnel the traffic through J to some device somewhere beyond J; therefore, every mechanism beyond loop-free alternates must use some form of tunneling to resolve the Fast Reroute problem. Calculating the point to which G needs to tunnel is the topic of the remaining mechanisms.

Not-Via

Even though we might be working with a link state protocol, it is easiest to understand *Not-via* in terms of a distance-vector protocol and split horizon. Not-via essentially begins with the observation that G does not have an alternate path to A through J in this case because J will not advertise such a route. *J is, in fact, using G as its best path toward A, so the path from G through J to A cannot be viable.*

The solution is not just simply having J advertise the route to A because traffic forwarded by G toward A through J will simply be looped back to G itself. So what is the solution?

In the case of Not-via, F advertises a route to itself through H only (not through G). This route will be advertised through H, then J, and finally to G. When G receives this route, it can determine that this path is an alternate path to A because its best path to A is normally through F. Any path that can reach F not through (or not via) its best path to F must, necessarily, be a loop-free alternate path to F. To reach A through F, however, G must tunnel to F directly, thereby avoiding the problem of J returning traffic destined to A back to G.

The address F advertises through H only is called "F Not-via G," and that is why this system is called "Not-via." This mechanism works in every topology (so long as an alternate path exists). The one downside to Not-via is that for each protected link or node, a new advertisement must be built and advertised through the network.

Disjoint Topologies

The problem of finding a next hop that passes over the split-horizon point can also be solved using the ability to form multiple disjoint topologies—multiple topologies that do not share the same links (or nodes, in some cases) to reach the same set of destinations. If this information sounds complex, that is because it is complex; a lot of hours and thought have gone into various systems to build and use multiple disjoint topologies within a single physical network. But there is a moderately simple way, referring back to Figure 2. In this network, G can take the following steps:

1. Remove the G → F link from its local database temporarily (just for this calculation).
2. Calculate the best path to F.
3. If an alternate path to F exists, mark this alternate path as a second topology.

4. If its path to F fails, place all traffic that would normally pass across G → F on this alternate topology.

It might not be obvious from this set of actions, but these actions will actually cause G to discover that it is, in fact, on a ring, and that it can place traffic on the opposite direction on this ring to get traffic to the same destination. Placing the traffic it would normally send to F via G → F on a separate topology overcomes the forwarding table at J, a process that would loop the traffic back to G itself. You could use a tunnel to F instead of a separate topology; tunnels are, in effect, a disjoint topology seen in a different way.

Conclusion

What advantage does IP Fast Reroute provide the network designer? The ability to reduce the amount of physical redundancy while maintaining the same actual level of redundancy in the network. Moving to Not-via or disjoint topology solutions removes the need to manually manage link costs as well, while adding only moderate complexity at the protocol level.

IP Fast Reroute is an interesting technology just on the edge of adoption that will be useful in campus, data center (through Layer 2 routing), and standard Layer 3 network designs.

Letters to the Editor

Ed.: We received several letters in response to the article "A Retrospective: Twenty-Five Years Ago," by Geoff Huston, published in the previous issue of this journal. Here is some of the feedback:

Hi Geoff,

Just wanted to show my appreciation for your nice article. As an ex-DEC who moved to WorldCom after my MSc in Computer Engineering & Telecoms with a Master's project on IP signaling over ATM, I can certainly relate to a large part (not all ;–) of what you wrote.

I normally don't read such long articles, but had to make an exception as I kept interested until the end!

Thank you!

—*Pedro Paiva, Etoy, Switzerland*
pedro.paiva@a3.epfl.ch

Greetings Geoff,

I just wanted to let you know that I really enjoyed your recent article, "A Retrospective: Twenty-Five Years Ago," published in *The Internet Protocol Journal*. I lived through most of the history that you talked about as I came up through the telecom industry and then finished off my career at Cisco.

It certainly is interesting to reflect back on all the past controversy around network infrastructure design and how competing ideas and philosophies played out. (Talk about losers, remember *Switched Multi-megabit Data Service* (SMDS) driven by the *Regional Bell Operating Companies* (RBOCs)? While at Nortel, I remember once in a design review meeting that one of our BNR geeks put up a slide (overhead foil back then) that showed various network evolution scenarios. The last one was an "oh-by-the-way, there's this theory that the Internet could take over the world" (of network infrastructure). All the room snickered. Who's laughing now?

There was as much energy, maybe more, put into defending architectures based on market control as there was on technological elegance. Still, it is a fascinating and dynamic industry full of extremely smart people with clever ideas, and I enjoyed every minute of it.

I started at "the phone company" in the late 1960s and it has been quite a journey from relay-driven switches controlling tip and ring loops to the current *Multiprotocol Label Switching* (MPLS) backbone networks, terabit switching, and hitching rides on photons.

Thanks for your insight and for your well-written article.

Best regards,

—Marc Williams
willimarc@gmail.com

The author responds:

Hi Marc,

Thanks for your note and your recollections from some 25 years ago.

I recall SMDS as well. If I recall correctly, this was an invention coming out of a university in Western Australia. Elsewhere in the world it was marketed as a 34-Mbps product. In Australia it was marketed in 2-Mbps and 10-Mbps forms (evidently the telco thought that we primitive Aussies were not "ready" for any higher speed!). I was a customer of their 10-Mbps product, and experienced some disappointment when it became evident that 10 Mbps was a theoretical peak that was simply unachievable because the inline PCs that were used for packet accounting slowed the throughput of any SMDS link down to just 3 Mbps! So in Australia SMDS was largely killed by the telco and it was never really used for high-speed digital trunk services.

I experienced a similar reaction to the Internet in the late 1980s as you have observed, when, in response to suggesting that the universities were about to build a national IP network, many of the telco managers did the polite snicker performance and then suggested that we should "get with the times," sign up as customers of their national ATM network, and leave the engineering to them. I'm glad the universities saw through it and supported me in persisting along the path to a national IP network. It was a strange moment some 6 years later when the same telco came knocking on our door to make an offer to buy the network from the universities because their own efforts to construct an IP product were simply getting nowhere at the time.

It has indeed been quite a journey, and I too have enjoyed every bit of it!

Kind regards,

—Geoff, Chief Scientist, APNIC
gih@apnic.net

Hello Geoff!

I haven't chuckled that much in years; what great memories. A few of my strong memories:

- Lack of documentation for new functions in software required an off-net test network and a Sniffer. The amount of hours spent figuring exactly what the function was doing or wasn't doing could fill an ocean. Absolutely my favorite activity and still is.
- I inherited a stat-mux system that was transporting ASCII terminals back to a centralized DEC terminal server arrangement. Hated it with a passion. One day, after a couple of beers, a light bulb came on that Ethernet is a stat-mux, so I bought a couple of Cisco AGS units, remotely installed a terminal server and an AGS, hauled it back to the other AGS in the central location and danced a jig, and then I started ripping out the old WAN stat-mux the following week.
- Anything relying on a token for timing is pure evil. You never know when you've engineered a TTL exhaust until it happens, and that can be based on Distance + Nodes or pure application coincidence. Ring resets are the devil's work. Token-based systems are not stat-muxs, but Ethernets are; that's why Ethernet survived and is the "last man standing."
- I totally agree with your comments surrounding the "cloud." I can remember that the distributed-versus-centralized fad has occurred at least four times over the past 25 years ...
- Z80: I built my first PC with a Z80; thank goodness for the peek-and-poke function!
- OEM would claim anything was portable as long as it had a carrying handle attached, even if it took two people to carry it.
- I fell in love with TCP/IP very early for the simple reason that it has the best of both worlds: a tightly coupled connection and connectionless protocol. It is much faster to troubleshoot or modify because IP requires a different expertise than TCP, and when you run across individuals who can work across the layers, hire them!

So, a lot of fond memories. I started out as a telemetry engineer on the Apollo project and I thought that was challenging and fulfilling. But, it doesn't hold a candle to the 1984–1995 period.

Oh, one other thing; I take umbrage to "...the annoying persistence of FORTRAN." That's the first language I learned back in the late '60s and I still have an active compiler on an old laptop that I still program on ... LOL!!

Keep attacking the certificate situation! The current situation is a disgrace, and I fully support the concept presented by Barnes: let's hurry it up!

Regards,

—Paul Dover
pdover@centeriem.com

The author responds:

Hi Paul,

Thanks for those recollections. I too spent a massive amount of time starting as a protocol analyzer, trying to make an IBM PC look enough like a Uniscope to allow file transfer between the PC and the Univac mainframe—no doubt it was a character-forming experience, but all I can say now is thank goodness for *tcpdump* and *wireshark*!

Thanks for your note—I truly appreciate the feedback!

Warm regards,

—Geoff, Chief Scientist, APNIC
gih@apnic.net

Dear Ole,

Congratulations on your 25-year anniversary!

You can tell how well people enjoy their professions by how great their products are, and yours is in the "excellent" category.

Regards,

—Paul Dover
pdover@centeriem.com

Ole,

Congratulations on your reaching a major milestone: 25 years of technology publishing! We are glad that you are continuing this service through *The Internet Protocol Journal* and look forward to many more years in this field.

Best,

—T. Sridhar
tsridhar@ieee.org

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ contains standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

From The Editor

Internet devices use various forms of timers and timestamps to determine everything from when a given e-mail message arrives to the number of seconds since a particular device was rebooted. Most systems use the *Network Time Protocol* (NTP) to obtain the current time from a large network of Internet time servers. NTP will be the subject of a future article in this journal. This time we will focus our attention on the *Leap Second,* which is occasionally applied to *Coordinated Universal Time* (UTC) in order to keep its time of day close to the *Mean Solar Time*. Geoff Huston explains the mechanism and describes what happened to some Internet systems on July 1, 2012, as a result of a leap second addition.

The Internet of Things (IoT) is a phrase used to describe networks where not only computers, smartphones, and tablets are Internet-aware, but also autonomous sensors, control systems, light switches, and thousands of other embedded devices. In our second article, David Lake, Ammar Rayes, and Monique Morrow give an overview of this emerging field which already has its own conferences and journals.

The *World Wide Web* became a reality in the early 1990s, thanks mostly to the efforts of Tim Berners Lee and Robert Cailliau. The web has been a wonderful breeding ground for new protocols and technologies associated with access to and presentation of all kinds of media. The phrase *Web 2.0,* coined in 1999, has, per Wikipedia, "...been used to describe web sites that use technology beyond the static pages of earlier web sites." David Strom argues that the term is no longer appropriate and that we have moved on to a new phase of the web, dominated by mobile devices and Social Networking.

The last few years have seen great advances in Internet-based collaboration tools. Sometimes referred to as *Telepresence,* these systems allow not only high-quality audio and videoconferencing, but also the use of shared whiteboards and other presentation material. In our final article, Pat Jensen describes one important component of such systems, namely the *Binary Floor Control Protocol* (BFCP), which the IETF's XCON Centralized Conferencing working group has developed.

As always we welcome your feedback on anything you read in this journal. Contact us by e-mail at ipj@cisco.com

—Ole J. Jacobsen, Editor and Publisher
ole@cisco.com

Leaping Seconds

by Geoff Huston, APNIC

The tabloid press is never lost for a good headline, but in July 2012 this one in particular caught my eye: "Global Chaos as Moment in Time Kills the Interwebs."[1] I am pretty sure that "global chaos" is somewhat "over the top," but a problem did happen on July 1 this year, and yes, it affected the Internet in various ways, as well as affecting many other enterprises that rely on IT systems. And yes, the problem had a lot to do with time and how we measure it. In this article I will examine the cause of this problem in a little more detail.

What Is a Second?

I would like to start with a rather innocent question: What exactly is a *second?* Obviously it is a unit of time, but what defines a second? Well, there are 60 seconds in a minute, 60 minutes in an hour, and 24 hours in a day. That information would infer that a "second" is 1/86,400 of a day, or 1/86,400 of the length of time it takes for the Earth to rotate about its own axis. Yes?

Almost, but this definition is still a little imprecise. What is the frame of reference that defines a unit of rotation of the Earth? As was established in the work a century ago in attempting to establish a frame of reference for the measurement of the speed of light, these frame-of-reference questions can be quite tricky!

What is the frame of reference to calibrate the Earth's rotation about its own axis? A set of distant stars? The Sun? These days we use the Sun, a choice that seems logical in the first instance. But cosmology is far from perfect, and far from being a stable measurement, the length of time it takes for the Earth to rotate once about its axis relative to the Sun varies month by month by up to some 30 seconds from its mean value. This variation in the Earth's rotational period is an outcome of both the Earth's elliptical orbit around the Sun and the Earth's axial tilt. These variations mean that by the time of the March equinox the *Solar Day* is some 18 seconds shorter than the mean, at the time of the June solstice it is some 13 seconds longer, at the September equinox it is some 21 seconds shorter, and in December it is some 29 seconds longer.

This variation in the rotational period of the Earth is unhelpful if you are looking for a stable way to measure time. To keep this unit of time at a constant value, then the definition of a second is based on an ideal version of the Earth's rotational period, and we have chosen to base the unit of measurement of time on *Mean Solar Time*. This mean solar time is the average time for the Earth to rotate about its own axis, relative to the Sun.

This value is relatively constant, because the variations in solar time work to cancel out each other in the course of a full year. So a second is defined as 1/86,400 of mean solar time, or in other words 1/86,400 of the average time it takes for the Earth to rotate on its axis. And how do we measure this mean solar time? Well, in our search for precision and accuracy the measurement of mean solar time is not, in fact, based on measurements of the sun, but instead is derived from baseline interferometry from numerous distant radio sources. However, the measurement still reflects the average duration of the Earth's rotation about its own axis relative to the Sun.

So now we have a second as a unit of the measurement of time, based on the Earth's rotation about its own axis, and this definition allows us not only to construct a uniform time system to measure intervals of time, but also to all agree on a uniform value of absolute time. From this analysis we can make calendars that are not only "stable," in that the calendar does not drift forward or backward in time from year to year, but also accurate in that we can agree on absolute time down to units of minute fractions of a second. Well, so one would have thought, but the imperfections of cosmology intrude once again.

The Earth has the Moon, and the Earth generates a tidal acceleration of the Moon, and, in turn the Moon decelerates the Earth's rotational speed. In addition to this long-term factor arising from the gravitational interaction between the Earth and the Moon, the Earth's rotational period is affected by climatic and geological events that occur on and within the Earth[2]. Thus it is possible for the Earth's rotation to both slow down and speed up at times. So the two requirements of a second—namely that it is a constant unit of time and it is defined as 1/86,400 of the mean time taken for the Earth to rotate on its axis—cannot be maintained. Either one or the other has to go.

In 1955 we went down the route of a standard definition of a second, which was defined by the *International Astronomical Union* as 1⁄31,556,925.9747 of the 1900.0 *Mean Tropical Year.* This definition was also adopted in 1956 by the *International Committee for Weights and Measures* and in 1960 by the *General Conference on Weights and Measures,* becoming a part of the *International System of Units* (SI). This definition addressed the problem of the drift in the value of the mean solar year by specifying a particular year as the baseline for the definition.

However, by the mid-1960s this definition was also found to be inadequate for precise time measure-ments, so in 1967 the SI second was again redefined, this time in experimental terms as a repeatable measurement. The new definition of a second was 9,192,631,770 periods of the radiation emitted by a Caesium-133 atom in the transition between the two hyperfine levels of its ground state.

Leaping Seconds

So we have the concept of a second as a fixed unit of time, but how does this relate to the astronomical measurement of time? For the past several centuries the length of the *Mean Solar Day* has been increasing by an average of some 1.7 milliseconds per century. Given that the solar day was fixed on the Mean Solar Day of the year 1900, by 1961 it was around a millisecond longer than 86,400 SI seconds. Therefore, absolute time standards that change the date after precisely 86,400 SI seconds, such as the *International Atomic Time* (TAI), get increasingly ahead of the time standards that are rigorously tied to the Mean Solar Day, such as *Greenwich Mean Time* (GMT).

When the *Coordinated Universal Time* (UTC) standard was instituted in 1961, based on atomic clocks, it was felt necessary that this time standard maintain agreement with the GMT time of day, which until then had been the reference for broadcast time services. Thus, from 1961 to 1971 the rate of broadcast time from the UTC atomic clock source had to be constantly slowed to remain synchronized with GMT. During that period, therefore, the "seconds" of broadcast services were actually slightly longer than the SI second and closer to the GMT seconds.

In 1972 the *Leap Second* system was introduced, so that the broadcast UTC seconds could be made exactly equal to the standard SI second, while still maintaining the UTC time of day and changes of UTC date synchronized with those of *UT1* (the solar time standard that superseded GMT). Reassuringly, a second is now a SI second in both the UTC and TAI standards, and the precise time when time transitions from one second to the next is synchronized in both of these reference frameworks. But this fixing of the two time standards to a common unit of exactly 1 second means that for the standard second to also track the time of day it is necessary to periodically add or remove entire standard seconds from the UTC time-of-day clock. Hence the use of so-called leap seconds. By 1972 the UTC clock was already 10 seconds behind TAI, which had been synchronized with UT1 in 1958 but had been counting true SI seconds since then. After 1972, both clocks have been ticking in SI seconds, so the difference between their readouts at any time is 10 seconds plus the total number of leap seconds that have been applied to UTC.

Since January 1, 1988, the role of coordinating the insertion of these leap-second corrections to the UTC time of day has been the responsibility of the *International Earth Rotation and Reference Systems Service* (IERS). IERS usually decides to apply a leap second whenever the difference between UTC and UT1 approaches 0.6 second in order to keep the absolute difference between UTC and the mean solar UT1 broadcast time from exceeding 0.9 second.

The UTC standard allows leap seconds to be applied at the end of any UTC month, but since 1972 all of these leap seconds have been inserted either at the end of June 30 or December 31, making the final minute of the month in UTC, either 1 second longer or 1 second shorter when the leap second is applied. IERS publishes announcements in its *Bulletin C* every 6 months as to whether leap seconds are to occur or not. Such announcements are typically published well in advance of each possible leap-second date—usually in early January for a June 30 scheduled leap second and in early July for a December 31 leap second. Greater levels of advance notice are not possible because of the degree of uncertainty in predicting the precise value of the cumulative effect of fluctuations of the deviation of the Earth's rotational period from the value of the Mean Solar Day. Or, in other words, the Earth is unpredictably wobbly!

Between 1972 and 2012 some 25 leap seconds have been added to UTC. On average this number implies that a leap second has been inserted about every 19 months. However, the spacing of these leap seconds is quite irregular: there were no leap seconds in the 7-year interval between January 1, 1999, and December 31, 2005, but there were 9 leap seconds in the 13 years between 1985 and 1997, as shown in Figure 1. Since December 31, 1998, there have been only 3 leap seconds, on December 31, 2005, December 31, 2008, and June 30, 2012, each of which has added 1 second to that final minute of the month, at the UTC time of day.

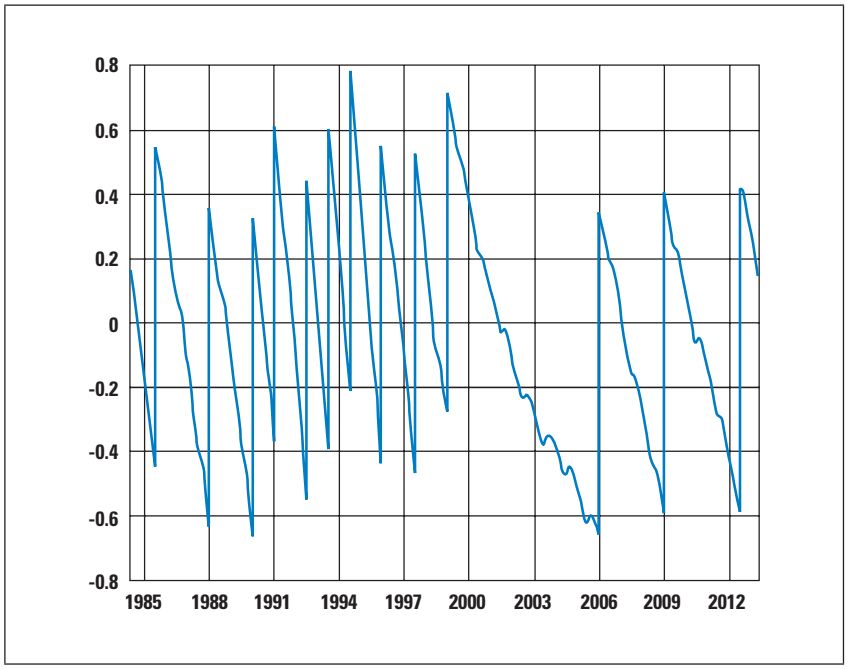

Figure 1: The difference between UT1 and UTC 1984–2012

Leaping Seconds and Computer Systems

The June 30, 2012 leap second did not pass without a hitch, as reported by the tabloid press. The side effect of this particular leap second appeared to include computer system outages and crashes—an outcome that was unexpected and surprising. This leap second managed to crash some servers used in the Amadeus airline management system, throwing the Qantas airline into a flurry of confusion on Sunday morning on July 1 in Australia. But not just the airlines were affected, because LinkedIn, Foursquare, Yelp, and Opera were among numerous online service operators that had their servers stumble in some fashion. This event managed to also affect some *Internet Service Providers* and data center operators. One Australian service provider has reported that a large number of its Ethernet switches seized up over a 2-hour period following the leap second.

It appears that one common element here was the use of the Linux operating system. But Linux is not exactly a new operating system, and the use of the *Leap Second Option* in the *Network Time Protocol* (NTP) [7–10] is not exactly novel either. Why didn't we see the same problems in early 2009, following the leap second that occurred on December 31, 2008?

Ah, but there *were* problems then, but perhaps they were blotted out in the post new year celebratory hangover! Some folks noticed something wrong with their servers on January 1, 2009. Problems with the leap second were recorded with Red Hat Linux following the December 2008 leap second, where kernel versions of the system prior to Version 2.6.9 could encounter a deadlock condition in the kernel while processing the leap second.[3]

> "[...] the leap second code is called from the timer interrupt handler, which holds *xtime_lock*. The leap second code does a *printk* to notify about the leap second. The *printk* code tries to wake up *klogd* (I assume to prioritize kernel messages), and (under some conditions), the scheduler attempts to get the current time, which tries to get *xtime_lock => deadlock*."[4]

The advice in January 2009 to sysadmins was to upgrade the systems to Version 2.6.9 or later, which contained a patch that avoided this kernel-level deadlock. This time it is a different problem, where the server CPU encountered a 100-percent usage level:

> "The problem is caused by a bug in the kernel code for high resolution timers *(hrtimers)*. Since they are configured using the CONFIG_HIGH_RES_TIMERS option and most systems manufactured in recent years include the *High Precision Event Timers* (HPET) supported by this code, these timers are active in the kernels in many recent distributions.

> "The kernel bug means that the *hrtimer* code fails to set the system time when the leap second is added. The result is that the *hrtimer* representation of the time taken from the kernel is a second ahead of the system time. If an application then calls a kernel function with a timeout of less than a second, the kernel assumes that the timeout has elapsed immediately after setting the timer, and so returns to the program code immediately. In the event of a timeout, many programs simply repeat the requested operation and immediately set a new timer. This results in an endless loop, leading to 100% CPU utilisation."[5]

Leap Smearing

Following a close monitoring of its systems in the earlier 2005 leap second, Google engineers were aware of problems in their operating system when processing this leap second. They had noticed that some clustered systems stopped accepting work during the leap second of December 31, 2005, and they wanted to ensure that this situation did not recur in 2008. Their approach was subtly different to that used by the Linux kernel maintainers.

Rather than attempt to hunt for bugs in the time management code streams in the system kernel, they noted that the intentional side effect of NTP was to continually perform slight time adjustments in the systems that are synchronizing their time according to the NTP signal. If the quantum of an entire second in a single time update was a problem to their systems, then what about an approach that allowed the 1-second time adjustment to be smeared across numerous minutes or even many hours? That way the leap second would be represented as a larger number of very small time adjustments that, in NTP terms, was nothing exceptional. The result of these changes was that NTP itself would start slowing down the time-of-day clock on these systems some time in advance of the leap second by very slight amounts, so that at the time of the applied leap second, at 23:59:59 UTC, the adjusted NTP time would have already been wound back to 23:59:58. The leap second, which would normally be recorded as 23:59:60 was now a "normal" time of 23:59:59, and whatever bugs that remained in the leap second time code of the system were not exercised.[6]

More Leaping?

The topic of leap seconds remains a contentious one. In 2005 the United States made a proposal to the *ITU Radiocommunication Sector* (ITU-R) Study Group 7's Working Party 7-A to eliminate leap seconds. It is not entirely clear whether these leap seconds would be replaced by a less frequent *Leap Hour,* or whether the entire concept of attempting to link UTC and the Mean Solar Day would be allowed to drift, and over time we would see UTC time shifting away from the UT1 concept of solar day time.

This proposal was most recently considered by the ITU-R in January 2012, and there was evidently no clear consensus on this topic. France, Italy, Japan, Mexico, and the United States were reported to be in favor of abandoning leap seconds, whereas Canada, China, Germany, and the United Kingdom were reportedly against these changes to UTC. At present a decision on this topic, or at the least a discussion on this topic, is scheduled for the 2015 *World Radio Conference*.

Although these computing problems with processing leap seconds are annoying and for some folks extremely frustrating and sometimes expensive, I am not sure this factor alone should affect the decision process about whether to drop leap seconds from the UTC time framework. With our increasing dependence on highly available systems, and the criticality of accurate time-of-day clocks as part of the basic mechanisms of system security and integrity, it would be good to think that we have managed to debug this processing of leap seconds.

It is often the case in systems maintenance that the more a bug is exercised the more likely it is that the bug will be isolated and corrected. However, with leap seconds, this task is a tough one because the occurrence of leap seconds is not easily predicted. The next time we have to leap a second in time, about the best we can do is hope that we are ready for it.

For Further Reading

The story of calendars, time, time of day, and time reference standards is a fascinating one. It includes ancient stellar observatories, the medieval quest to predict the date of Easter, the quest to construct an accurate clock that would allow the calculation of longitude, and the current constellations of time and location reference satellites. These days much of this material can be found on the Internet.

The Internet of Things

by David Lake, Ammar Rayes, and Monique Morrow, Cisco Systems

Until a point in time around 2008 or 2009, there were more human beings in the world than devices connected to the Internet. That is no longer the case.

In 2010, the global average of connected devices per person was 1.84. Taking only those people who use the Internet (around 2 billion in 2010), that figure becomes 6 devices per person.[1] Chip makers such as ARM have targeted developments of low-power CPUs and predicts up to 50 billion devices connected by 2020.[2]

Today, most of these devices are entities that the user interacts directly with—a PC or Mac, smartphone, tablet, etc. But what is changing is that other devices used every day to orchestrate and manage the world we live in are becoming connected entities in their own right.

They consist not just of users interacting with the end devices—the source and treatment of the information garnered will now occur autonomously, potentially linking to other networks of similarly interconnected entities.

Growing to an estimated 25 billion connected devices by 2015, the rapid explosion of devices on the Internet presents some new and interesting challenges.[3]

A Definition of the Internet of Things

The *Internet of Things* (IoT) consists of networks of sensors attached to objects and communications devices, providing data that can be analyzed and used to initiate automated actions. The attributes of this world of things may be characterized by low energy consumption, auto-configuration, embeddable objects, etc. The data also generates vital intelligence for planning, management, policy, and decision making. In essence, the five properties that characterize the Internet of Things are as follows:

- *A Unique Internet Address* by which each connected physical object and device will be identified, and therefore be able to communicate with one another.
- *A Unique Location—can be fixed or mobile—within a network or system* (for example, a smart electricity grid) that makes sense of the function and purpose of the object in its specified environment, generating intelligence to enable autonomous actions in line with that purpose.
- *An Increase in Machine-Generated and Machine-Processed Information* that will surpass human-processed information, potentially linking in with other systems to create what some have called "the nervous system of the planet."

- *Complex New Capabilities in Security, Analytics, and Management,* achievable through more powerful software and processing devices, that enable a network of connected devices and systems to cluster and interoperate transparently in a "network of networks."
- *Time and Location Achieve New Levels of Importance* in information processing as Internet-connected objects work to generate ambient intelligence; for example, on the *Heating, Ventilation, and Air Conditioning* (HVAC) efficiency of a building, or to study soil samples and climatic change in relation to crop growth.

The concepts and technologies that have led to the IoT, or the interconnectivity of real-world objects, have existed for some time. Many people have referred to *Machine-to-Machine* (M2M) communications and IoT interchangeably and think they are the same. In reality, M2M is only a subset; IoT is a more encompassing phenomenon because it also includes *Machine-to-Human* communication (M2H). *Radio Frequency Identification* (RFID), *Location-Based Services* (LBS), *Lab-on-a-Chip* (LOC) sensors, *Augmented Reality* (AR), robotics, and vehicle telematics are some of the technology innovations that employ both M2M and M2H communications within the IoT as it exists today. They were spun off from earlier military and industrial supply chain applications; their common feature is to combine embedded sensory objects with communication intelligence, running data over a mix of wired and wireless networks.

What has really helped IoT gain traction outside these specific application areas is the greater commoditization of IP as a standard communication protocol, and the advent of IPv6 to allow for a unique IP address for each connected device and object. Researchers and early adopters have been further encouraged by advancements in wireless technologies, including radio and satellite; miniaturization of devices and industrialization; and increasing bandwidth, computing, and storage power.

All these factors have played a part in pushing the boundaries toward generating more context from data capture, communication, and analytics through various devices, objects, and machines in order to better understand our natural and man-made worlds. In exploring the relationship between the IoT and *Information-Centric Networking* (ICN), embedded distributed intelligence will be an important attribute for ICN. Context that is distributed as opposed to centralized is a core architectural component of the IoT for three main reasons:

- *Data Collection:* Centralized data collection and smart object management do not provide the scalability required by the Internet. Managing several hundreds of millions of sensors and actuators in a *Smart Grid* network, for example, cannot be done using a centralized approach.

- *Network Resource Preservation:* Network bandwidth is scarce and some smart objects are not mains-powered, meaning that collecting environmental data from a central point in the network unavoidably leads to using a large amount of the network capacity.
- *Closed-Loop Functioning:* The IoT needs reduced reaction times. For instance, sending an alarm via multiple hops from a sensor to a centralized system, which runs analytics before sending an order to an actuator, would entail unacceptable delays.

Service Management Systems (SMS) (also known as Management Systems, Network Management Systems, or back-end systems) are the brain in the IoT. SMS interacts with intelligent databases that contain *Intellectual Capital* (IC) information, contract information, and manufacturing and historical data. SMS also supports image-recognition technologies to identify objects, people, buildings, places, logos, and anything else that has value to consumers and enterprises. Smartphones and tablets equipped with cameras have pushed this technology from mainly industrial applications to broad consumer and enterprise applications.

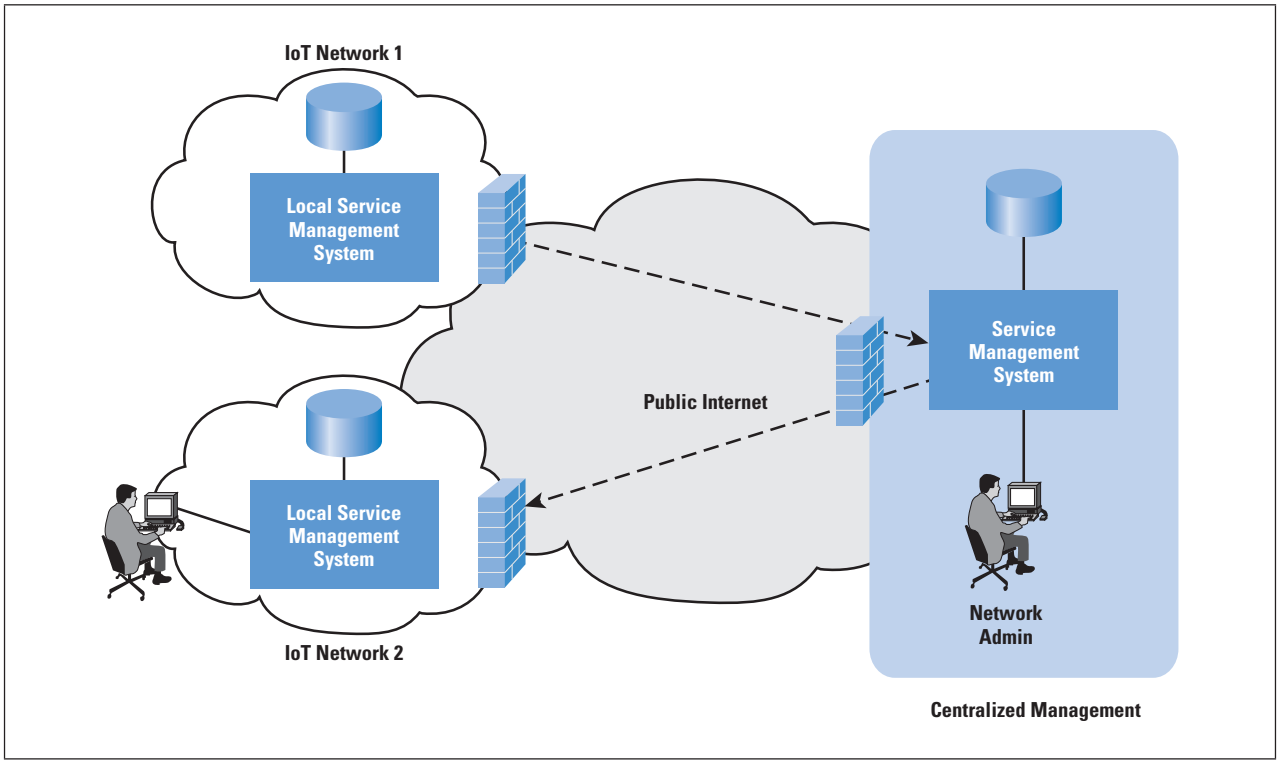
IC information includes intelligence of the vendor's (for example, Cisco) databases and systems such as contract DB, Manufacturing DB, and more importantly thousands of specific roles that are captured over the years by analyzing software bugs, technical support cases, etc.; that is, Cisco knows which devices were manufactured for which customers and with what features. Data collected by the collector is analyzed and correlated with the repository of proprietary Intellectual Capital, turning it into actionable intelligence to help network planners and administrators increase IT value, simplify IT infrastructure, reduce cost, and streamline processes.

Secure communications allow collected data to be sent securely from the agents or collection system to the SMS. SMS includes a database that stores the collected data and algorithms to correlate the collected data with Intellectual Capital information, turning the data into actionable intelligence that network planners and administrators can use with advanced analytics to determine the optimal solution for a problem (or potential problem) after the data is analyzed and corrected. More importantly, a secure mechanism allows the vendor to connect to the network remotely and take action. Secure communications also allows the SMS (automatically or via a network administer) to communicate back with the device to take action when needed.

However, centralized SMS for a large number of entities is very challenging given the near-real-time requirements and the effect on the network performance (see Figure 1). At the same time, centralized intelligence will be required for many IoT networks to interact with back-end centralized databases that are very difficult to distribute (for example, supplier Intellectual Capital databases).

This centralization is more demanding than the traditional multitier environments, servers, and back-end database types of applications where database caching was an effective approach to achieve high scalability and performance. Solution architects need to consider an optimal hybrid model that supports centralized and distributed systems at the same time. Distributed SMS may need to make sub-optimal decisions by using only narrow information to address real-time (or near-real-time) performance problems.

Figure 1: Typical Deployment of an IoT Network



Device and Data Security

The IoT will comprise many small devices, with varying operating systems, CPU types, memory, etc. Many of these devices will be inexpensive, single-function devices—for example, a temperature or pressure sensor—and could have rudimentary network connectivity. In addition, these devices could be in remote or inaccessible locations where human intervention or configuration is impossible.

The nature of sensors is such that they are embedded in what they are sensing—one can envisage a new workplace, hospital, or school construction project where the technology is introduced during the construction phase as part of the final fit rather than after completion as is common today. This paradigm in itself creates new challenges because the means of connectivity may exist only after the installation teams have left the site.

Additionally, methods must be taken to ensure that the authenticity of the data, the path from the sensor to the collector, and the connectivity authentication parameters cannot be compromised between the initial installation or configuration of the device and its eventual presence on the IoT infrastructure.

The challenges of designing and building IoT devices can be summarized as follows:

- IoT devices are typically small, inexpensive devices.
- They are designed to operate autonomously in the field.
- They may be installed prior to network availability.
- After deployment, these devices may require secure remote management.
- The computing platform may not support traditional security algorithms.

Because the IoT will not be a single-use, single-ownership "solution" with sources and the platform on which data may be consumed could be in different ownership, managerial, and connectivity domains, devices will be required to have equal and open access to numerous data consumers concurrently, while still retaining privacy and exclusivity of data where that is required between those consumers.

This requirement was neatly summarized by the IETF Security Area Directors as follows: "A house only needs one toaster even if it serves a family of four!"[4]

So we have seemingly competing, complex security requirements to be deployed on a platform with limited resources:

- Authenticate to multiple networks securely.
- Ensure that data is available to multiple endpoints.
- Manage the contention between that data access.
- Manage privacy concerns among multiple consumers.
- Provide strong authentication and data protection that cannot be compromised.

And we have to manage existing challenges that all network-attached devices have to contend with such as *Denial of Service* (DoS) attacks, transaction replays, compromised identity through subscriber theft, device theft, or compromised encryption.

These problems have particular relevance in the IoT, where the availability of data is of paramount importance. For example, a critical industrial process may rely on accurate and timely temperature measurement—if that sensor is undergoing a DoS attack, the process collection agent must understand that, and be able to either source data from another location or take evasive action.

It must also be able to distinguish between loss of data because of an ongoing DoS attack and loss of the device because of a catastrophic event in the plant. This ability could mean the difference between a safe shut-down and a major incident.

Authentication and authorization will require reengineering to be appropriate for the IoT. Today's strong encryption and authentication schemes are based on cryptographic suites such as *Advanced Encryption Standard* (AES), *Rivest-Shamir-Adelman* (RSA) for digital signatures and key transport, and *Diffie-Hellman* (DH) for key agreement. Although the protocols are robust, they make very high demands of the compute platform—resources that may not exist in all IoT-attached devices.

These authentication and authorization protocols also require a degree of user intervention in terms of configuration. However, many IoT devices will have limited access; initial configuration needs to be protected from tampering, stealing, and other forms of compromise between device build and install, and also for its usable life, which could be many years.

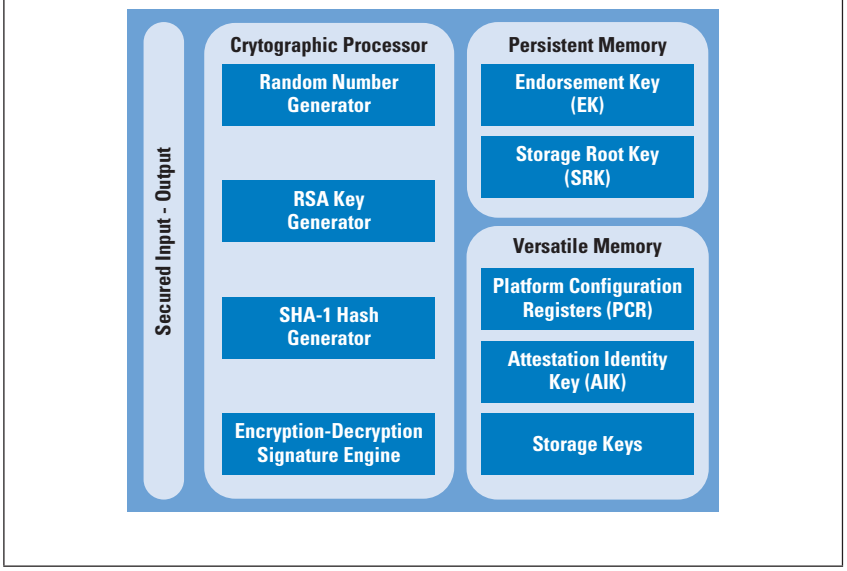
In order to overcome these difficulties, new authentication schemes that allow for strong authentication to many domains while building on the experience of today's strong encryption and authentication algorithms are required.

One possible approach could be to extend methodologies used in the PC industry such as the *Trusted Computing Group's Trusted Platform Model* (TPM).[5,6]

TPM-enabled devices are fitted at build time with a highly secure hardware device containing a variety of cryptographic elements. Keys and other factors known from this device by trusted third parties are then used in an attestation—a request to validate the authenticity of one device from known parameters.

Because the cryptographic keys are burned into the device during build and the signatures are known to a controlled, trusted third party, a high degree of confidence in the authenticity of the device being queried can be obtained. A typical TPM-compliant cryptographic chip is shown in Figure 2.

Figure 2: Trusted Platform Module



TPM has traditionally been limited by requiring access not only between the devices, but also to a trusted third party. In the IoT, where connectivity may be transient, this requirement is obviously a limitation. Extensions to the TPM to allow for high-confidence attestation between devices without involving a third party have been built; for example, *Direct Anonymous Attestation* (DAA).[7]

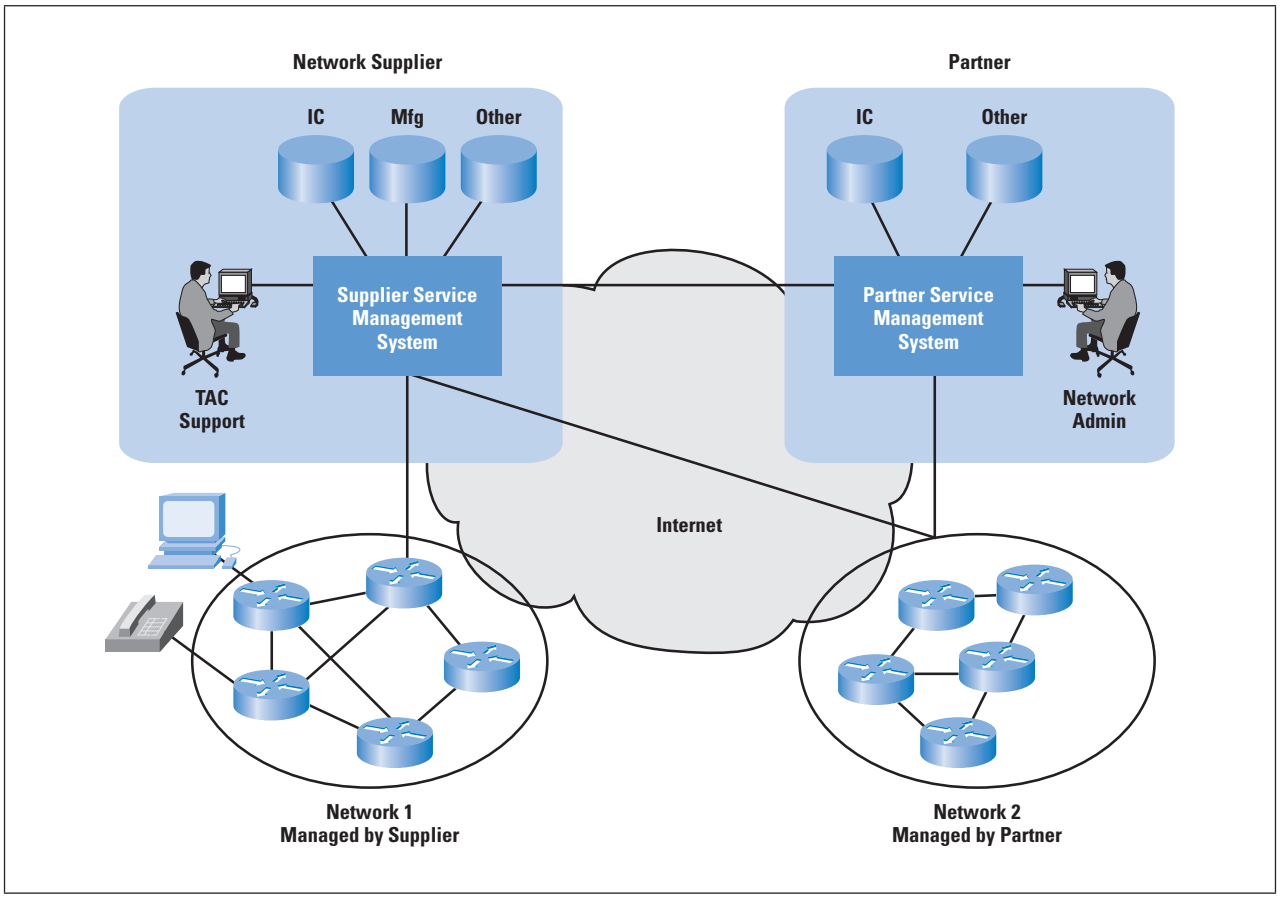
Other elements in security that could be considered include strong authentication between the device and the network attachment point (such as through electrical signatures at the *Media Access Control* [MAC] layer), application of geographic location and privacy levels to data, strengthening of other network-centric methods such as the *Domain Name System* (DNS) and the *Dynamic Host Configuration Protocol* (DHCP) to prevent attacks, and adoption of other protocols that are more tolerant to delay or transient connectivity (such as *Delay Tolerant Networks*).[8]

An IoT Case Study

The concepts behind the IoT allow management of assets within an enterprise with responsibility shared among customer, partner, and manufacturer in a manner that would previously have been difficult to control.

A typical IT network consists of routers, switches, IP phones, telepresence systems, network management systems such as call managers, data center managers, and many other entities (also known as "machines") with unique identification (for example, serial number, MAC address, or other address (for example, IP address). Such a solution is depicted in Figure 3.

Figure 3: Example of Smart Services



The system has the following components:

- The IT IP-based network: The network typically is owned by a business customer or an end customer (for example, a small business network). It includes IP devices that may be managed either by the supplier (via service contract), by a third party, Partner 2, or by the customer network administer.
- Smart agent or collection system (or sensor): An external collection system (for example, a server) or smart agent or collection systems on the managed devices gather the device and network information via numerous methods including *Simple Network Management Protocol* (SNMP) requests, *Command-Line Interface* (CLI) commands, syslog, etc. Collected information includes inventory, security data, performance data such as service-level agreement parameters, fault messages, etc.
- Supplier or partner back-end service management system: A service management system collects data from various devices and networks, correlates the collected data against intelligent Intellectual Capital rules and important databases (for example, Manufacturing database or Contact Management database), analyzes the results, and produces actionable and trending reports that examine the network and predict the performance.

- Two-way connectivity: Connectivity allows the front-end system (that is, smart agents and collection systems) to send data securely to the supplier or partner service management systems. It also allows the service management system to access the device or network secularly to take action when required.
- Secure entitlement and data-transfer capability to register and entitle customer networks and communicate securely (via encryption and security keys) with service providers or network vendors: Such capability is typically deployed on the collector and back-end systems.

A Smart Service provides a proactive intelligence-based solution addressing the installed-based lifecycle and *Fault, Configuration, Accounting, Performance, and Security* (FCAPS) management with the unique benefit of correlating data with the supplier's Intellectual Capital and recognized best practices. Using smart agents, Smart Services collects basic inventory information from the network in order to establish Install Base context.

Conclusions

The implications of the IoT on today's Internet are vast. With such a large number of devices and highly constrained network environments, provisioning and management of the IoT needs to be a part of the architecture. It is both unwise and impractical to provision each active device in the network manually throughout its lifecycle. Earlier technologies, including IP phones, wireless access points, or service provider *Customer Premises Equipment* (CPE), have demonstrated that provisioning can be carried out securely over the network.

The IoT encompasses heterogeneous types of devices that can be on public or private IP networks: from low-powered, low-cost sensors, to fully functioning multipurpose computers with commercial operating systems. For this reason, there can be no "one-size-fits-all" approach to IoT security. What is required is a series of architectural approaches that are dictated by specific IoT use cases. In certain industry solutions, most notably healthcare, security is not just important; information privacy is specifically mandated in many countries.

The challenges of designing, deploying, and supporting billions of IP-enabled endpoints, each producing data that needs to be analyzed and acted on, present exciting opportunities for the next generation of the Internet.

The Demise of Web 2.0 and Why You Should Care

by David Strom

The term Web 2.0 has been around for about a decade[1], but we are finally seeing its disuse. No, the web itself is not going away, but the notion that an interactive layer of applications, protocols, programming languages, and tools has become subsumed into a new kind of web—one where everything is a *service,* mobile browsing is more important, and social networking has helped discover and promote new content. As a result, we do not really need the term anymore, because it is so much of what the web has become.

Think of this concept as going beyond the 2.0 label of the web: now we have a richer world of interactions that is just the beginning of how we use that tired old TCP port 80. All these developments mean that the readers of *The Internet Protocol Journal* are well poised to help others take advantage of this new complex web environment, because it has become the norm rather than some fancy address in the better part of town. Understanding its new structure and purpose is critical to building the next generation of websites and interactive applications.

Back in the early days of the web in the mid-1990s, it was largely static content that a browser would access from a web server. The notion of having dynamic pages that would automatically update from a database server was exciting and difficult to accomplish without a lot of programming help.

But then came Web 2.0, where the interactive web was born. We had blogging tools such as Google's *Blogger* and Automattic's *Wordpress,* and anyone could create a website that could be easily changed and instantly updated. Web and database servers became better connected, and new protocols were invented to better marry the two.

Everything as a Service

The past few years have seen the rise of *Software as a Service, Infrastructure as a Service,* and even *Platforms as a Service*.[2] The coming of *Cloud Computing* has meant that just about anything can be virtualized and moved into a far-away data center, where it can be managed and replicated easily, obviating the need for any physical infrastructure in the traditional enterprise data center.

Why is this change relevant for the modern web era? Four reasons:

- The web browser is still used as the main remote-access tool to configure and manage a wide variety of applications, network equipment, and servers, including all kinds of cloud-based infrastructures.

- Most of these "as-a-service" entities still run over ports 80 and 443 and piggyback on top of web protocols, for better or worse. We have gotten used to having these ports carry all sorts of traffic that has nothing to do with ordinary web browsing, and we have to do a better job of sorting out the ways apps use the traditional web ports too.
- We do not need to buy any software or install it on our own desktops; everything is available in the cloud at a moment's notice. What is more, we have gotten used to having the web as the go-to place to get new tools, software drivers, and programs. Software repositories such as *GitHub* and open source projects such as *Apache* have blossomed into places that corporate developers use daily for building their own apps. And why not? They have large support communities and hundreds of projects that are as well tended as something out of Oracle or Microsoft (and some would argue better, too).
- The days of a simple web server serving up pages is ever more complex, with typical commercial websites having ad servers, built-in analytics to track page views and visitors, discussion forums to moderate comments, connections to share the post on *Twitter* and *Facebook* (more on these in a moment), and videos embedded in various ways. All of these websites require coordinated applications and add-ons to the basic web server that require various cloud services. For example, the sites that I run for *ReadWriteWeb* use *Moveable Type* for our content, *Google Analytics*, *Disqus* discussions, interactive polls from `PollDaddy.com`, and custom-built advertising servers, just to name a few of the numerous add-ons. The ever increasing numbers of add-ons means maintaining this system is not easy, and it requires a lot of detailed adjustments on a too-frequent basis.

The Rise of Mobile Browsers

According to the research firm NetApplications[3], the share of web browsing originating from mobile devices has more than doubled in the past year. Although desktops still account for more than 90 percent of the data accessed from browsers, mobile devices are consuming the web at an increasing rate.

Part of this trend is that we are using more devices and they have become more capable. Android-based phones constitute the largest market share, and they have the fastest-growing consumer mobile phone adoption rate.[4] Certainly, more and more of us are browsing more webpages from mobile devices these days.

Another part of the trend of increased roaming on mobile devices is that more people are creating and using more mobile apps, too. Hundreds of new mobile apps with a wide variety of content are created every day. Professors at major universities teach computer science students how to code mobile apps, and you can even take online courses on *Java* programming.

But mobile browsing poses a conundrum for web designers. One school of thought is to build custom tablet applications for your website, to show off the features of the tablet interface and to make it easier for tablet users to interact with your content. The U.K. *Guardian,* for example, is leading the way in this area.[5]

Another school of thought is to improve the mobile experience, by either building a separate site that is optimized for smaller screens and lower bandwidth connections or allowing the site to work automatically under the constraints of the mobile browser itself.[6]

One real challenge for the mobile web browsing experience is the role of Adobe Flash and the newest of the *Hypertext Markup Language* (HTML) standards, HTMLv5. Apple decided when it released its first iPads to not support Flash, and since then there has been additional effort and movement to migrate many Flash-based sites, such as **YouTube.com**, toward HTMLv5, which is supported by Apple's tablets and can be more efficient for lower-bandwidth connections. Although this topic could easily be the subject of an entire article for this journal, our point in mentioning it here is that displaying video and similar content is still a problem for the web, even today.

Our mobile traffic at *ReadWriteWeb* has increased tremendously in the past year, and I suspect our site is typical of other sites. But this increase in traffic presents challenges for content creators: is it better to sell ad units around the content, even ads that have sub-par browsing experiences on mobile devices? Or code up your own iPad app (or use Verve's tools [**http://www.vervewireless.com/**] or something equivalent)? Certainly the level of engagement with the custom mobile app is greater, but it amazes me that sites with just static pages still are not optimized for mobile browsers yet, with large image downloads or multiple included links, for example.

Let's consider the site **Remodelista.com** as a case study of how to properly optimize a site for mobile browsing. The owners have implemented tricks to adjust its layout for different screen sizes. As you make your browsing window smaller (or as you run it on a mobile device with a small screen), the integrity of the site content remains intact, meaning that font sizes change and ad blocks appear on wider, higher-resolution screens and disappear on smaller ones, but the overall content stream remains the same, no matter what device is used to view it. This consistency is achieved by adding a lot of special coding to the webpages, as the following snippet shows:

```
<!--[if IEMobile 7]> <html class="no-js iem7 oldie" itemscope itemtype="http://schema org/"><![endif]-->

The Social Web Is Now Everywhere

It used to be the odd person in your professional circle who did not have or use an Internet e-mail account. Now the odd person is the one who does not have an account on Facebook or some other social networking site. What began in a Harvard dorm room in this decade has turned into a juggernaut of more than a billion users—and it is growing rapidly.

But the social web is more than a bunch of college kids swapping photos of their party pictures. A recent study from the University of Massachusetts at Dartmouth[7] shows that nearly 75 percent of the Inc. 500 (the fastest-growing 500 American private companies) are using *Facebook* or *LinkedIn,* a level that is about twice the percentage that are using corporate blogs. "Ninety percent of responding executives report that social media tools are important for brand awareness and company reputation. Eighty-eight percent see these tools as important for generating web traffic while 81% find them important for lead generation. Seventy-three percent say that social media tools are important for customer support programs." Clearly, these tools have become the accepted corporate intranet, the mainstream mechanism for communications among distributed work teams, and the way that many of us share events in our professional lives as well.

The social web means more than a "Like" button on a particular page of content; it is a way to curate and disseminate that content quickly and easily. It has replaced the Usenet *news groups* that many of us remember with a certain fondness for their arcane and complex structure. Or maybe that is just nostalgia talking.

In the presocial web past, even in the days when Web 2.0 was the rage, sharing and curation was not easy. If you wanted to share something you found online, more than likely you would e-mail your colleagues a URL. Now you can *Tweet,* post on *Facebook* and *Google+,* add an update to your *LinkedIn* account, put up a page on your corporate `Yammer.com` or `tibbr.com` server, or use one of dozens more services that will stream your likes and notable sites to the world at large. Or you likely have to do all of these tasks.

Back in the days of yore (say 2000), when I wrote a freelance article, it was sufficient to post a link to the story on my own personal website, in addition to perhaps sending an e-mail message or two to the people I thought might be interested in reading the content. Those days seem so quaint. Today, the process of writing the article is actually just the beginning, not the end. When the article appears online, a whole series of promotional activities must take place, including monitoring online discussions and adding my own comments, posting on the various social media sites, and re-Tweeting a link to my article several times over the next several days—all to ensure generation of lots of traffic.

There are even services such as **Ping.fm** and **Graspr.com** that can coordinate batch updates to numerous services, so that at the push of a button all of your social media will get your news at once. Or services such as **Nimble.com** that attempt to coordinate your entire social graph (as it is called) of friends and admirers so you can track what is going out across all your various networks.

Where We Go from Here

I have just tried to touch on a few topics to show that the days of the simple static web are "so over," as Generation Y says. Clearly, we have a long and rich future ahead of us for more interesting web applications.

Binary Floor Control Protocol

by Pat Jensen, Cisco Systems

Over the last decade, communication technologies have evolved to encompass new modalities of collaboration across IP networks—from instant messaging on a personal computer, to being able to make *Voice-over-IP* (VoIP) calls and also now including the growing adoption of *High-Definition* (HD) videoconferencing.

Operating systems, device types, and physical locations now are less affected as continued growth in networking has evolved to promote high bandwidth across wireless and wired networks. An example is the emergence of growing network-access technologies such as *Multiprotocol Label Switching* (MPLS), *Very-High-Speed Digital Subscriber Line 2* (VDSL2), *Long Term Evolution* (LTE), and *Data over Cable Service Interface Specification* (DOCSIS). With both availability of bandwidth and broadband user penetration increasing, the user's expectation of delivering immersive collaboration now becomes more apparent.

This evolution includes modern use cases accelerating the adoption of videoconferencing, such as enabling telemedicine for remote surgeries and diagnostic procedures as well as distance learning applications being used to connect educators with students across the globe.

This article introduces the *Binary Floor Control Protocol* (BFCP) as a standard for managing floor control during collaboration sessions across dedicated video endpoints, mobile devices, and personal computers running collaboration software. These capabilities can be delivered using an enabled *Session Initiation Protocol* (SIP) standards-based endpoint or as a software implementation in a collaboration application stack.

History

BFCP is a deliverable developed as part of the *Internet Engineering Task Force* (IETF) XCON Centralized Conferencing working group. The IETF XCON working group was formed to focus on delivering a standards-based approach to managing IP conferencing while promoting broad interoperability between software and equipment vendors.[1]

This mandate includes defining the objects, mechanisms, and provisions to assist in scheduling conferencing resources. These resources could be consumed as a conference enabled in a web browser, via an audio conference call or during a videoconference.

As defined, privacy, security, and authorization are considered integral in protecting the ability to join, participate in, and manage each conference session. The IETF XCON working group's initial focus was on unicast media conferences.

The IETF XCON working group was proposed in August 2003, with work starting early in October of that year.[2] Early requirements for BFCP were defined in RFC 4376, which describes important concepts, including a model for floor control and how it should be integrated in a conferencing platform.[3] Other important aspects such as security, including using authentication and encryption to provide protection against man-in-the-middle attacks, were also outlined.

In November 2006, Gonzalo Camarillo, Joerg Ott, and Keith Drage authored RFC 4582, which defined the Binary Floor Control Protocol.[4]

Besides BFCP, other standardization efforts around conference role and content management also were defined, including the ITU-T H.239 recommendation.[5] Unlike BFCP, H.239 applies specifically to H.323-enabled *Integrated Services Digital Network* (ISDN) and IP conferencing endpoints, whereas BFCP is designed to be agnostic of the underlying signaling protocol.

Protocol Details

The basic concept of floor control is analogous to managing a live in-person presentation, where you want to control who is presenting, manage and transition your presenters, and maintain a feedback loop. Also important is the ability to allow a presenter to show slides and share with your audience a white board or transparency projector.

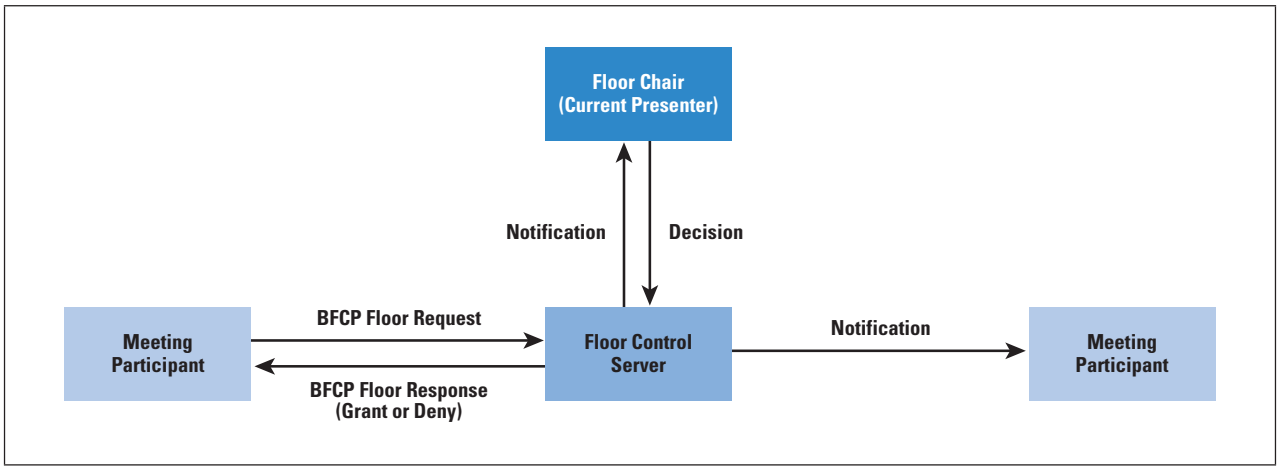
During an active collaboration session, a presenter may choose to present material to a remote user, or optionally to an audience on a call with multiple endpoints through a *Multipoint Control Unit* (MCU). This session could include many additional sources; for example, using a secondary video camera to show zoomed-in content (that is, an optical examination camera used in telemedicine) or any external video source.

This floor-control mechanism can also encompass functions available in a collaboration application stack, such as the ability to share the content of the presenter's desktop, application, or web browser.

BFCP provides the ability to manage multiple streams being presented during a collaboration session using floor control. BFCP accomplishes this management using a token-based mechanism where a single presenter can request control of the floor from the floor-control server.

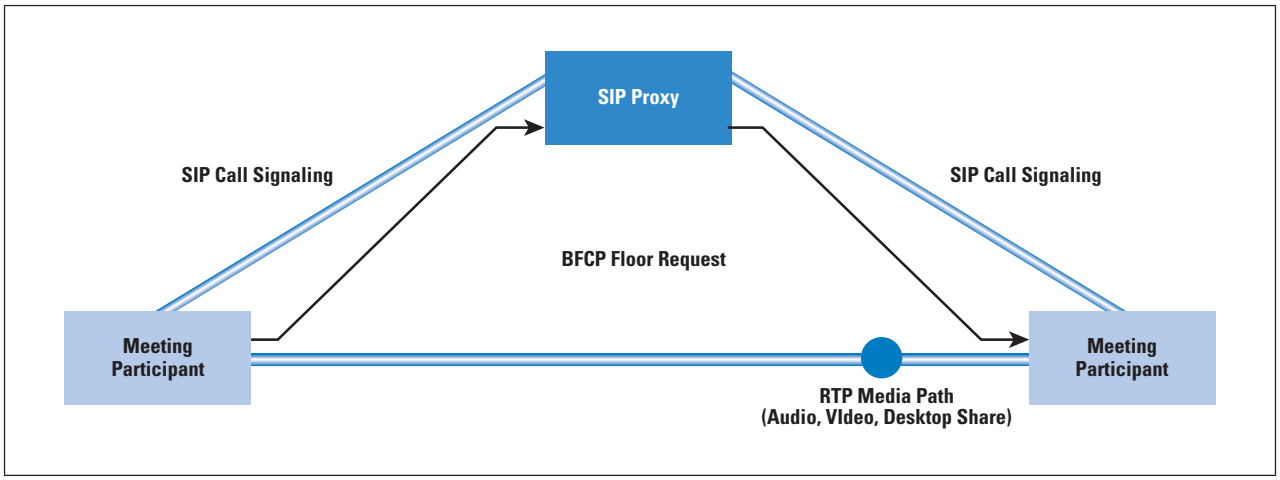
When this request is granted, the presenter holds the token and has the ability to open an additional stream to provide presentation data. Figure 1 examines this process in detail, with a meeting attendee requesting the token from the floor-control server to become an active presenter during the session.

Figure 1: BFCP Floor Request from Floor-Control Server



This same interaction can also take place during a point-to-point audio or video call with only two parties. In this case, a token can be used to signify which party will be presenting an additional stream, such as a secondary camera or application providing a desktop sharing session. Figure 2 shows an overview of this process. One of the critical differences here is that in a point-to-point call, the floor-control server capability is being provided by the user's device or application instead of using a multipoint control unit or conference server.

Figure 2: BFCP Floor Request in a Point-to-Point SIP Call



For instance, as a presenter, you can choose to present auxiliary streams via your application or endpoint and determine whether it is your primary, secondary, or tertiary stream. As a conference participant, you can also choose which stream you are currently viewing, also including the definition and quality of the secondary stream. In this case, current network conditions such as bandwidth and latency will also dictate the quality of additional streams.

BFCP is designed to be signaling protocol–agnostic, in that it is relying on the capabilities of the underlying signaling and transport protocols to set up each stream that is being managed, including whether voice, video, or content is being provided in the *Real-Time Transport Protocol* (RTP) stream.

For example, using a standards-based endpoint and *Session Initiation Protocol* (SIP), a SIP INVITE message is sent with the media capabilities line specifying the session description information about the stream. This data provides relevant information about the underlying video codec being used and the bit rate that is required to support the video and presentation streams.

In this case as multiple RTP media streams are transported across the network carrying audio and video traffic, *Call Admission Control* (CAC) and *Quality of Service* (QoS) tagging can be applied and enforced by the call-control platform, providing the ability to limit bandwidth usage and helping ensure that bandwidth is available on the network after the additional media stream is added.

Also important to note, BFCP can use *Transport Layer Security* (TLS) to provide encryption of floor information pertaining to each resource that is being controlled as well as the participants using and viewing them. BFCP provides the ability to support anonymous users as well for sessions where you may have a large audience or where anonymity is desired. An example of where this feature could be used is hosting a large web conferencing event where you have external attendees who may be outside of your organization.

One use case for BFCP includes the ability to focus on the presenter while the presenter is sharing a desktop application. With the ability to control the presenter's media stream, this feature adds additional immersion in a collaboration session, allowing you to both identify the presenter's visual cues and posture as well as focus on relevant content the presenter supplies.

Summary

The Binary Floor Control Protocol plays a very important role in helping manage diverse types of content being shared across multiple parties in a conference session. Today's modern implementations of BFCP span web conferencing applications as well as video and audio conferencing solutions across a wide array of vendors.

While these vendors are focused on delivering these capabilities across screen-led PC-centric types of devices, because of its inherent transport-agnostic capabilities, it is likely we will see BFCP being used to enable new modalities of content sharing across collaboration applications in the future.

Industry efforts are focusing on promoting collaboration applications across new arrays of devices, including using touchscreen technology on handheld computers and stationary LCD televisions to manipulate and visualize data in new ways.

Concepts such as manipulating session content using cognitive mapping as an evolution of electronic whiteboarding and transitioning an active conference from a tablet device to another type of room-based video-enabled endpoint during a collaboration session are two powerful examples of ways BFCP could be used in the future. On the horizon, touchscreen-enabled tablet and smartphone devices and HTML5-enabled web browsers also provide yet another avenue to enable rich standards-based multimedia conferencing with advanced content management.

Pierre Ouedraogo Receives 2012 Jonathan B. Postel Service Award

The Internet Society recently announced that its prestigious *Jonathan B. Postel Service Award* was presented to Pierre Ouedraogo for his exceptional contributions to the growth and vitality of the Internet in Africa. The international award committee, comprised of former Jonathan B. Postel award winners, noted that Mr. Ouedraogo played a significant role in the growth of the Internet in Africa and demonstrated an extraordinary commitment to training young engineers and participating in regional Internet organizations.

Mr. Ouedraogo is the Director of Digital Francophonie at *Organisation Internationale de la Francophonie* (OIF) based in Paris, France. Over the years, he has established networks of IT experts to coordinate African efforts to develop IT and use it as a tool for development. Mr. Ouedraogo initiated many IT technical workshops in Africa and is a founding member of numerous African regional organizations, including AfriNIC (the African Internet Registry for IP addresses); AfTLD *(African Internet Top Level Domain Names Association);* AFNOG *(African Network Operators Group);* AfCERT *(African CERT network),* and AfrICANN *(African network of participants to the ICANN process).*

"Pierre Ouedraogo is a highly-regarded technical leader in Africa, and he has been instrumental in bringing the Internet to Burkina Faso as well as other French-speaking African countries," said Lynn St. Amour, President and Chief Executive Officer of the Internet Society."

"His commitment to the expansion of the Internet and encouragement of young engineers to help them build their skills through training workshops has had a profound impact on the growth of the Internet across Africa."

The Postel Award was established by the Internet Society to honour individuals or organisations that, like Jon Postel, have made outstanding contributions in service to the data communications community. The committee places particular emphasis on candidates who have supported and enabled others in addition to their own specific actions. The award is focused on sustained and substantial technical contributions, service to the community, and leadership.

For more information about the Internet Society and the Postel award, see: **http://www.internetsociety.org/**

Atsushi Seike (L) with Vint Cerf and Jun Murai.

Vint Cerf Awarded Honorary Doctorate by Keio University

Keio University in Tokyo recently awarded Dr. Vinton Gray Cerf an honorary doctorate in Media and Governance for his work in the creation and governance of our modern Internet over the last forty years. On the recommendation of Professor Jun Murai, dean of the Faculty of Environment and Information Studies, Keio University president Atsushi Seike presented Dr. Cerf with the degree. The ceremony was held in the Enzetsu-kan, the historic public speaking hall on Keio's Mita Campus in Tokyo, and streamed live via the Internet to viewers around the world.

Professor Murai's recommendation for the degree, read during the ceremony, said that not only is Dr. Cerf the founding father of internetworking technology, "he is the global leader in many ways of the largest innovation for the 21st century, the Internet itself, which has become the core of today's information-based society." In addition to his work on TCP/IP with Robert Khan, Dr. Cerf's work in establishing the Internet Society and his stewardship of ICANN as its chairman were highlighted. Also mentioned was his role in *Delay/Disruption-Tolerant Networking* (DTN) and the first experiments connecting a space probe twenty million miles away using Internet protocols.

In his remarks, President Seike mentioned Dr. Cerf's forty-year commitment to advancing the role of networks in creating our global society, from the earliest days of the ARPANET through today's Internet. "[Dr. Cerf] understood quickly and clearly the international nature of the Internet and its potential for having a positive impact on the lives of not just the technical elite, but for all of the people of the world, as a tool for education, commerce, and the advance of democracy," he noted. Professor Seike compared Dr. Cerf's role in using technology to make the world a better place to the efforts of Yukichi Fukuzawa, the founder of Keio University, who in the mid-19th century was instrumental in bringing knowledge to Japan from the outside world, not as an academic exercise but in order to improve society.

Following the ceremony, Dr. Cerf gave an invited technical talk titled "Re-Inventing the Internet." He discussed the potential of DTN and *Mobile Ad Hoc Networks* as tools for disaster recovery. He presented his view of urgent technical problems, including the need for strong authentication and digital forensics. He also outlined society's need for preserving data, the programs that create and manipulate that data, and even the systems that are used to run those programs. Without such an effort, we will fail to preserve our own technical and cultural history for the thousands of years we have come to expect, he noted.

Dr. Cerf left behind the inscription, "I cannot imagine a greater honor than to be brought into this august and highly regarded university where contrary thinking is rewarded! I am most grateful to my good friend, Jun Murai, for his decades long commitment to the Internet."

From The Editor

Accurate timekeeping has long been an engineering challenge if not obsession in some circles. Take for example the iconic Swiss *chronometer* watch or the pendulum-controlled clock mechanism in London's Palace of Westminster, often referred to as "Big Ben." Such mechanical systems—accurate as they may be—are no match for the clocks we use in telecommunication and computer networks. In our last issue, Geoff Huston described the glitches encountered last June when a *Leap Second* was applied to *Coordinated Universal Time* (UTC). In this issue he explains the operation of the *Network Time Protocol* (NTP). The article is another installment in our series "Protocol Basics."

It is difficult to believe that it has been more than 25 years since the first publication of Douglas Comer's book series *Internetworking With TCP/IP*. Volume 1 of this series will soon be available in its sixth edition, and we asked the author to write an article about *Packet Classification* based on material in the book.

The recent *World Conference on International Telecommunications* (WCIT) did not have the outcome with respect to the Internet that many had hoped for. We plan to publish an analysis of this event in our next issue. This time—in our "Fragments" section—we have some reactions from the *Number Resource Organization* (NRO) and the Internet Society, as well as pointers to further information about WCIT.

January 1, 2013, marked the 30th anniversary of the *Transmission Control Protocol/Internet Protocol* (TCP/IP). A transition from the earlier *Network Control Program* (NCP) took place on January 1, 1983, also known as "Flag Day." Such an instant technology change would have been desirable for the transition from IPv4 to IPv6, but sadly this isn't possible. Instead we are happy to honor those who dedicate their careers to IPv6 deployment with an *Itojun Service Award*. See page 25 for more details.

On page 30 you will find some frequently asked questions about subscriptions to this journal. If you have other questions or comments, please contact us at ipj@cisco.com

Protocol Basics: The Network Time Protocol

by Geoff Huston, APNIC

Back at the end of June 2012[0] there was a brief IT hiccup as the world adjusted the *Coordinated Universal Time* (UTC) standard by adding an extra second to the last minute of the 31st of June. Normally such an adjustment would pass unnoticed by all but a small dedicated collection of time keepers, but this time the story spread out into the popular media as numerous Linux systems hiccupped over this additional second, and they supported some high-profile services, including a major air carrier's reservation and ticketing backend system. The entire topic of time, time standards, and the difficulty of keeping a highly stable and regular clock standard in sync with a slightly wobbly rotating Earth has been a longstanding debate in the *International Telecommunication Union Radiocommunication Sector* (ITU-R) standards body that oversees this coordinated time standard. However, I am not sure that anyone would argue that the challenges of synchronizing a strict time signal with a less than perfectly rotating planet is sufficient reason to discard the concept of a coordinated time standard and just let each computer system drift away on its own concept of time. These days we have become used to a world that operates on a consistent time standard, and we have become used to our computers operating at sub-second accuracy. But how do they do so? In this article I will look at how a consistent time standard is spread across the Internet, and examine the operation of the *Network Time Protocol* (NTP).

Some communications protocols in the IP protocol suite are quite recent, whereas others have a long and rich history that extends back to the start of the Internet. The ARPANET switched over to use the TCP/IP protocol suite in January 1983, and by 1985 NTP was in operation on the network. Indeed it has been asserted that NTP is the longest running, continuously operating, distributed application on the Internet[1].

The objective of NTP is simple: to allow a client to synchronize its clock with UTC time, and to do so with a high degree of accuracy and a high degree of stability. Within the scope of a WAN, NTP will provide an accuracy of small numbers of milliseconds. As the network scope gets finer, the accuracy of NTP can increase, allowing for sub-millisecond accuracy on LANs and sub-microsecond accuracy when using a precision time source such as a *Global Positioning System* (GPS) receiver or a caesium oscillator.

If a collection of clients all use NTP, then this set of clients can operate with a synchronized clock signal. A shared data model, where the modification time of the data is of critical importance, is one example of the use of NTP in a networked context.

(I have relied on NTP timer accuracy at the microsecond level when trying to combine numerous discrete data sources, such as a web log on a server combined with a *Domain Name System* (DNS) query log from DNS resolvers and a packet trace.)

NTP, Time, and Timekeeping

To consider NTP, it is necessary to consider the topic of timekeeping itself. It is useful to introduce some timekeeping terms at this juncture:

Stability	How well a clock can maintain a constant frequency
Accuracy	How well the frequency and absolute value of the clock compares with a standard reference time
Precision	How well the accuracy of a clock can be maintained within a particular timekeeping system
Offset	The time difference in the absolute time of two clocks
Skew	The variation of offset over time (first-order derivative of offset over time)
Drift	The variation of skew over time (second-order derivative of offset over time)

NTP is designed to allow a computer to be aware of three critical metrics for timekeeping: the *offset* of the local clock to a selected reference clock, the *round-trip delay* of the network path between the local computer and the selected reference clock server, and the *dispersion* of the local clock, which is a measure of the maximum error of the local clock relative to the reference clock. Each of these components is maintained separately in NTP. They provide not only precision measurements of offset and delay, to allow the local clock to be adjusted to synchronize with a reference clock signal, but also definitive maximum error bounds of the synchronization process, so that the user interface can determine not only the time, but the quality of the time as well.

Universal Time Standards

It would be reasonable to expect that the time is just the time, but that is not the case. The Universal Time reference standard has several versions, but these two standards are of interest to network timekeeping.

UT1 is the principal form of Universal Time. Although conceptually it is *Mean Solar Time* at 0° longitude, precise measurements of the Sun are difficult. Hence, it is computed from observations of distant quasars using long baseline interferometry, laser ranging of the Moon and artificial satellites, as well as the determination of GPS satellite orbits. UT1 is the same everywhere on Earth, and is proportional to the rotation angle of the Earth with respect to distant quasars, specifically the *International Celestial Reference Frame* (ICRF), neglecting some small adjustments.

The observations allow the determination of a measure of the Earth's angle with respect to the ICRF, called the *Earth Rotation Angle* (ERA), which serves as a modern replacement for *Greenwich Mean Sidereal Time*). UT1 is required to follow the relationship

ERA = 2π(0.7790572732640 + 1.00273781191135448Tu) radians
where Tu = (Julian UT1 date – 2451545.0)

Coordinated Universal Time (UTC) is an atomic timescale that approximates UT1. It is the international standard on which civil time is based. It ticks SI seconds, in step with *International Atomic Time* (TAI). It usually has 86,400 SI seconds per day, but is kept within 0.9 seconds of UT1 by the introduction of occasional intercalary leap seconds. As of 2012 these leaps have always been positive, with a day of 86,401 seconds.[9]

NTP uses UTC, as distinct from the *Greenwich Mean Time* (GMT), as the reference clock standard. UTC uses the TAI time standard, based on the measurement of 1 second as 9,192,631,770 periods of the radiation emitted by a caesium-133 atom in the transition between the two hyperfine levels of its ground state, implying that, like UTC itself, NTP has to incorporate leap second adjustments from time to time.

NTP is an "absolute" time protocol, so that local time zones—and conversion of the absolute time to a calendar date and time with reference to a particular location on the Earth's surface—are not an intrinsic part of the NTP protocol. This conversion from UTC to the wall-clock time, namely the local date and time, is left to the local host.

Servers and Clients

NTP uses the concepts of *server* and *client*. A server is a source of time information, and a client is a system that is attempting to synchronize its clock to a server.

Servers can be either a *primary server* or a *secondary server*. A primary server (sometimes also referred to as a *stratum 1* server using terminology borrowed from the time reference architecture of the telephone network) is a server that receives a UTC time signal directly from an authoritative clock source, such as a configured atomic clock or—very commonly these days—a GPS signal source. A *secondary server* receives its time signal from one or more *upstream servers*, and distributes its time signal to one of more *downstream servers* and *clients*. Secondary servers can be thought of as clock signal repeaters, and their role is to relieve the client query load from the primary servers while still being able to provide their clients with a clock signal of comparable quality to that of the primary servers. The secondary servers need to be arranged in a strict hierarchy in terms of upstream and downstream, and the stratum terminology is often used to assist in this process.

As noted previously, a stratum 1 server receives its time signal from a UTC reference source. A stratum 2 server receives its time signal from a stratum 1 server, a stratum 3 server from stratum 2 servers, and so on. A stratum *n* server can peer with many stratum *n* – 1 servers in order to maintain a reference clock signal. This stratum framework is used to avoid synchronization loops within a set of time servers.

Clients peer with servers in order to synchronize their internal clocks to the NTP time signal.

The NTP Protocol

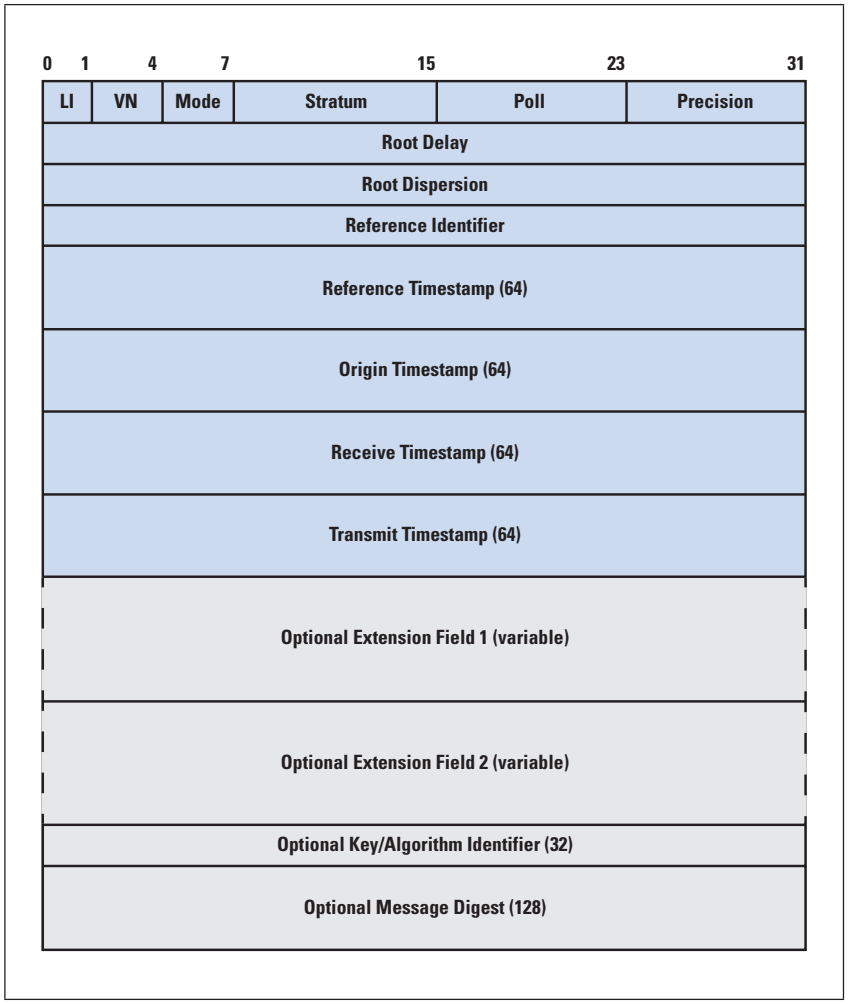
At its most basic, the NTP protocol is a clock request transaction, where a client requests the current time from a server, passing its own time with the request. The server adds its time to the data packet and passes the packet back to the client. When the client receives the packet, the client can derive two essential pieces of information: the reference time at the server and the elapsed time, as measured by the local clock, for a signal to pass from the client to the server and back again. Repeated iterations of this procedure allow the local client to remove the effects of network jitter and thereby gain a stable value for the delay between the local clock and the reference clock standard at the server. This value can then be used to adjust the local clock so that it is synchronized with the server. Further iterations of this protocol exchange can allow the local client to continuously correct the local clock to address local clock skew.

NTP operates over the *User Datagram Protocol* (UDP). An NTP server listens for client NTP packets on port 123. The NTP server is stateless and responds to each received client NTP packet in a simple transactional manner by adding fields to the received packet and passing the packet back to the original sender, without reference to preceding NTP transactions.

Upon receipt of a client NTP packet, the receiver time-stamps receipt of the packet as soon as possible within the packet assembly logic of the server. The packet is then passed to the NTP server process. This process interchanges the IP Header Address and Port fields in the packet, overwrites numerous fields in the NTP packet with local clock values, time-stamps the egress of the packet, recalculates the checksum, and sends the packet back to the client.

The NTP packets sent by the client to the server and the responses from the server to the client use a common format, as shown in Figure 1.

Figure 1: NTP Message Format



The header fields of the NTP message are as follows:

LI Leap Indicator (2 bits)
This field indicates whether the last minute of the current day is to have a leap second applied. The field values follow:

0: No leap second adjustment
1: Last minute of the day has 61 seconds
2: Last minute of the day has 59 seconds
3: Clock is unsynchronized

VN NTP Version Number (3 bits) (current version is 4).

Mode	NTP packet mode (3 bits) The values of the Mode field follow: 0: Reserved 1: Symmetric active 2: Symmetric passive 3: Client 4: Server 5: Broadcast 6: NTP control message 7: Reserved for private use
Stratum	Stratum level of the time source (8 bits) The values of the Stratum field follow: 0: Unspecified or invalid 1: Primary server 2–15: Secondary server 16: Unsynchronized 17–255: Reserved
Poll	Poll interval (8-bit signed integer) The $\log_2$ value of the maximum interval between successive NTP messages, in seconds.
Precision	Clock precision (8-bit signed integer) The precision of the system clock, in $\log_2$ seconds.
Root Delay	The total round-trip delay from the server to the primary reference sourced. The value is a 32-bit signed fixed-point number in units of seconds, with the fraction point between bits 15 and 16. This field is significant only in server messages.
Root Dispersion	The maximum error due to clock frequency tolerance. The value is a 32-bit signed fixed-point number in units of seconds, with the fraction point between bits 15 and 16. This field is significant only in server messages.
Reference Identifier	For stratum 1 servers this value is a four-character ASCII code that describes the external reference source (refer to Figure 2). For secondary servers this value is the 32-bit IPv4 address of the synchronization source, or the first 32 bits of the *Message Digest Algorithm 5* (MD5) hash of the IPv6 address of the synchronization source.

Figure 2: Reference Identifier Codes (from RFC 4330)

Code	External Reference Source
LOCL	uncalibrated local clock
CESM	calibrated Cesium clock
RBDM	calibrated Rubidium clock
PPS	calibrated quartz clock or other pulse-per-second source
IRIG	Inter-Range Instrumentation Group
ACTS	NIST telephone modem service
USNO	USNO telephone modem service
PTB	PTB (Germany) telephone modem service
TDF	Allouis (France) Radio 164 kHz
DCF	Mainflingen (Germany) Radio 77.5 kHz
MSF	Rugby (UK) Radio 60 kHz
WWV	Ft. Collins (US) Radio 2.5, 5, 10, 15, 20 MHz
WWVB	Boulder (US) Radio 60 kHz
WWVH	Kauai Hawaii (US) Radio 2.5, 5, 10, 15 MHz
CHU	Ottawa (Canada) Radio 3330, 7335, 14670 kHz
LORC	LORAN-C radionavigation system
OMEG	OMEGA radionavigation system
GPS	Global Positioning Service

The next four fields use a 64-bit time-stamp value. This value is an unsigned 32-bit seconds value, and a 32-bit fractional part. In this notation the value 2.5 would be represented by the 64-bit string:

0000|0000|0000|0000|0000|0000|0000|0010.|1000|0000|0000|0000|0000|0000|0000|0000

The unit of time is in seconds, and the epoch is 1 January 1900, meaning that the NTP time will cycle in the year 2036 (two years before the 32-bit Unix time cycle event in 2038).

The smallest time fraction that can be represented in this format is 232 picoseconds.

Reference Timestamp This field is the time the system clock was last set or corrected, in 64-bit time-stamp format.

Originate Timestamp This value is the time at which the request departed the client for the server, in 64-bit time-stamp format.

Receive Timestamp This value is the time at which the client request arrived at the server in 64-bit time-stamp format.

Transmit Timestamp This value is the time at which the server reply departed the server, in 64-bit time-stamp format.

The basic operation of the protocol is that a client sends a packet to a server and records the time the packet left the client in the *Origin Timestamp* field (T1). The server records the time the packet was received (T2). A response packet is then assembled with the original Origin Timestamp and the *Receive Timestamp* equal to the packet receive time, and then the *Transmit Timestamp* is set to the time that the message is passed back toward the client (T3). The client then records the time the packet arrived (T4), giving the client four time measurements, as shown in Figure 3.

Figure 3: NTP Transaction Timestamps (from RFC 4330)

Timestamp Name	ID	When Generated
Originate Timestamp	T1	time request sent by client
Receive Timestamp	T2	time request received by server
Transmit Timestamp	T3	time reply sent by server
Destination Timestamp	T4	time reply received by client

These four parameters are passed into the client timekeeping function to drive the clock synchronization function, which we will look at in the next section.

The optional Key and Message Digest fields allow a client and a server to share a secret 128-bit key, and use this shared secret to generate a 128-bit MD5 hash of the key and the NTP message fields. This construct allows a client to detect attempts to inject false responses from a man-in the-middle attack.

The final part of this overview of the protocol operation is the polling frequency algorithm. A NTP client will send a message at regular intervals to a NTP server. This regular interval is commonly set to be 16 seconds. If the server is unreachable, NTP will back off from this polling rate, doubling the back-off time at each unsuccessful poll attempt to a minimum poll rate of 1 poll attempt every 36 hours. When NTP is attempting to resynchronize with a server, it will increase its polling frequency and send a burst of eight packets spaced at 2-second intervals.

When the client clock is operating within a sufficient small offset from the server clock, NTP lengthens the polling interval and sends the eight-packet burst every 4 to 8 minutes (or 256 to 512 seconds).

Timekeeping on the Client

The next part of the operation of NTP is how an NTP process on a client uses the information generated by the periodic polls to a server to moderate the local clock.

From an NTP poll transaction, the client can estimate the delay between the client and the server. Using the time fields described in Figure 3, the transmission delay can be calculated as the total time from transmission of the poll to reception of the response minus the recorded time for the server to process the poll and generate a response:

$$\delta = (T4 - T1) - (T3 - T2)$$

The offset of the client clock from the server clock can also be estimated by the following:

$$\Theta = \tfrac{1}{2}\,[(T2 - T1) + (T3 - T4)]$$

It should be noted that this calculation assumes that the network path delay from the client to the server is the same as the path delay from the server to the client.

NTP uses the minimum of the last eight delay measurements as δ_0. The selected offset, Θ_0, is one measured at the lowest delay. The values (Θ_0,δ_0) become the NTP update value.

When a client is configured with a single server, the client clock is adjusted by a slew operation to bring the offset with the server clock to zero, as long as the server offset value is within an acceptable range.

When a client is configured with numerous servers, the client will use a selection algorithm to select the preferred server to synchronize against from among the candidate servers. Clustering of the time signals is performed to reject outlier servers, and then the algorithm selects the server with the lowest stratum with minimal offset and jitter values. The algorithm used by NTP to perform this operation is *Marzullo's Algorithm*[2].

When NTP is configured on a client, it attempts to keep the client clock synchronized against the reference time standard. To do this task NTP conventionally adjusts the local time by small offsets (larger offsets may cause side effects on running applications, as has been found when processing leap seconds). This small adjustment is undertaken by an *adjtime()* system call, which slews the clock by altering the frequency of the software clock until the time correction is achieved. Slewing the clock is a slow process for large time offsets; a typical slew rate is 0.5 ms per second.

Obviously this informal description has taken a rather complex algorithm and some rather detailed math formulas without addressing the details. If you are interested in how NTP operates at a more detailed level, consult the references that follow, which will take you far deeper into the algorithms and the underlying models of clock selection and synchronization than I have done here.

Conclusion

NTP is in essence an extremely simple stateless transaction protocol that provides a quite surprising outcome. From a regular exchange of simple clock readings between a client and a server, it is possible for the client to train its clock to maintain a high degree of precision despite the possibility of potential problems in the stability and accuracy of the local clock and despite the fact that this time synchronization is occurring over network paths that impose a noise element in the form of jitter in the packet exchange between client and server. Much of today's distributed Internet service infrastructure relies on a common time base, and this base is provided by the common use of the Network Time Protocol.

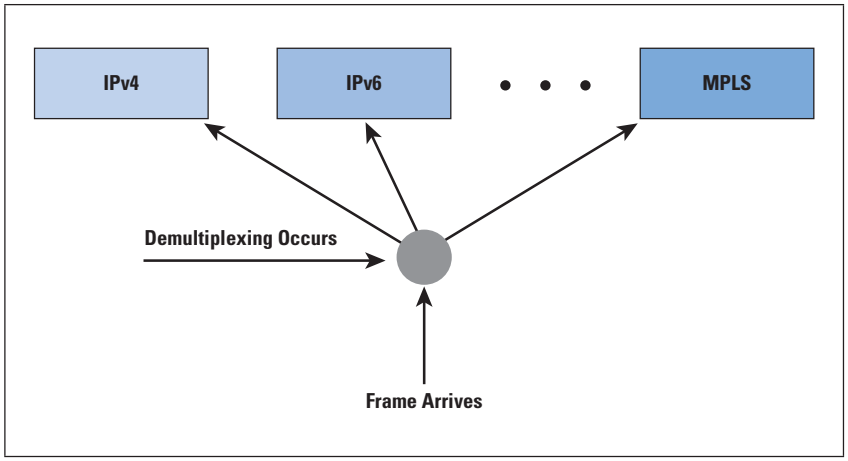
Packet Classification: A Faster, More General Alternative to Demultiplexing

by Douglas Comer, Purdue University

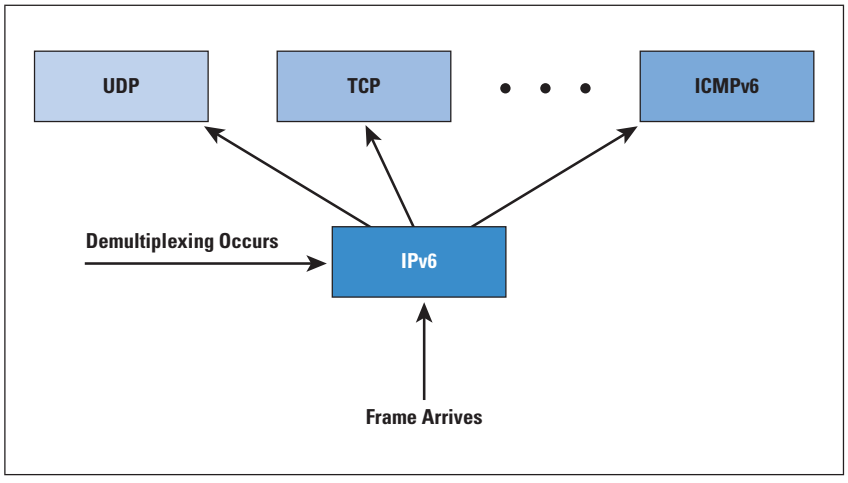
Traditional packet-processing systems use an approach known as *demultiplexing* to handle incoming packets (refer to [1] for details). When a packet arrives, protocol software uses the contents of a *Type Field* in a protocol header to decide how to process the payload in the packet. For example, the Type field in a frame is used to select a Layer 3 module to handle the frame, as Figure 1 illustrates.

Figure 1: Frame Demultiplexing



Demultiplexing is repeated at each level of the protocol stack. For example, IPv6 uses the *Next Header* field to select the correct transport layer protocol module, as Figure 2 illustrates.

Figure 2: Demultiplexing at Layer 3



Modern, high-speed network systems take an entirely different view of packet processing. In place of demultiplexing, they use a technique known as *classification*[2]. Instead of assuming that a packet proceeds through a protocol stack one layer at a time, they allow processing to cross layers. (In addition to being used by companies such as Cisco and Juniper, classification has been used in Linux[3] and with network processors by companies such as Intel and Netronome[4].)

Packet classification is especially pertinent to three key network technologies. First, Ethernet switches use classification instead of demultiplexing when they choose how to forward packets. Second, a router that sends incoming packets over *Multiprotocol Label Switching* (MPLS) tunnels uses classification to choose the appropriate tunnel. Third, classification provides the basis for *Software-Defined Networking* (SDN) and the *OpenFlow* protocol.

Motivation for Classification

To understand the motivation for classification, consider a network system that has protocol software arranged in a traditional layered stack. Packet processing relies on demultiplexing at each layer of the protocol stack. When a frame arrives, protocol software looks at the Type field to learn about the contents of the frame payload. If the frame carries an IP datagram, the payload is sent to the IP protocol module for processing. IP uses the destination address to select a next-hop address. If the datagram is in *transit* (that is, passing through the router on its way to a destination), IP forwards the datagram by sending it back out one of the interfaces. A datagram reaches TCP only if the datagram is destined for the router itself. TCP then uses the protocol port numbers in the TCP segment to further demultiplex the incoming datagram among multiple application programs.

To understand why traditional layering does not solve all problems, consider MPLS processing. In particular, consider a router at the border between a traditional internet and an MPLS core. Such a router must accept packets that arrive from the traditional internet and choose an MPLS path over which to send the packet. Why is layering pertinent to path selection? In many cases, network managers use transport layer protocol port numbers when choosing a path. For example, suppose a manager wants to send all web traffic down a specific MPLS path. All the web traffic will use TCP port 80, meaning that the selection must examine TCP port numbers.

Unfortunately, in a traditional demultiplexing scheme, a datagram does not reach the transport layer unless the datagram is destined for the local network system. Therefore, protocol software must be reorganized to handle MPLS path selection. We can summarize:

> *A traditional protocol stack is insufficient for the task of MPLS path selection because path selection often involves transport layer information and a traditional stack will not send transit datagrams to the transport layer.*

Classification Instead of Demultiplexing

How should protocol software be structured to handle tasks such as MPLS path selection? The answer lies in the use of *classification*. A classification system differs from conventional demultiplexing in two ways:

- Ability to cross multiple layers
- Higher speed than demultiplexing

To understand classification, imagine a packet that has been received at a router and placed in memory. *Encapsulation* means that the packet will have a set of contiguous protocol headers at the beginning. For example, Figure 3 illustrates the headers in a TCP packet (for example, a request sent to a web server) that has arrived over an Ethernet.

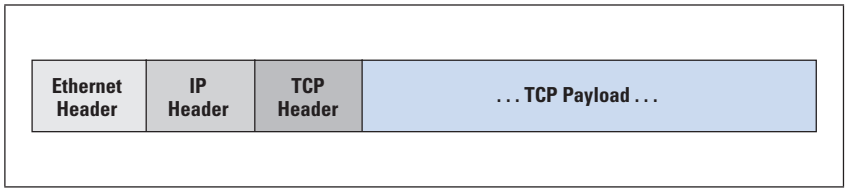


Figure 3: Layout of a Packet in Memory

Given a packet in memory, how can we quickly determine whether the packet is destined to the web? A simplistic approach simply looks at one field in the headers: the TCP destination port number. However, it could be that the packet is not a TCP packet at all. Maybe the frame is carrying *Address Resolution Protocol* (ARP) data instead of IP. Or maybe the frame does indeed contain an IP datagram, but instead of TCP the transport layer protocol is the *User Datagram Protocol* (UDP). To make certain that it is destined for the web, software needs to verify each of the headers: the frame contains an IP datagram, the IP datagram contains a TCP segment, and the TCP segment is destined for the web.

Instead of parsing protocol headers, think of the packet as an array of octets in memory. Consider IPv4 as an example. To be an IPv4 datagram, the Ethernet Type field (located in array positions 12 and 13) must contain `0x0800`. The IPv4 Protocol field, located at position 23, must contain `6` (the protocol number for TCP). The Destination Port field in the TCP header must contain `80`. To know the exact position of the TCP header, we must know the size of the IP header. Therefore, we check the header length octet of the IPv4 header. If the octet contains `0x45`, the TCP destination port number will be found in array positions 36 and 37.

As another example, consider classifying *Voice over IP* (VoIP) traffic that uses the *Real-Time Transport Protocol* (RTP). Because RTP is not assigned a specific UDP port, vendors use a heuristic to determine whether a given packet carries RTP traffic: check the Ethernet and IP headers to verify that the packet carries UDP, and then examine the octets at a known offset in the RTP packet to verify that the value matches the value used by a known codec.

Observe that all the checks described in the preceding paragraphs require only array lookup. That is, the lookup mechanism treats the packet as an array of octets and merely checks to verify that location *X* contains value *Y*, location *Z* contains value *W*, and so on—the mechanism does not need to understand any of the protocol headers or the meaning of values. Furthermore, observe that the lookup scheme crosses multiple layers of the protocol stack.

We use the term *classifier* to describe a mechanism that uses the lookup approach described previously, and we say that the result is a packet *classification*. In practice, a classification mechanism usually takes a list of classification *rules* and applies them until a match is found. For example, a manager might specify three rules: send all web traffic to MPLS path *1*, send all FTP traffic to MPLS path *2*, and send all VPN traffic to MPLS path *3*.

Layering When Classification Is Used

If classification crosses protocol layers, how does it relate to traditional layering diagrams? We can think of classification as an extra layer that has been squeezed between Layer 2 and Layer 3. When a packet arrives, the packet passes from a Layer 2 module to the classification module. All packets proceed to the classifier; no demultiplexing occurs before classification. If any of the classification rules matches the packet, the classification layer follows the rule. Otherwise, the packet proceeds up the traditional protocol stack. For example, Figure 4 illustrates layering when classification is used to send some packets across MPLS paths.

Interestingly, a classification layer can subsume all demultiplexing. That is, instead of classifying packets only for MPLS paths, the classifier can be configured with additional rules that check the Type field in a frame for IPv4, IPv6, ARP, *Reverse ARP* (RARP), and so on.

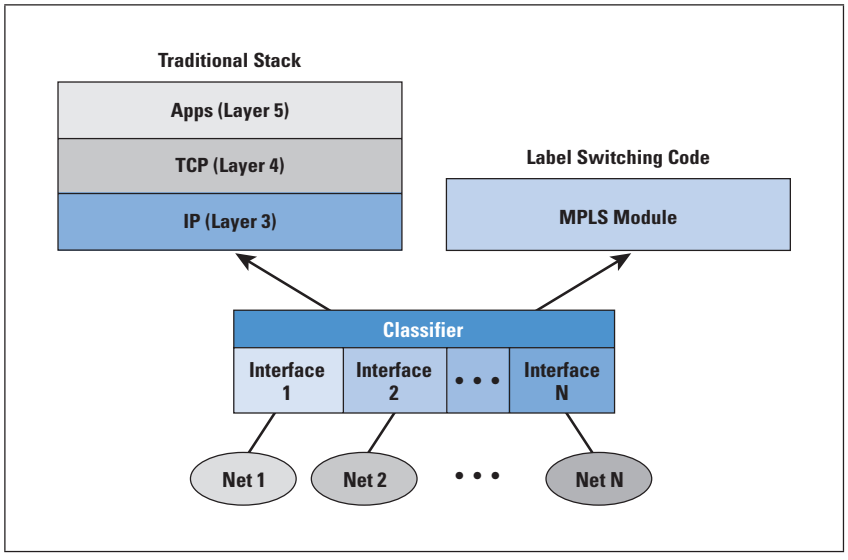

Figure 4: Layering in a Router that Uses Classification to Select MPLS Paths

Classification Hardware and Network Switches

The text in the previous section describes a classification mechanism that is implemented in software—an extra layer is added to a software protocol stack that classifies frames after they arrive at a router. Classification can also be implemented in hardware. In particular, Ethernet switches and other packet-processing hardware devices contain classification hardware that allows packet classification and forwarding to proceed at high speed. The next sections explain hardware classification mechanisms.

We think of network devices, such as switches, as being divided into broad categories by the level of protocol headers they examine and the consequent level of functions they provide:

- Layer 2 Switching
- Layer 2 *Virtual Local-Area Network* (VLAN) Switching
- Layer 3 Switching
- Layer 4 Switching

A *Layer 2 Switch* examines the *Media Access Control* (MAC) source address in each incoming frame to learn the MAC address of the computer that is attached to each port. When a switch learns the MAC addresses of all the attached computers, the switch can use the destination MAC address in each frame to make a forwarding decision. If the frame is unicast, the switch sends only one copy of the frame on the port to which the specified computer is attached. For a frame destined to the broadcast or a multicast address, the switch delivers a copy of the frame to all ports.

A *VLAN Switch* adds one level of virtualization by permitting a manager to assign each port to a specific VLAN. Internally, VLAN switches extend forwarding in a minor way: instead of sending broadcasts and multicasts to all ports on the switch, a VLAN switch consults the VLAN configuration and sends them only to ports on the same VLAN as the source.

A *Layer 3 Switch* acts like a combination of a VLAN switch and a router. Instead of using only the Ethernet header when forwarding a frame, the switch can look at fields in the IP header. In particular, the switch watches the source IP address in incoming packets to learn the IP address of the computer attached to each switch port. The switch can then use the IP destination address in a packet to forward the packet to its correct destination.

A *Layer 4 Device* extends the examination of a packet to the transport layer. That is, the device can include the TCP or UDP Source and Destination Port fields when making a forwarding decision.

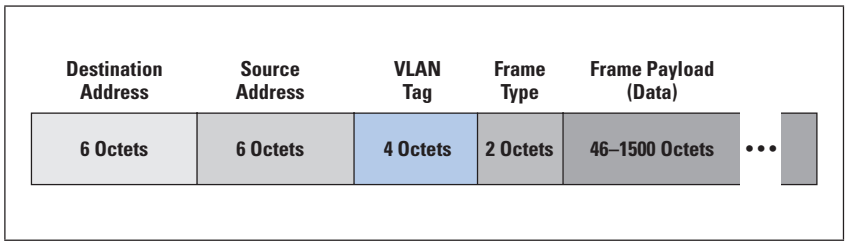
Switching Decisions and VLAN Tags

All types of switching hardware described previously use classification. That is, switches operate on packets as if a packet is merely an array of octets, and individual fields in the packet are specified by giving offsets in the array. Thus, instead of demultiplexing packets, a switch treats a packet syntactically by applying a set of classification rules similar to the rules described previously.

Surprisingly, even VLAN processing is handled in a syntactic manner. Instead of merely keeping VLAN information in a separate data structure that holds meta information, the switch inserts an extra field in an incoming packet and places the VLAN number of the packet in the extra field. Because it is just another field, the classifier can reference the VLAN number just like any other header field.

We use the term *VLAN Tag* to refer to the extra field inserted in a packet. The tag contains the VLAN number that the manager assigned to the port over which the frame arrived. For Ethernet, IEEE standard 802.1Q specifies placing the VLAN Tag field after the MAC Source Address field. Figure 5 illustrates the format.

Figure 5: An Ethernet Frame with a VLAN Tag Inserted



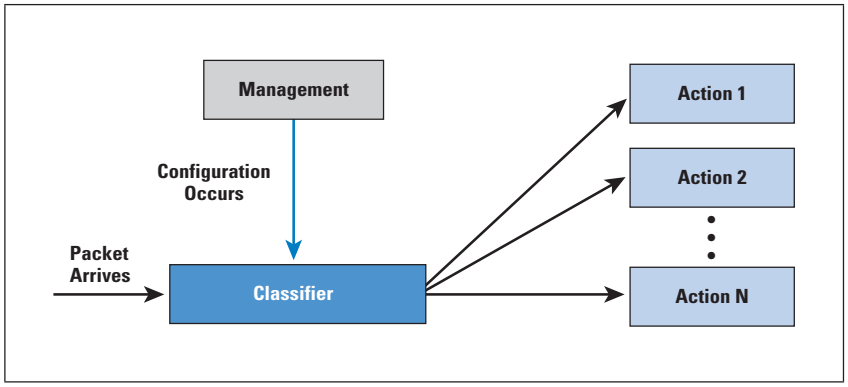
A VLAN tag is used only internally—after the switch has selected an output port and is ready to transmit the frame, the tag is removed. Thus, when computers send and receive frames, the frames do not contain a VLAN tag.

An exception can be made to the rule: a manager can configure one or more ports on a switch to leave VLAN tags in frames when sending the frame. The purpose is to allow two or more switches to be configured to operate as a single, large switch. That is, the switches can share a set of VLANs—a manager can configure each VLAN to include ports on one or both of the switches.

Classification Hardware

We can think of hardware in a switch as being divided into three main components: a classifier, a set of units that perform actions, and a management component that controls the overall operation. Figure 6 illustrates the overall organization and the flow of packets.

Figure 6: Hardware Components Used for Classification



As black arrows in the figure indicate, the classifier provides the high-speed data path that packets follow. When a packet arrives, the classifier uses the rules that have been configured to choose an action. The management module usually consists of a general-purpose processor that runs management software. A network administrator can interact with the management module to configure the switch, in which case the management module can create or modify the set of rules the classifier follows.

A network system, such as a switch, must be able to handle two types of traffic: transit traffic and traffic destined for the switch itself. For example, to provide management or routing functions, a switch may have a local TCP/IP protocol stack and packets destined for the switch must be passed to the local stack. Therefore, one of the actions a classifier takes may be *"pass packet to the local stack for Demultiplexing"*.

High-Speed Classification and TCAM

Modern switches can allow each interface to operate at 10 Gbps. At 10 Gbps, a frame takes only 1.2 microseconds to arrive, and a switch usually has many interfaces. A conventional processor cannot handle classification at such speeds, so a question arises: how can a hardware classifier achieve high speed? The answer lies in a hardware technology known as *Ternary Content Addressable Memory* (TCAM).

TCAM uses parallelism to achieve high speed—instead of testing one field of a packet at a given time, TCAM checks all fields simultaneously. Furthermore, TCAM performs multiple checks at the same time. To understand how TCAM works, think of a packet as a string of bits. We imagine TCAM hardware as having two parts: one part holds the bits from a packet and the other part is an array of values that will be compared to the packet. Entries in the array are known as *slots*. Figure 7 illustrates the idea.

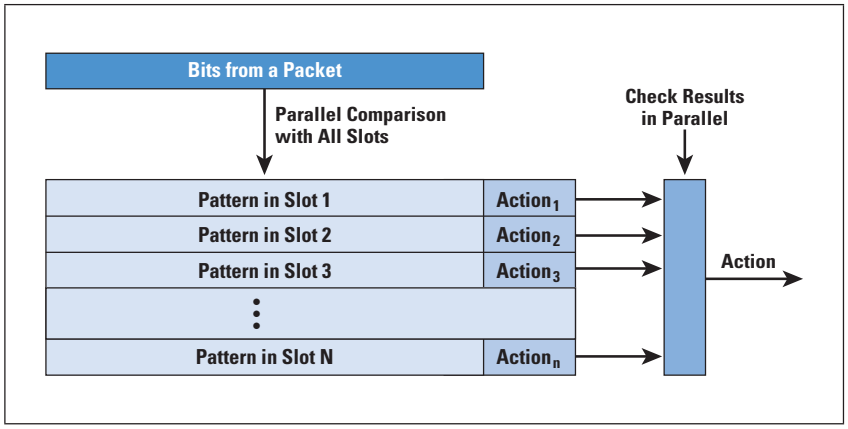


Figure 7: The Conceptual Organization of TCAM

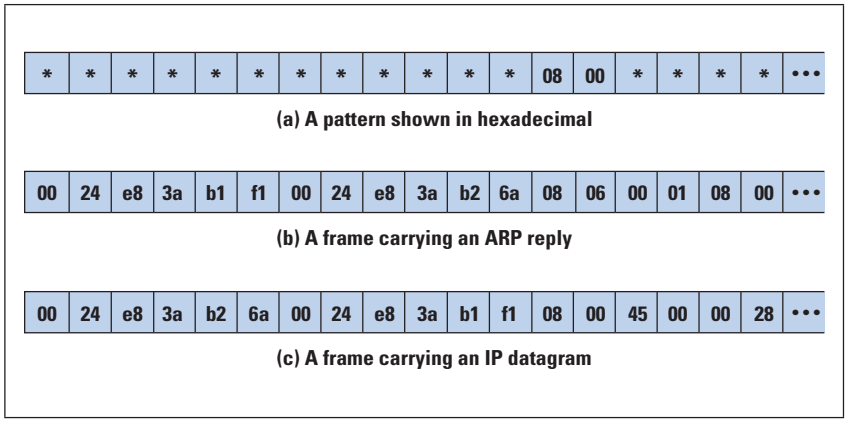
In the figure, each slot contains two parts. The first part consists of hardware that compares the bits from the packet to the pattern stored in the slot. The second part stores a value that specifies an action to be taken if the pattern matches the packet. If a match occurs, the slot hardware passes the action to the component that checks all the results and announces an answer.

One of the most important details concerns the way TCAM handles multiple matches. In essence, the output circuitry selects one match and ignores the others. That is, if multiple slots each pass an action to the output circuit, the circuit accepts only one and passes the action as the output of the classification. For example, the hardware may choose the lowest slot that matches. In any case, the action that the TCAM announces corresponds to the action from one of the matching slots.

The figure indicates that a slot holds a *pattern* rather than an exact value. Instead of merely comparing each bit in the pattern to the corresponding bit in the packet, the hardware performs a pattern match. The adjective *ternary* is used because each bit position in a pattern can have three possible values: a one, a zero, or a "don't care". When a slot compares its pattern to the packet, the hardware checks only the one and zero bits in the pattern—the hardware ignores pattern bits that contain "don't care". Thus, a pattern can specify exact values for some fields in a packet header and omit other fields.

To understand TCAM pattern matching, consider a pattern that identifies IP packets. Identifying such packets is easy because an Ethernet frame that carries an IPv4 datagram will have the value `0x0800` in the Ethernet Type field. Furthermore, the Type field occupies a fixed position in the frame: bits 96 through 111. Thus, we can create a pattern that starts with 96 "don't care" bits (to cover the Ethernet destination and source MAC addresses) followed by 16 bits with the binary value `0000100000000000` (the binary equivalent of `0x0800`) to cover the Type field. All remaining bit positions in the pattern will be "don't care". Figure 8 illustrates the pattern and example packets.

Figure 8: A TCAM Pattern and Example Packets



Although a TCAM hardware slot has one position for each bit, the figure does not display individual bits. Instead, each box corresponds to one octet, and the value in a box is a hexadecimal value that corresponds to 8 bits. We use hexadecimal simply because binary strings are too long to fit into a figure comfortably.

The Size of a TCAM

A question arises: how large is a TCAM? The question can be divided into two important aspects:

- *The number of bits in a slot:* The number of bits per slot depends on the type of Ethernet switch. A basic switch uses the destination MAC address to classify a packet. Because a MAC address is 48 bits, TCAM in a basic switch needs only 48 bit positions. A VLAN switch needs 128 bit positions to cover the VLAN tag as well as source and destination MAC addresses. A Layer 3 switch must have sufficient bit positions to cover the IP header as well as the Ethernet header. For IPv6, the header size is large and variable—in most cases, a pattern will need to cover extension headers as well as the base header.
- *The total number of slots:* The total number of TCAM slots determines the maximum number of patterns a classifier can hold. When a switch learns the MAC address of a computer that has been plugged into a port, the switch can store a pattern for the address. For example, if a computer with MAC address X is plugged into port 29, the switch can create a pattern in which destination address bits match X and the action is *"send packet to output port 29"*.

A switch can also use patterns to control broadcasting. When a manager configures a VLAN, the switch can add an entry for the VLAN broadcast. For example, if a manager configures VLAN 9, an entry can be added in which the destination address bits are all 1s (that is, the Ethernet broadcast address) and the VLAN tag is 9. The action associated with the entry is *"broadcast on VLAN 9"*.

A Layer 3 switch can learn the IP source address of computers attached to the switch, and can use TCAM to store an entry for each IP address. Similarly, it is possible to create entries that match Layer 4 protocol port numbers (for example, to direct all web traffic to a specific output). SDN technologies allow a manager to place patterns in the classifier to establish paths through a network and direct traffic along the paths. Because such classification rules cross multiple layers of the protocol stack, the potential number of items stored in a TCAM can be large.

TCAM seems like an ideal mechanism because it is both extremely fast and versatile. However, TCAM has two significant drawbacks: cost and heat. The cost is high because TCAM has parallel hardware for each slot and the overall system is designed to operate at high speed. In addition, because it operates in parallel, TCAM consumes much more energy than conventional memory (and generates more heat). Therefore, designers minimize the amount of TCAM to keep costs and power consumption low. A typical switch has 32,000 entries.

Classification-Enabled Generalized Forwarding

Perhaps the most significant advantage of a classification mechanism arises from the generalizations it enables. Because classification examines arbitrary fields in a packet before any demultiplexing occurs, cross-layer combinations are possible. For example, classification can specify that all packets from a given MAC address should be forwarded to a specific output port regardless of the packet contents. In addition, classification can make forwarding decisions depend on combinations of source and destination. An *Internet Service Provider* (ISP) can choose to forward all packets with IP source address X that are destined for web server W along one path while forwarding packets with IP source address Y that are destined to the same web server along another path.

ISPs need the generality that classification offers to handle traffic engineering that is not usually available in a conventional protocol stack. In particular, classification allows an ISP to offer tiered services in which the path a packet follows depends on a combination of the type of traffic and how much the customer pays.

Summary

Classification is a fundamental performance optimization that allows a packet-processing system to cross layers of the protocol stack without demultiplexing. A classifier treats each packet as an array of bits and checks the contents of fields at specific locations in the array.

Classification offers high-speed forwarding for network systems such as Ethernet switches and routers that send packets across MPLS tunnels. To achieve the highest speed, classification can be implemented in hardware; a hardware technology known as TCAM is especially useful because it employs parallelism to perform classification at extremely high speed.

The generalized forwarding capabilities that classification provides allow ISPs to perform traffic engineering. When making a forwarding decision, a classification mechanism can use the source of a packet as well as the destination (for example, to choose a path based on the tier of service to which a customer subscribes).

Internet Society Disappointed over Fundamental Divides at WCIT-12

On December 14, 2012, The Internet Society released the following statement from President and CEO Lynn St. Amour:

"The Internet Society, like other participants at the *World Conference on International Telecommunications* (WCIT), came to this conference looking for a successful outcome. We were hopeful that it would result in a treaty that would enable growth, further innovation, and advance interoperability in international telecommunications. It was extremely important that this treaty not extend to content, or implicitly or explicitly undermine the principles that have made the Internet so beneficial.

While progress was made in some areas such as transparency in international roaming fees, fundamental divides were exposed leaving a significant number of countries unable to sign the *International Telecommunication Regulations* (ITRs). Statements made by a host of delegations today made it very clear that Internet issues did not belong in the ITRs and that they would not support a treaty that is inconsistent with the multi-stakeholder model of Internet Governance.

We are disappointed that the conference has not been successful in reaching consensus. The Internet Society is dedicated to working with all stakeholders around the world to create the environment that will allow the Internet to grow for the betterment of all people."

NRO Observations on WCIT-12 Process

The *Number Resource Organization* (NRO), representing the world's five *Regional Internet address Registries* (RIRs), issued the following statement from Dubai, the site of the recent *World Conference on International Telecommunications* (WCIT):

The conference has clearly not met expectations of many *International Telecommunications Union* (ITU) Member States, and with this unfortunate outcome now clear, we feel compelled to put the following observations on record.

The NRO is concerned about aspects of the WCIT-12 meetings, which have just ended in Dubai, particularly with events in the last days of the conference. Neither the content of this conference, nor its conduct during this critical final period, have met community expectations or satisfied public assurances given prior to the event.

Internet stakeholders around the world watched the WCIT preparations closely, and were hopeful, throughout those processes, of two things: that WCIT would have no bearing on the Internet, its governance or its content; and that the event would allow all voices to be heard. The ITU Secretary General himself made these assurances on multiple occasions, and reiterated them in his opening remarks to the conference.

Regrettably, expected WCIT discussions on traditional telecommunication issues were eclipsed by debates about Internet-related issues. The intensity and length of these debates revealed clearly the depth of genuine concern about the proposals, and also the determination of those who brought them to the meeting.

Perhaps more importantly, an open multi-stakeholder conduct of the WCIT conference did not eventuate. Plenary sessions of the conference were webcast, but contributions were allowed only from official Government delegates and ITU officials, relegating all other stakeholders to an observer role.

Furthermore, an important number of critical negotiations occurred in small groups accessible only to Member States; and key experts and other stakeholders were unable even to observe them.

The NRO strongly supports the principles established in 2005 by the *World Summit on the Information Society,* which call for Internet Governance to be carried out in a multi-stakeholder manner, and we note that these represent the view of the global community as expressed through the United Nations system itself.

The NRO has also participated in many ITU conferences and study groups over the years, at very substantial cost, in genuine efforts to build relationships between our communities and to demonstrate the value of multi-stakeholder cooperation and collaboration. The NRO will continue to participate in the ITU, itself a member of the UN system, in expectation that its processes can evolve visibly, and much more rapidly, towards these accepted principles.

John Jason Brzozowski, Donn Lee, and Paul Saab win 2012 Itojun Awards

The fourth annual *Itojun Service Awards* were recently presented to John Jason Brzozowski for his tireless efforts in providing IPv6 connectivity to cable broadband users across North America and evangelizing the importance of IPv6 deployment globally, and to Donn Lee and Paul Saab for their efforts in making high-profile online content available over IPv6 and for their key contributions to *World IPv6 Day* and *World IPv6 Launch*. The awardees were recognized at the *Internet Engineering Task Force* (IETF) 85 meeting in November 2012 in Atlanta, Georgia.

First awarded in 2009, the award honors the memory of Dr. Junichiro "Itojun" Hagino, who passed away in 2007 at the age of 37. The award, established by the friends of Itojun and administered by the Internet Society, recognizes and commemorates the extraordinary dedication exercised by Itojun over the course of IPv6 development. IPv6, the next-generation Internet protocol developed within the IETF, provides more than 340 trillion, trillion, trillion addresses, enabling billions of people and a huge range of devices to connect with one another, and helping ensure the Internet continues its current growth rate indefinitely.

"The combined work of John, Donn, and Paul has made IPv6 a technology used every day by people around the world as they access some of the most popular websites from their homes and offices," said Jun Murai of the Itojun Service Award committee and founder of the WIDE Project.

"On behalf of the Itojun Service Award committee, I am extremely pleased to present this award to them for their ongoing efforts that have made IPv6 a mainstream technology for global web companies looking to ensure their continued growth."

The Itojun Service Award is focused on pragmatic contributions to developing and deploying IPv6 in the spirit of serving the Internet. With respect to the spirit, the selection committee seeks contributors to the Internet as a whole; open source developers are a common example of such contributors, although this is not a requirement for expected nominees.

While the committee primarily considers practical contributions such as software development or network operation, higher level efforts that help those direct contributions will also be appreciated in this regard. The contribution should be substantial, but could be at an immature stage or be ongoing; this award aims to encourage the contributor to continue their efforts, rather than just recognizing well established work. Finally, contributions of a group of individuals will be accepted, as deployment work is often done by a large project, not just a single outstanding individual.

The award includes a presentation crystal, a US$3,000 honorarium, and a travel grant.

John Jason Brzozowski said, "It is truly humbling to be a recipient of the Itojun Service Award, being recognized with others that have worked tirelessly to make IPv6 a reality is rewarding personally and professionally. I would like to thank the award committee and the Internet Society as well as my family and co-workers for their support. As many are aware, the IPv6 journey at Comcast has been unfolding since 2005. It is an honor and pleasure to provide the technical and strategic leadership for IPv6 that has led to the success of our program and the widespread adoption of IPv6."

Donn Lee said, "Deploying IPv6 continues to be an amazing experience. I'm thankful to be sharing this award with my colleagues Paul and John, whom I have worked alongside through the challenging and exciting milestones of World IPv6 Day 2011 and World IPv6 Launch 2012. I especially want to thank the award committee for this honor that remembers Itojun, a truly inspirational IPv6 scientist, leader, and visionary."

Paul Saab said, "I'm honored to be sharing the Itojun Service Award with Donn and John. We should never forget that we would not be here today if it were not for Itojun's trailblazing work and passion for IPv6. To be recognized is extremely humbling, as Facebook's participation could not have been done without our amazing co-workers and their own hard work to bring IPv6 to our users. Thank you for recognizing us and remember that this journey is only 2% complete."

For more information about the Itojun Service Award see:

Leading Global Standards Organizations Endorse "OpenStand" Principles

Five leading global organizations—the *Institute for Electrical and Electronics Engineers* (IEEE), the *Internet Architecture Board* (IAB), *the Internet Engineering Task Force* (IETF), the *Internet Society* and the *World Wide Web Consortium* (W3C)—recently announced that they have signed a statement affirming the importance of a jointly developed set of principles establishing a modern paradigm for global, open standards. The shared "OpenStand" principles—based on the effective and efficient standardization processes that have made the Internet and Web the premiere platforms for innovation and borderless commerce—are proven in their ability to foster competition and cooperation, support innovation and interoperability and drive market success.

The IEEE, IAB, IETF, Internet Society and W3C invite other standards organizations, governments, corporations and technology innovators globally to endorse the principles, available at `open-stand.org`

The OpenStand principles strive to encapsulate that successful standardization model and make it extendable across the contemporary, global economy's gamut of technology spaces and markets. The principles comprise a modern paradigm in which the economics of global markets—fueled by technological innovation—drive global deployment of standards, regardless of their formal status within traditional bodies of national representation. The OpenStand principles demand:

- Cooperation among standards organizations;
- Adherence to due process, broad consensus, transparency, balance and openness in standards development;
- Commitment to technical merit, interoperability, competition, innovation and benefit to humanity;
- Availability of standards to all; and
- Voluntary adoption.

"New dynamics and pressures on global industry have driven changes in the ways that standards are developed and adopted around the world," said Steve Mills, president of the IEEE Standards Association.

"Increasing globalization of markets, the rapid advancement of technology and intensifying time-to-market demands have forced industry to seek more efficient ways to define the global standards that help expand global markets. The OpenStand principles foster the more efficient international standardization paradigm that the world needs."

Added Leslie Daigle, chief Internet technology officer with the Internet Society: "International standards development for borderless economics is not ad hoc; rather, it has a paradigm—one that has demonstrated agility and is driven by technical merit.

The OpenStand principles convey the power of bottom-up collaboration in harnessing global creativity and expertise to the standards of any technology space that will underpin the modern economy moving forward."

Standards developed and adopted via the OpenStand principles include IEEE standards for the Internet's physical connectivity, IETF standards for end-to-end global Internet interoperability and the W3C standards for the World Wide Web.

"The Internet and World Wide Web have fueled an economic and social transformation, touching billions of lives. Efficient standardization of so many technologies has been key to the success of the global Internet," said Russ Housley, IETF chair. "These global standards were developed with a focus toward technical excellence and deployed through collaboration of many participants from all around the world. The results have literally changed the world, surpassing anything that has ever been achieved through any other standards-development model."

Globally adopted design-automation standards, which have paved the way for a giant leap forward in industry's ability to define complex electronic solutions, provide another example of standards developed in the spirit of the OpenStand principles. Another technology space that figures to demand such standards over the next decades is the global smart-grid effort, which seeks to augment regional facilities for electricity generation, distribution, delivery and consumption with a two-way, end-to-end network for communications and control.

"Think about all that the Internet and Web have enabled over the past 30 years, completely transforming society, government and commerce," said W3C chief executive officer Jeff Jaffe. "It is remarkable that a small number of organizations following a small number of principles have had such a huge impact on humanity, innovation and competition in global markets."

Bernard Aboba, chair of the IAB said: "The Internet has been built on specifications adopted voluntarily across the globe. By valuing running code, interoperability and deployment above formal status, the Internet has democratized the development of standards, enabling specifications originally developed outside of standards organizations to gain recognition based on their technical merit and adoption, contributing to the creation of global communities benefiting humanity. We now invite standards organizations, as well as governments, companies and individuals to join us at **`open-stand.org`** in order to affirm the principles that have nurtured the Internet and underpin many other important standards—and will continue to do so."

New Year's Day 2013 Marks 30th Anniversary of Major Milestone for the Internet

On January 1, 1983, the ARPANET, a direct predecessor of today's Internet, implemented the *Transmission Control Protocol/Internet Protocol* (TCP/IP) in a transition that required all connected computers to convert to the protocol simultaneously. The open TCP/IP protocol is now a foundational technology for the networks around the world that make up the global Internet and interconnect billions of devices. The transition, which was carefully planned over several years before it actually took place, is documented in RFC 801[1] authored by Jon Postel[2].

Throughout its history, the Internet has continued to evolve. Today, deploying IPv6, the latest generation of the IP protocol, is critical to ensuring the Internet's continued growth and to connect the billions of people not yet online. Thousands of major *Internet Service Providers* (ISPs), home networking equipment manufacturers, and web companies around the world are coming together to permanently enable IPv6 for their products and services through efforts such as *World IPv6 Launch*[3] organized by the Internet Society.

For more information about the Internet Society's work to facilitate the open development of standards, protocols, and administration, and to ensure a robust, secure technical infrastructure, see the *Internet Technology Matters* blog[4] and the *Deploy360 Programme*[5]. For further details about the Internet's history and development, see [6].

IPJ Subscription FAQ

What is my "Subscription ID" for The Internet Protocol Journal (IPJ) and where do I find it?

Your Subscription ID is a unique combination of letters and numbers used to locate your subscription in our database. It is printed on the back of your IPJ issue or on the envelope. You will also find information about your subscription expiration date near your Subscription ID. Here is an example:

How do I renew or update my subscription?

From the IPJ homepage (**www.cisco.com/ipj**) click "Subscriber Service" and then enter your Subscription ID and your e-mail address in the boxes. After you click "Login" the system will send you an e-mail message with a unique URL that allows access to your subscription record. You can then update your postal and e-mail details, change delivery options, and of course *renew* your subscription.

What will you use my e-mail address and postal address for?

This information is used *only* to communicate with you regarding your subscription. You will receive renewal reminders as well as other information about your subscription. We will never use your address for any form of marketing or unsolicited e-mail.

I didn't receive the special URL that allows me to renew or update my Subscription. Why?

This is likely due to some form of spam filtering. Just send an e-mail message to **ipj@cisco.com** with your Subscription ID and any necessary changes and we will make the changes for you.

Do I need my Subscription ID to read IPJ online? What is my username and password?

Your Subscription ID is used *only* for access to your subscription record. No username or password is required to read IPJ. All back issues are available for online browsing or for download at **www.cisco.com/ipj**

I can't find my Subscription ID and I have since changed e-mail address anyway; what do I do now?

Just send a message to **ipj@cisco.com** and we will take care of it for you.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ contains standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

From The Editor

This is the 60th edition of *The Internet Protocol Journal,* and in June we will celebrate our 15th anniversary. Fifteen years is not a long time in absolute terms, but when it comes to networking technology a lot can happen in a short time.

Throughout this 15-year period we have published numerous articles on "emerging technologies," and in this issue we present yet another. *Software-Defined Networks* (SDNs) have become a mainstream topic for research, development, and standardization. We asked William Stallings to give us an overview of SDNs, and we plan further articles on this topic in the future.

A recurring theme in this journal has been Internet *security* at all levels of the protocol stack. We have covered security in routing, securing the *Domain Name System* (DNS), secure wireless networks, secure HTTP, and much more. This time, Scott Hogg discusses the advantages and disadvantages of using IPv4 or IPv6 addresses as a form of user authentication.

In our previous issue we published some reactions to the outcomes of the *World Conference on International Telecommunications* (WCIT) held in Dubai in December 2012. In this edition, Robert Pepper and Chip Sharp provide analysis and background on this conference and discuss how the revised *International Telecommunication Regulations* (ITRs) might affect the future of the Internet.

It has been some time since we have published a book review, but we are happy to bring you one in this issue. For the first time in history, we are reviewing a book that exists only in electronic form, another sign of a rapidly changing technology landscape. We are always looking for new book reviews. Please send your reviews, letters to the editor, or any subscription questions to **ipj@cisco.com**

If you want to look back at 15 years of IPJ, visit our website at **www.cisco.com/ipj** where you will find all of our back issues (as a single PDF file, as a collection of individual PDF files, or in HTML format), as well as an index of all IPJ articles.

—Ole J. Jacobsen, Editor and Publisher
ole@cisco.com

Software-Defined Networks and OpenFlow

by William Stallings

A network organizing technique that has come to recent prominence is the *Software-Defined Network* (SDN)[1]. In essence, an SDN separates the data and control functions of networking devices, such as routers, packet switches, and LAN switches, with a well-defined *Application Programming Interface* (API) between the two. In contrast, in most large enterprise networks, routers and other network devices encompass both data and control functions, making it difficult to adjust the network infrastructure and operation to large-scale addition of end systems, virtual machines, and virtual networks. In this article we examine the characteristics of an SDN, and then describe the *OpenFlow* specification, which is becoming the standard way of implementing an SDN.

Evolving Network Requirements

Before looking in more detail at SDNs, let us examine the evolving network requirements that lead to a demand for a flexible, response approach to controlling traffic flows within a network or the Internet.

One key leading factor is the increasingly widespread use of *Server Virtualization*. In essence, server virtualization masks server resources, including the number and identity of individual physical servers, processors, and operating systems, from server users. This masking makes it possible to partition a single machine into multiple, independent servers, conserving hardware resources. It also makes it possible to migrate a server quickly from one machine to another for load balancing or for dynamic switchover in the case of machine failure. Server virtualization has become a central element in dealing with "big data" applications and in implementing cloud computing infrastructures. But it creates problems with traditional network architectures (for example, refer to [2]). One problem is configuring *Virtual LANs* (VLANs). Network managers need to make sure the VLAN used by the *Virtual Machine* is assigned to the same switch port as the physical server running the virtual machine. But with the virtual machine being movable, it is necessary to reconfigure the VLAN every time that a virtual server is moved. In general terms, to match the flexibility of server virtualization, the network manager needs to be able to dynamically add, drop, and change network resources and profiles. This process is difficult to do with conventional network switches, in which the control logic for each switch is co-located with the switching logic.

Another effect of server virtualization is that traffic flows differ substantially from the traditional client-server model. Typically, there is a considerable amount of traffic among virtual servers, for such purposes as maintaining consistent images of the database and invoking security functions such as access control. These server-to-server flows change in location and intensity over time, demanding a flexible approach to managing network resources.

Another factor leading to the need for rapid response in allocating network resources is the increasing use by employees of mobile devices such as smartphones, tablets, and notebooks to access enterprise resources. Network managers must be able to respond to rapidly changing resource, *Quality of Service* (QoS), and security requirements.

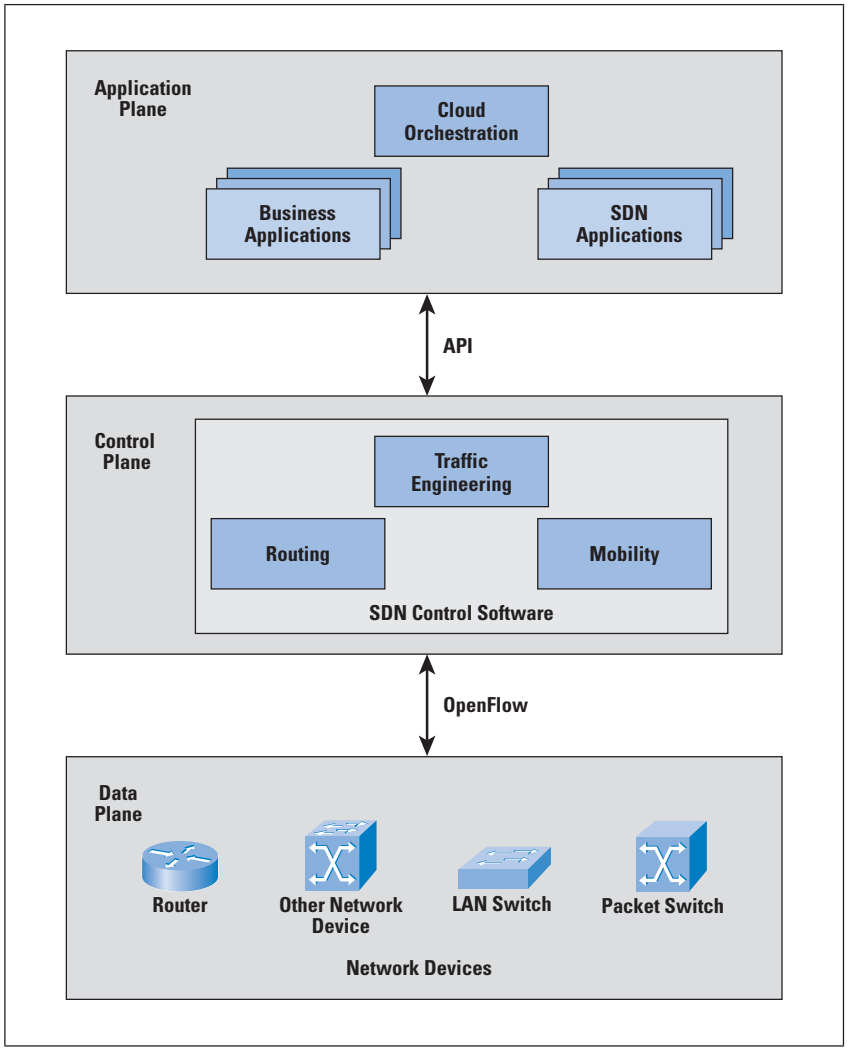
Existing network infrastructures can respond to changing requirements for the management of traffic flows, providing differentiated QoS levels and security levels for individual flows, but the process can be very time-consuming if the enterprise network is large and/or involves network devices from multiple vendors. The network manager must configure each vendor's equipment separately, and adjust performance and security parameters on a per-session, per-application basis. In a large enterprise, every time a new virtual machine is brought up, it can take hours or even days for network managers to do the necessary reconfiguration[3].

This state of affairs has been compared to the mainframe era of computing[4]. In the era of the mainframe, applications, the operating system, and the hardware were vertically integrated and provided by a single vendor. All of these ingredients were proprietary and closed, leading to slow innovation. Today, most computer platforms use the x86 instruction set, and a variety of operating systems (Windows, Linux, or Mac OS) run on top of the hardware. The OS provides APIs that enable outside providers to develop applications, leading to rapid innovation and deployment. In a similar fashion, commercial networking devices have proprietary features and specialized control planes and hardware, all vertically integrated on the switch. As will be seen, the SDN architecture and the OpenFlow standard provide an open architecture in which control functions are separated from the network device and placed in accessible control servers. This setup enables the underlying infrastructure to be abstracted for applications and network services, enabling the network to be treated as a logical entity.

SDN Architecture

Figure 1 illustrates the logical structure of an SDN. A central controller performs all complex functions, including routing, naming, policy declaration, and security checks. This plane constitutes the *SDN Control Plane,* and consists of one or more SDN servers.

Figure 1: SDN Logical Structure



The *SDN Controller* defines the data flows that occur in the *SDN Data Plane*. Each flow through the network must first get permission from the controller, which verifies that the communication is permissible by the network policy. If the controller allows a flow, it computes a route for the flow to take, and adds an entry for that flow in each of the switches along the path. With all complex functions subsumed by the controller, switches simply manage flow tables whose entries can be populated only by the controller. Communication between the controller and the switches uses a standardized protocol and API. Most commonly this interface is the OpenFlow specification, discussed subsequently.

The SDN architecture is remarkably flexible; it can operate with different types of switches and at different protocol layers. SDN controllers and switches can be implemented for Ethernet switches (Layer 2), Internet routers (Layer 3), transport (Layer 4) switching, or application layer switching and routing. SDN relies on the common functions found on networking devices, which essentially involve forwarding packets based on some form of flow definition.

In an SDN architecture, a switch performs the following functions:

- The switch encapsulates and forwards the first packet of a flow to an SDN controller, enabling the controller to decide whether the flow should be added to the switch flow table.
- The switch forwards incoming packets out the appropriate port based on the flow table. The flow table may include priority information dictated by the controller.
- The switch can drop packets on a particular flow, temporarily or permanently, as dictated by the controller. Packet dropping can be used for security purposes, curbing *Denial-of-Service* (DoS) attacks or traffic management requirements.

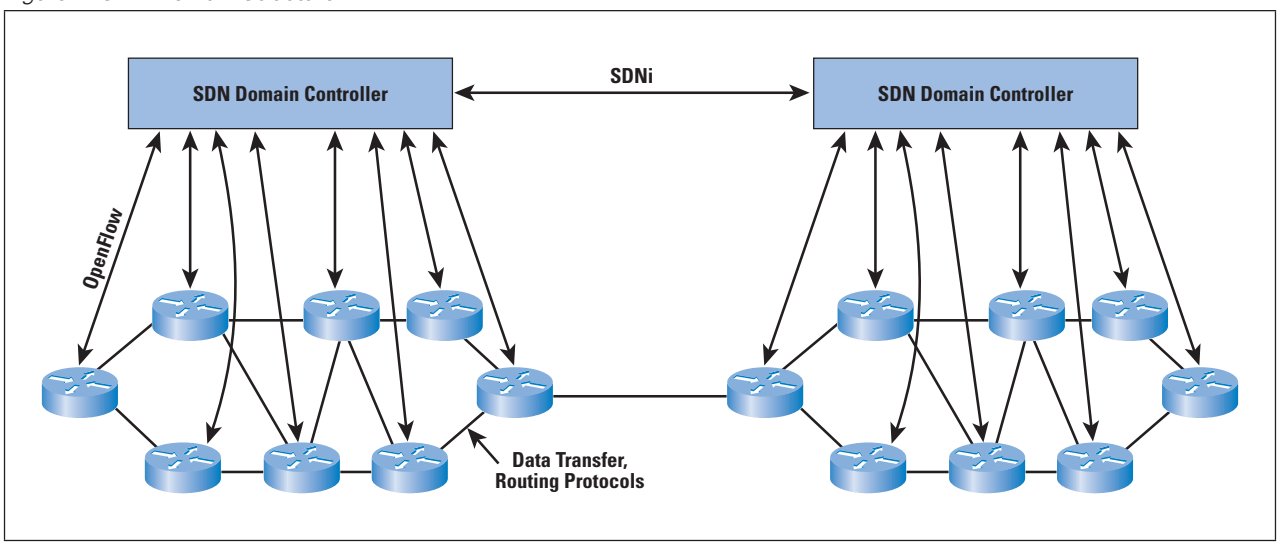
In simple terms, the SDN controller manages the forwarding state of the switches in the SDN. This management is done through a vendor-neutral API that allows the controller to address a wide variety of operator requirements without changing any of the lower-level aspects of the network, including topology.

With the decoupling of the control and data planes, SDN enables applications to deal with a single abstracted network device without concern for the details of how the device operates. Network applications see a single API to the controller. Thus it is possible to quickly create and deploy new applications to orchestrate network traffic flow to meet specific enterprise requirements for performance or security.

SDN Domains

In a large enterprise network, the deployment of a single controller to manage all network devices would prove unwieldy or undesirable. A more likely scenario is that the operator of a large enterprise or carrier network divides the whole network into numerous nonoverlapping SDN domains as shown in Figure 2.

Figure 2: SDN Domain Structure



Reasons for using SDN domains include the following:

- *Scalability:* The number of devices an SDN controller can feasibly manage is limited. Thus, a reasonably large network may need to deploy multiple SDN controllers.
- *Privacy:* A carrier may choose to implement different privacy policies in different SDN domains. For example, an SDN domain may be dedicated to a set of customers who implement their own highly customized privacy policies, requiring that some networking information in this domain (for example, network topology) not be disclosed to an external entity.
- *Incremental deployment:* A carrier's network may consist of portions of traditional and newer infrastructure. Dividing the network into multiple, individually manageable SDN domains allows for flexible incremental deployment.

The existence of multiple domains creates a requirement for individual controllers to communicate with each other via a standardized protocol to exchange routing information. The IETF is currently working on developing a protocol, called *SDNi,* for "interfacing SDN Domain Controllers"[5]. SDNi functions include:

- Coordinate flow setup originated by applications containing information such as path requirement, QoS, and service-level agreements across multiple SDN domains.
- Exchange reachability information to facilitate inter-SDN routing. This information exchange will allow a single flow to traverse multiple SDNs and have each controller select the most appropriate path when multiple such paths are available.

The message types for SDNi tentatively include the following:

- Reachability update
- Flow setup/tear-down/update request (including application capability requirements such as QoS, data rate, latency etc.)
- Capability update (including network-related capabilities such as data rate and QoS, and system and software capabilities available inside the domain)

OpenFlow

To turn the concept of SND into practical implementation, two requirements must be met. First, there must be a common logical architecture in all switches, routers, and other network devices to be managed by an SDN controller. This logical architecture may be implemented in different ways on different vendor equipment and in different types of network devices, so long as the SDN controller sees a uniform logical switch function. Second, a standard, secure protocol is needed between the SDN controller and the network device.

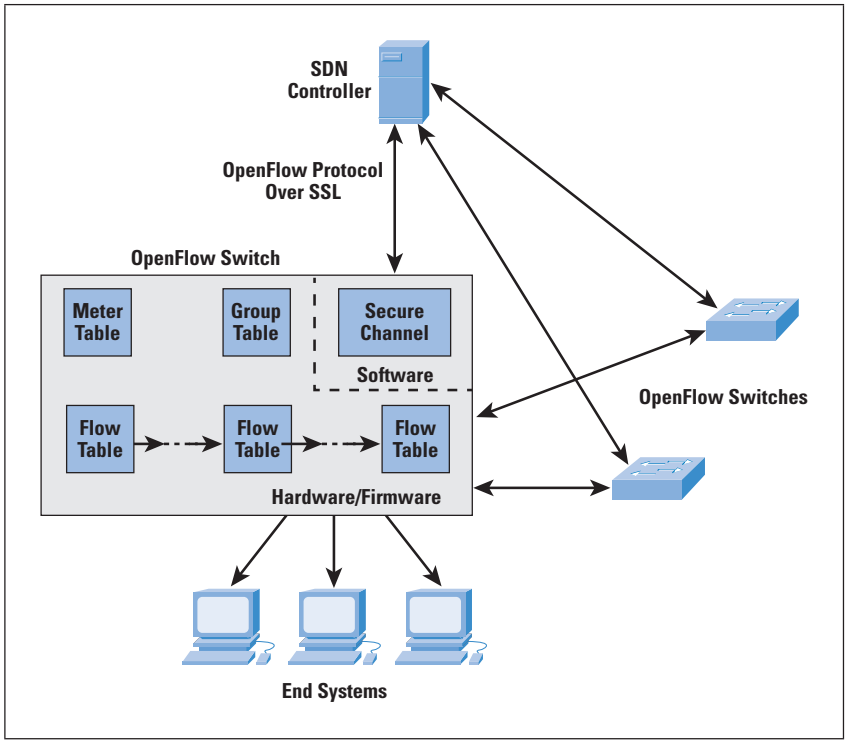
Both of these requirements are addressed by *OpenFlow,* which is both a protocol between SDN controllers and network devices, as well as a specification of the logical structure of the network switch functions[6, 7]. OpenFlow is defined in the *OpenFlow Switch Specification,* published by the *Open Networking Foundation* (ONF). ONF is a consortium of software providers, content delivery networks, and networking equipment vendors whose purpose is to promote software-defined networking.

This discussion is based on the current OpenFlow specification, Version 1.3.0, June 25, 2012[8]. The original specification, 1.0, was developed at Stanford University and was widely implemented. OpenFlow 1.2 was the first release from ONF after inheriting the project from Stanford. OpenFlow 1.3 significantly expands the functions of the specification. Version 1.3 is likely to become the stable base upon which future commercial implementations for OpenFlow will be built. ONF intends for this version to be a stable target for chip and software vendors, so little if any change is planned for the foreseeable future[9].

Logical Switch Architecture

Figure 3 illustrates the basic structure of the OpenFlow environment. An SDN controller communicates with OpenFlow-compatible switches using the OpenFlow protocol running over the *Secure Sockets Layer* (SSL). Each switch connects to other OpenFlow switches and, possibly, to end-user devices that are the sources and destinations of packet flows. Within each switch, a series of tables—typically implemented in hardware or firmware—are used to manage the flows of packets through the switch.

Figure 3: OpenFlow Switch



The OpenFlow specification defines three types of tables in the logical switch architecture. A *Flow Table* matches incoming packets to a particular flow and specifies the functions that are to be performed on the packets. There may be multiple flow tables that operate in a pipeline fashion, as explained subsequently. A flow table may direct a flow to a *Group Table*, which may trigger a variety of actions that affect one or more flows. A *Meter Table* can trigger a variety of performance-related actions on a flow.

Before proceeding, it is helpful to define what the term *flow* means. Curiously, this term is not defined in the OpenFlow specification, nor is there an attempt to define it in virtually all of the literature on OpenFlow. In general terms, a flow is a sequence of packets traversing a network that share a set of header field values. For example, a flow could consist of all packets with the same source and destination IP addresses, or all packets with the same VLAN identifier. We provide a more specific definition subsequently.

Flow-Table Components

The basic building block of the logical switch architecture is the flow table. Each packet that enters a switch passes through one or more flow tables. Each flow table contains entries consisting of six components:

- *Match Fields:* Used to select packets that match the values in the fields.
- *Priority:* Relative priority of table entries.
- *Counters:* Updated for matching packets. The OpenFlow specification defines a variety of timers. Examples include the number of received bytes and packets per port, per flow table, and per flow-table entry; number of dropped packets; and duration of a flow.
- *Instructions:* Actions to be taken if a match occurs.
- *Timeouts:* Maximum amount of idle time before a flow is expired by the switch.
- *Cookie:* Opaque data value chosen by the controller. May be used by the controller to filter flow statistics, flow modification, and flow deletion; not used when processing packets.

A flow table may include a *table-miss* flow entry, which renders all Match Fields wildcards (every field is a match regardless of value) and has the lowest priority (priority 0). The Match Fields component of a table entry consists of the following required fields:

- *Ingress Port:* The identifier of the port on the switch where the packet arrived. It may be a physical port or a switch-defined virtual port.
- *Ethernet Source and Destination Addresses:* Each entry can be an exact address, a bitmasked value for which only some of the address bits are checked, or a wildcard value (match any value).

- *IPv4 or IPv6 Protocol Number:* A protocol number value, indicating the next header in the packet.
- *IPv4 or IPv6 Source Address and Destination Address:* Each entry can be an exact address, a bitmasked value, a subnet mask value, or a wildcard value.
- *TCP Source and Destination Ports:* Exact match or wildcard value.
- *User Datagram Protocol (UDP) Source and Destination Ports:* Exact match or wildcard value.

The preceding match fields must be supported by any OpenFlow-compliant switch. The following fields may be optionally supported:

- *Physical Port:* Used to designate underlying physical port when packet is received on a logical port.
- *Metadata:* Additional information that can be passed from one table to another during the processing of a packet. Its use is discussed subsequently.
- *Ethernet Type:* Ethernet Type field.
- *VLAN ID and VLAN User Priority:* Fields in the IEEE 802.1Q Virtual LAN header.
- *IPv4 or IPv6 DS and ECN:* Differentiated Services and Explicit Congestion Notification fields.
- *Stream Control Transmission Protocol (SCTP) Source and Destination Ports:* Exact match or wildcard value.
- *Internet Control Message Protocol (ICMP) Type and Code Fields:* Exact match or wildcard value.
- *Address Resolution Protocol (ARP) Opcode:* Exact match in Ethernet Type field.
- *Source and Target IPv4 Addresses in Address Resolution Protocol (ARP) Payload:* Can be an exact address, a bitmasked value, a subnet mask value, or a wildcard value.
- *IPv6 Flow Label:* Exact match or wildcard.
- *ICMPv6 Type and Code fields:* Exact match or wildcard value.
- *IPv6 Neighbor Discovery Target Address:* In an IPv6 Neighbor Discovery message.
- *IPv6 Neighbor Discovery Source and Target Addresses:* Link-layer address options in an IPv6 Neighbor Discovery message.
- *Multiprotocol Label Switching (MPLS) Label Value, Traffic Class, and Bottom of Stack (BoS):* Fields in the top label of an MPLS label stack.

Thus, OpenFlow can be used with network traffic involving a variety of protocols and network services. Note that at the MAC/link layer, only Ethernet is supported. Thus, OpenFlow as currently defined cannot control Layer 2 traffic over wireless networks.

We can now offer a more precise definition of the term *flow.* From the point of view of an individual switch, a flow is a sequence of packets that matches a specific entry in a flow table. The definition is packet-oriented, in the sense that it is a function of the values of header fields of the packets that constitute the flow, and not a function of the path they follow through the network. A combination of flow entries on multiple switches defines a flow that is bound to a specific path.

The *instructions component* of a table entry consists of a set of instructions that are executed if the packet matches the entry. Before describing the types of instructions, we need to define the terms "Action" and "Action Set." Actions describe packet forwarding, packet modification, and group table processing operations. The OpenFlow specification includes the following actions:

- *Output:* Forward packet to specified port.
- *Set-Queue:* Sets the queue ID for a packet. When the packet is forwarded to a port using the output action, the queue id determines which queue attached to this port is used for scheduling and forwarding the packet. Forwarding behavior is dictated by the configuration of the queue and is used to provide basic QoS support.
- *Group:* Process packet through specified group.
- *Push-Tag/Pop-Tag:* Push or pop a tag field for a VLAN or MPLS packet.
- *Set-Field:* The various Set-Field actions are identified by their field type; they modify the values of respective header fields in the packet.
- *Change-TTL:* The various Change-TTL actions modify the values of the IPv4 Time To Live (TTL), IPv6 Hop Limit, or MPLS TTL in the packet.

An *Action Set* is a list of actions associated with a packet that are accumulated while the packet is processed by each table and executed when the packet exits the processing pipeline. Instructions are of four types:

- *Direct packet through pipeline:* The Goto-Table instruction directs the packet to a table farther along in the pipeline. The Meter instruction directs the packet to a specified meter.
- *Perform action on packet:* Actions may be performed on the packet when it is matched to a table entry.
- *Update action set:* Merge specified actions into the current action set for this packet on this flow, or clear all the actions in the action set.
- *Update metadata:* A metadata value can be associated with a packet. It is used to carry information from one table to the next.

Flow-Table Pipeline

A switch includes one or more flow tables. If there is more than one flow table, they are organized as a pipeline as shown in Figure 4, with the tables labeled with increasing numbers starting with 0.

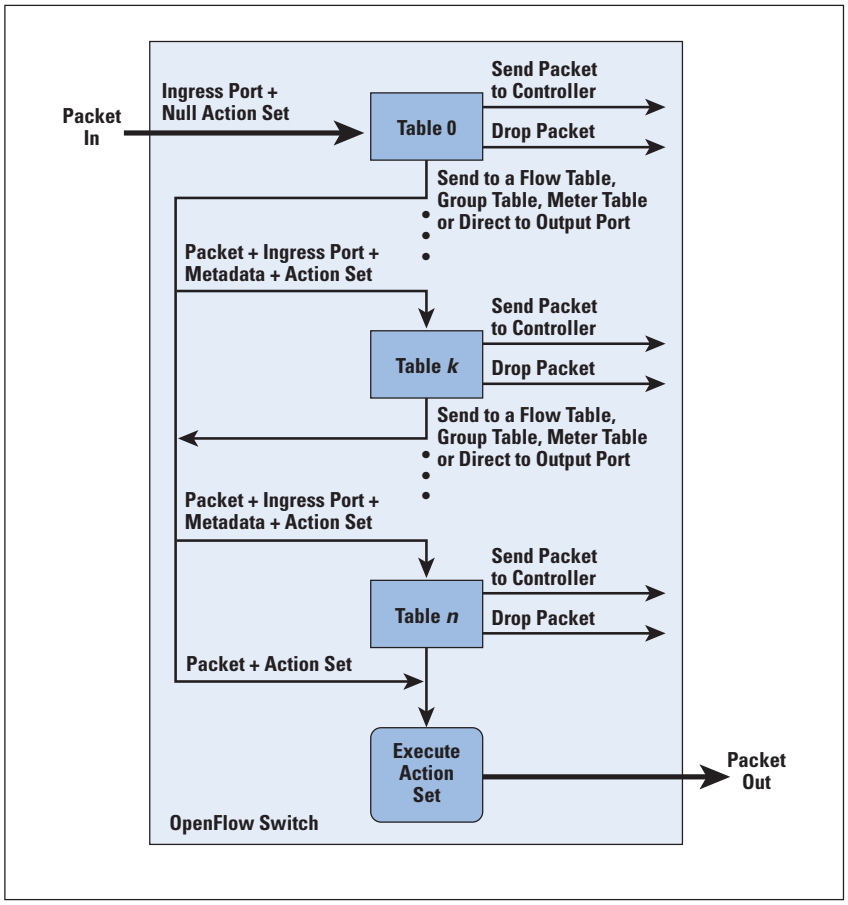


Figure 4: Packet Flow Through OpenFlow-Compliant Switch

When a packet is presented to a table for matching, the input consists of the packet, the identity of the ingress port, the associated metadata value, and the associated action set. For Table 0, the metadata value is blank and the action set is null. Processing proceeds as follows:

1. Find the highest-priority matching flow entry. If there is no match on any entry and there is no table-miss entry, then the packet is dropped. If there is a match only on a table-miss entry, then that entry specifies one of three actions:

   a. Send packet to controller. This action will enable the controller to define a new flow for this and similar packets, or decide to drop the packet.

   b. Direct packet to another flow table farther down the pipeline.

   c. Drop the packet.

2. If there is a match on one or more entries other than the table-miss entry, then the match is defined to be with the highest-priority matching entry. The following actions may then be performed:
   a. Update any counters associated with this entry.
   b. Execute any instructions associated with this entry. These instructions may include updating the action set, updating the metadata value, and performing actions.
   c. The packet is then forwarded to a flow table further down the pipeline, to the group table, or to the meter table, or it could be directed to an output port.

For the final table in the pipeline, forwarding to another flow table is not an option.

If and when a packet is finally directed to an output port, the accumulated action set is executed and then the packet is queued for output.

OpenFlow Protocol

The OpenFlow protocol describes message exchanges that take place between an OpenFlow controller and an OpenFlow switch. Typically, the protocol is implemented on top of SSL or *Transport Layer Security* (TLS), providing a secure OpenFlow channel.

The OpenFlow protocol enables the controller to perform add, update, and delete actions to the flow entries in the flow tables. It supports three types of messages, as shown in Table 1.

- *Controller-to-Switch:* These messages are initiated by the controller and, in some cases, require a response from the switch. This class of messages enables the controller to manage the logical state of the switch, including its configuration and details of flow- and group-table entries. Also included in this class is the Packet-out message. This message is used when a switch sends a packet to the controller and the controller decides not to drop the packet but to direct it to a switch output port.
- *Asynchronous:* These types of messages are sent without solicitation from the controller. This class includes various status messages to the controller. Also included is the Packet-in message, which may be used by the switch to send a packet to the controller when there is no flow-table match.
- *Symmetric:* These messages are sent without solicitation from either the controller or the switch. They are simple yet helpful. Hello messages are typically sent back and forth between the controller and switch when the connection is first established. Echo request and reply messages can be used by either the switch or controller to measure the latency or bandwidth of a controller-switch connection or just verify that the device is operating. The Experimenter message is used to stage features to be built into future versions of OpenFlow.

Table 1: OpenFlow Messages

Message	Description
Controller-to-Switch	
Features	Request the capabilities of a switch. Switch responds with a features reply that specifies its capabilities.
Configuration	Set and query configuration parameters. Switch responds with parameter settings.
Modify-State	Add, delete, and modify flow/group entries and set switch port properties.
Read-State	Collect information from switch, such as current configuration, statistics, and capabilities.
Packet-out	Direct packet to a specified port on the switch.
Barrier	Barrier request/reply messages are used by the controller to ensure message dependencies have been met or to receive notifications for completed operations.
Role-Request	Set or query role of the OpenFlow channel. Useful when switch connects to multiple controllers.
Asynchronous-Configuration	Set filter on asynchronous messages or query that filter. Useful when switch connects to multiple controllers.
Asynchronous	
Packet-in	Transfer packet to controller.
Flow-Removed	Inform the controller about the removal of a flow entry from a flow table.
Port-Status	Inform the controller of a change on a port.
Error	Notify controller of error or problem condition.
Symmetric	
Hello	Exchanged between the switch and controller upon connection startup.
Echo	Echo request/reply messages can be sent from either the switch or the controller, and they must return an echo reply.
Experimenter	For additional functions.

The OpenFlow protocol enables the controller to manage the logical structure of a switch, without regard to the details of how the switch implements the OpenFlow logical architecture.

Summary

SDNs, implemented using OpenFlow, provide a powerful, vendor-independent approach to managing complex networks with dynamic demands. The software-defined network can continue to use many of the useful network technologies already in place, such as virtual LANs and an MPLS infrastructure. SDNs and OpenFlow are likely to become commonplace in large carrier networks, cloud infrastructures, and other networks that support the use of big data.

IPv4 and IPv6 Address Authentication

by Scott Hogg, GTRI

Some Internet services use the source address of the client's computer as a form of authentication. These systems keep track of the *Internet Protocol* (IP) address that an end user used the last time that user accessed the site and try to determine if the user is legitimate. When that same user accesses the site from a different source IP address, the site asks for further authentication to revalidate the client's computer. The theory is that a user's typical location computer has a somewhat persistent IP address, but when the user has a new address, that user may be mobile or using a less secure wireless media, and then require further authentication. For example, many organizations have firewall policies with objects named like "Bob's Laptop" with the single IP address of his computer. This technique is used by some banking sites, some online gaming sites, and Gmail (for example, *Google Authenticator*)[1].

Some online retailers track the client IP address for Business Intelligence or fraud detection and forensics purposes. The retailer tracks the client IP address using the source address to analyze fraudulent purchases and to track down criminal activity. Some industries frequently use the customer's IP address as a form of authentication. Also, many sites that use *Server Load Balancers* (SLBs) and *Application Delivery Controllers* (ADCs) use *X-forwarded-for* (XFF)[2] or *Hypertext Transfer Protocol* (HTTP) header insertion so that the back-end real servers are aware of the client's original IP address associated with the reverse proxy connection. The application can then use the IP address for tracking purposes or simply log the address with the transaction details.

Other applications try to validate the client's source IP address when the server receives an inbound connection. E-mail *Simple Mail Transfer Protocol* (SMTP) servers or *Internet Relay Chat* (IRC) servers can use the *Ident* protocol[3] to try to validate the originating e-mail server or client computer validity. SMTP e-mail servers[4] also use other protocols such as *SenderID*[5], *Sender Policy Framework* (SPF)[6], and *DomainKeys Identified Mail* (DKIM)[7] in an effort to restrict spam. *Domain Name System* (DNS) *pointer* (PTR) records are sometimes used as a way to confirm that the client IP address is configured in DNS (for example, forward-confirmed reverse DNS[8]).

Statically configured IP addresses are frequently used to signify some limited form of authentication. These addresses may not be used to authenticate a user, but authenticate IT systems to each other. Many manually configured systems rely on IP address to permit connectivity, including manually configured tunnels, *IP Security* (IPsec) peers, Apache `.htaccess`[9], `.rhosts`[10], SAMBA, and *Border Gateway Protocol* (BGP) peers, among many others.

The address is used as one part of the connection authentication. Obviously, IPsec connections are authenticated with certificates or preshared keys to strengthen their validation of the endpoints. Similarly, BGP peers use passwords (and/or *Time To Live* [TTL][11]) to help secure the peer beyond just IP address confirmation.

Identity-based firewalls police users' network behavior by IP address through *Windows Active Directory, Remote Authentication Dial-In User Service* (RADIUS), or *Lightweight Directory Access Protocol* (LDAP). Palo Alto firewalls championed the *UserID* concept as part of their analysis of connections to permit or deny authentication[12]. The Cisco *Adaptive Security Appliance* (ASA) firewalls running Version 8.4 or later can be configured for Identify firewall functions[13]. Firewalls have always used manually configured IP addresses as the fundamental element of their policies. The IP address is used in the policy as if that concretely defines a system and/or user. This process of adding rules based on IP address continues until the firewall is a pincushion full of pinholes.

Organizations that rely on using an IP address as a form of authentication run the risk of an attacker learning that IP address and attacking using that address. Attackers who know the addresses that are being used could perform a *Man-in-the-Middle* (MITM) attack or use TCP session hijacking. The attacker needs to know only the information about which IP addresses are used for the communications. The attacker might be able to ascertain the IP addresses the organization uses by guessing or by other means. The attacker could find the external IP address of the company's firewall and assume that IPv4 *Network Address Translation* (NAT)[24] was being performed. The attacker could also suppose the business partner IP address. Organizations that use these techniques are relying on the secrecy of their IP addressing for the purposes of security.

Address Quality

The quality of the IP address is an important concept to consider. For example, a global address is of higher surety and authenticity than a private address. Many organizations use private addresses and overlap between private networks, whereas global addresses are unique and they are registered to a specific entity. Public addresses can reveal the client's *Internet Service Provider* (ISP), the organization that has registered the IP addresses, and some geolocation information. However, any IP packet can be spoofed and the source-address modified or crafted. Of course, if the source IP addresses is spoofed, the return packets will not necessarily be sent back to the attacker's source in these cases, but one-way blind attacks are still possible. Furthermore, systems such as *Tor*[14] are intended to protect the identity of the end user.

Using the IP address as a form of authentication does not work if the client changes its location frequently. Today, many clients use mobile devices that can change their Layer 3 addresses often. The source IP address of the mobile device could change frequently and could even change during the transaction.

With increasing mobile device usage for business purposes, the ability to determine the typical IP address of the client becomes impossible. Increased scarcity of IPv4 addresses is leading service providers to use *Carrier-Grade NAT* (CGN) or *Large-Scale NAT* (LSN) and shorter and shorter *Dynamic Host Configuration Protocol* (DHCP) lease times, meaning that the client IP address is not static.

Many organizations and systems assume that a single computer with a single IP address represents a single user. The problem arises where IPv4 public addresses may not uniquely identify a single user. The industry may be trying to anticipate the implications of CGN/LSN and the effect of systems that rely on the uniqueness of a public IP address. Similar problems related to the mega-proxies of the late 1990s occurred (for example, AOL). With CGN/LSN systems in place, online retailers and banks will no longer be able to use the client IPv4 as the "real client IP." Instead, the IP address observed on the retailer's web servers will come from a pool of IPv4 addresses configured in the LSN system. In this situation, one bad actor could spoil that NAT pool IPv4 address for subsequent lawful users who follow. When a legitimate user tries to make an online purchase and that user's system happens to use that IPv4 address of the bad actor, then the purchase attempt might be blocked. This situation would be bad for business on Cyber-Monday, or any day for that matter.

Table 1 compares IPv4 and IPv6 for their authentication purposes.

Table 1: IPv4 vs. IPv6 for Authentication

IPv4	IPv6
Extensive use of NAT	No motivation for NAT
End users use private addresses	End users use global addresses
Use of CGN/LSN starting	Abundance of IPv6 addresses
Robust geolocation	Geolocation needs improvement
Addresses could be spoofed	Addresses could be spoofed

Public Addresses

Public IPv4 addresses are becoming increasingly scarce[15, 25], however, an abundance of global IPv6 addresses are available[16]. Global IPv6 addresses can be obtained from *Regional Internet Registries* (RIRs) or from an IPv6-capable service provider. Residential broadband Internet users today use private IPv4 addresses on their internal computers, but these computers will soon start to use global IPv6 addresses as they upgrade to IPv6-capable *Customer Premises Equipment* (CPE). IPv6-enabled residential subscribers and employees of IPv6-enabled enterprises will be using global addresses when they access an IPv6-capable Internet service.

To online retailers, this situation may represent a change to their IP address authentication measures. As IPv4 residential users start to go through CGN/LSN systems, their IPv4 addresses will be useless for authentication.

However, their IPv6 addresses will be global addresses with no NAT taking place between the client and the server[17]. It will be seemingly more accurate to use the IPv6 address to determine the validity of the source. IPv6 could potentially help to create an environment with more "trustworthiness" and less anonymity. For example, IPv6 IPsec connections could use the *Authentication Header* (AH) and *Encapsulating Security Payload* (ESP) together to create stronger connections, where IPv4 IPsec connections rely on NAT-Traversal and can use only ESP[18].

As we head toward an increasingly dual-stack world, applications will need to do "dual-checking" of both the client's IPv4 and IPv6 addresses. In a dual-stack world, there is more work to do[19], and servers using IP address authentication will need to understand that a single user will have both an IPv4 address and an IPv6 address and keep track of both. The other consideration is that IPv6 nodes may have multiple global IPv6 addresses in some situations.

Authentication with Addresses

Security experts know that the secrecy of the encryption algorithm is not important, but the secrecy of the key is vitally important (Kerckhoffs's Principle[20]). The same concept should hold true for an IP address. Users should not rely on the secrecy of their IP addresses to be secure; the security of the individual node should be strong enough to defend against attacks. To the extreme, users should feel confident enough in their security posture that they feel comfortable widely publicizing their IP address. However, even if you are using *LifeLock*[21], you should still keep your Social Security Number or government ID number private.

Security practitioners know that authentication should involve multiple factors. A combination of "something you are" (biometrics), "something you know" (username/password) and "something you have" (token, *Common Access Card*[22]) forms a more solid foundation for identifying a user. Combining two factors provides more assurance than just one factor. We are all aware of the weaknesses of using username and password as a means of authentication[23].

The systems mentioned so far in this article are three-factor systems (username, password, and IP address) which are presumably better than just username/password. However, we should acknowledge that an IP address is not a characteristic of a person. IP addresses have more to do with "somewhere you are," because the IP address reflects location within a network topology by the prefix/subnet. The last few bits of an IPv4 address representing the point-of-attachment or an IPv6 *Interface Identifier* (IID) do not necessarily uniquely identify a user. Having authentication based on your location becomes difficult with mobile devices that roam widely. However, controlling authentication to users who are within the office subnet rather than outside the office may be useful.

An IP address is not something anyone really owns outright. Few organizations actually have complete ownership of their IP addresses. Organizations should read the fine print in the policies of their RIR. Organizations just pay RIR annual fees for their addresses, but if they stop paying those dues, the IP address allocation is revoked and the addresses go back into a pool for reallocation to another organization. Therefore, public IP addresses do not truly represent unequivocal ownership or legitimacy of a network.

Conclusion

Many different types of systems use the client's source address as a form of authentication. Systems that rely on IP address checking will need to do so for IPv4 and will need to be modified to use IPv6 addresses. IPv6 systems will use global addresses without NAT, so the security systems must stand on their own even though the IPv6 address is publicized. IPv4 and IPv6 addresses can be spoofed, and as CGN/LSN systems become widely deployed the validity of a public IPv4 address decreases. However, IPv6 addresses are not necessarily any more trustworthy than IPv4 addresses when used for authentication. Regardless, the IP address should not be the only factor used for authentication, and we should not be using IPv4 or IPv6 addresses as a form of authentication. The truth is that the IT industry needs to be aware of where IP addresses are used as a form of authentication and seek out better forms of authentication beyond just username, password, and IP address.

Summary Report of the ITU-T World Conference on International Telecommunications

by Robert Pepper and Chip Sharp, Cisco Systems

From 3–14 December, 2012, 151 Member States of the *International Telecommunication Union* (ITU) met in Dubai[0] at the *World Conference on International Telecommunications* (WCIT-12)[1] to revise the *International Telecommunication Regulations* (ITRs), a treaty-level document establishing policies governing international telecommunications services. During the 2-week conference the delegates debated several proposed changes on topics such as international mobile roaming, numbering, naming, addressing, fraud, the Internet, *Quality of Service* (QoS), etc. In the end, a revised version of the treaty was finalized[2], but only 89 of the 151 Member States attending signed it.

There have been many articles discussing different aspects of the conference and its outcomes. This article provides background on the ITRs and focuses on the potential impact of the WCIT and its revised treaty on development of the Internet.

Background

The ITRs originated from the development of international telegraphy in Europe in the late 1800s and the need for a treaty defining how the government-operated national telegraph networks would interconnect and interoperate[3]. As telephony and radio communications were invented, new treaties were developed to regulate their international operation. Up until the 1980s most telephone and telegraph companies were government-owned monopolies with some government licensed private companies operating as a monopoly. In 1988, the separate telegraph and telephone treaties were merged into the International Telecommunications Regulations while the *Radio Regulations* remained a separate treaty. By 1988, though some liberalization and privatization had started in a few countries in some regions, most international telecommunications services globally were still provided by monopoly, government-owned carriers, and services were dominated by voice rather than data. International Internet connectivity and traffic were practically nonexistent in most countries. Of course, international data traffic (including Internet) was growing in importance to some countries such as the United States and some large multinational companies such as IBM (which wanted to provide international *Virtual Private Networks* [VPNs]).

One important aspect of the ITRs in 1988 was the telephony accounting rate system. Briefly, this system consisted of a calling-party-pays business model for telephony in which the originating country pays the terminating country settlements based on a bilaterally agreed-upon accounting rate. Because developed countries tended to make more calls to developing countries than conversely and the accounting rate tended to be substantially above cost in many cases, the accounting rate system effectively became a subsidy program and a source for hard currency for developing countries.

Since 1988 market liberalization, reduced regulation, increased competition, and the rise of the Internet and mobile wireless industries have drastically changed the global communications landscape. In 1997, the U.S. *Federal Communications Commission* (FCC) opted out of the accounting rate system defined in the ITRs[4], with many countries subsequently following suit. Voice over the Internet, arbitrage, hubbing, and other factors have reduced the telephony settlements revenue for developing countries. The 1988 ITRs[5] allowed for special arrangements between network operators outside the rules of the ITRs. These special arrangements allowed for the international physical connectivity on which growth of the international Internet depended.

As the Internet grew and the telecom market changed, there was increased pressure from some countries to revise the ITRs. Contributions submitted in the preparatory meetings for WCIT-12 reflected widely varying views on the nature and extent of possible changes to the ITRs to account for this greatly changed environment. Although some countries believed that the ITRs should set forth high-level strategic and policy principles that could adapt to further changes in the market, others proposed the inclusion of expanded regulatory provisions of a detailed and specific nature in the ITRs to address a wide range of new concerns and services, including the Internet, or even to include the intergovernmental regulation of content (for example, spam and information security).

High-Level Take-Aways

Out of 151 countries attending the conference, the treaty was signed by 89 countries, consisting of mostly emerging countries led by Russia, China, Brazil, and the Arab States; 55 countries, including the United States, Japan, Australia, Canada, United Kingdom, and most of Europe, did not sign at the time. Countries that did not sign the treaty in Dubai can accede to the treaty after the WCIT by notifying the Secretary-General of the ITU. It is quite likely that some countries that did not sign the treaty will accede to it over the next few years.

The treaty takes effect on January 1, 2015 (after the 2014 *Plenipotentiary Conference*). Each signing country has to go through its national process for approval (for example, ratification) before the treaty takes effect for that country.

Although there has been a lot of negative commentary on the WCIT in the Internet community, in the end there are some important positive results for the Internet:

- No provisions were added to treaty text explicitly concerning the Internet, Internet Governance, or information security.
- No provisions were added to the treaty text concerning naming or addressing.
- No provisions modifying the basic business models of the Internet or mandating QoS on the Internet were made.

- The updated treaty explicitly recognizes commercial arrangements in addition to the old accounting rate regime for telecommunications.
- Article 9 on *Special Arrangements* allowing for telecommunications arrangements outside the treaty was retained mostly unchanged, thus allowing such special arrangements to continue to be used even between nonsignatory and signatory countries.
- A new resolution on landlocked countries could encourage access of such countries to landing stations in other countries and ease landlocked countries' ability to acquire international connectivity.

Some results that could be of concern to the Internet follow:

- The term identifying the operators to which the treaty applies ("authorized operating agencies") was modified. The supporters of the new term claim it does not expand the scope of the treaty, but it will bear watching.
- A provision on "unsolicited bulk electronic communications," developed after a long debate on spam, could lead governments to regulate and filter e-mail in addition to having unintended consequences such as disallowing bulk electronic emergency warning systems.
- Numbering provisions and requirements to deliver *Calling Party Number* were intended by some countries to allow for restrictions on international *Voice over IP* (VoIP) and VoIP services (including VoIP over the Internet).
- A new provision on network security could encourage more multilateral discussions in an intergovernmental setting (as opposed to multistakeholder).
- A new Resolution 3 on the Internet instructs the Secretary-General to engage further in Internet Governance discussions and further supports intergovernmental Internet policy processes.
- A new Resolution 5 mentions the transition to IP-based networks. It originally was aimed at over-the-top providers, but was modified to apply to service providers of international services. The end result is rather ambiguous in many respects and will bear watching.
- A new Article was added concerning telecommunication exchange points. Although the Internet is not mentioned explicitly, the originators of this article intended for it to apply to Internet Exchange Points. This Article could be used to support development of an enabling environment for regional telecommunication connectivity, but could also be used to justify regulation of Internet Exchange Points.
- Resolution Plen/4 requires PP'14 to consider a review of the ITRs every 8 years. This provision could result in another WCIT in 2020.

Table 1 lists the Member States that signed and did not sign the treaty in Dubai[6].

Table 1: Treaty Signatories and Nonsignatories

Signatories			Nonsignatories	
Afghanistan	Guatemala	Qatar	Albania	Latvia
Algeria	Guyana	Russia	Andorra	Lichtenstein
Angola	Haiti	Rwanda	Armenia	Lithuania
Argentina	Indonesia	Saint Lucia	Australia	Luxembourg
Azerbaijan	Iran	Saudi Arabia	Austria	Malawi
Bahrain	Iraq	Senegal	Belarus	Malta
Bangladesh	Jamaica	Sierra Leone	Belgium	Marshall Islands
Barbados	Jordan	Singapore	Bulgaria	Moldova
Belize	Kazakhstan	Somalia	Canada	Mongolia
Benin	Korea (Rep. of)	South Africa	Chile	Montenegro
Bhutan	Kuwait	South Sudan	Colombia	Netherlands
Botswana	Kyrgyzstan	Sri Lanka	Costa Rica	New Zealand
Brazil	Lebanon	Sudan	Croatia	Norway
Brunei	Lesotho	Swaziland	Cyprus	Philippines
Burkina Faso	Liberia	Tanzania	Czech Republic	Poland
Burundi	Libya	Thailand	Denmark	Peru
Cambodia	Malaysia	Togo	Estonia	Portugal
Cape Verde	Mali	Trinidad and Tobago	Finland	Serbia
Central African Rep.	Mauritius	Tunisia	France	Slovak Republic
China	Mexico	Turkey	Gambia	Slovenia
Comoros	Morocco	Uganda	Georgia	Spain
Congo	Mozambique	Ukraine	Germany	Sweden
Cote d'Ivoire	Namibia	UAE	Greece	Switzerland
Cuba	Nepal	Uruguay	Hungary	United Kingdom
Djibouti	Niger	Uzbekistan	India	United States
Dominican Rep.	Nigeria	Venezuela	Ireland	
Egypt	Oman	Vietnam	Israel	
El Salvador	Panama	Yemen	Italy	
Gabon	Papua New Guinea	Zimbabwe	Japan	
Ghana	Paraguay		Kenya	

Note: Other *United Nations* (UN) member states were not eligible to sign or did not attend the conference but might still accede to the treaty: Antigua and Barbuda, Bahamas, Bolivia, Bosnia and Herzegovina, Cameroon, Chad, Dem. People's Republic of Korea, Dem. Rep. of the Congo, Dominica, Ecuador, Equatorial Guinea, Eritrea, Ethiopia, Fiji, Grenada, Guinea, Guinea-Bissau, Honduras, Iceland, Kiribati, Lao P.D.R., T.F.Y.R. Macedonia, Madagascar, Maldives, Mauritania, Micronesia, Monaco, Myanmar, Nauru, Nicaragua, Pakistan, Romania, Saint Kitts and Nevis, Saint Vincent and the Grenadines, Samoa, San Marino, Sao Tome and Principe, Seychelles, Solomon Islands, Suriname, Syria, Tajikistan, Timor-Leste, Tonga, Turkmenistan, Tuvalu, Vanuatu, the Vatican, and Zambia.

Proposals and Outcomes

When the conference began there were several provisions that either explicitly or implicitly applied to the Internet, including:

- A proposal to define the term "Internet" and explicitly bring the Internet into the regulatory structure of the treaty
- Proposals to bring Internet naming, addressing, and identifiers into the treaty
- A proposal to include a provision on access to Internet websites
- A proposal on "traffic exchange points" that was intended to apply to *Internet Exchange Points*
- Proposals from multiple states on spam, information security, and *cybersecurity*

Although the Secretary-General of the ITU declared that the WCIT was not about the Internet or Internet Governance[7], by rule, the WCIT had to consider input from its Member States. Given that Member States submitted proposals on the Internet, the Internet and Internet Governance was a substantive topic of discussion.

The following sections provide a brief review of some of the more difficult discussions related to the Internet.

Security

There were several proposals[8] going into the WCIT to include cybersecurity, including information security, in the new ITRs. These proposals generated significant discussions and negotiations during the conference. The final text (Article 5A) is a great improvement over the proposals into the conference in that it focuses on the security and robustness of networks and prevention of technical harm to networks, with no mention of information security or cybersecurity.

The new provision mentions that Member States shall "collectively endeavour," a provision that could engender more multilateral discussions in an intergovernmental setting (for example, ITU).

Organizations to Which the Treaty Applies

The 1988 ITR treaty focused on licensed carriers and government-owned *Post, Telephone, and Telegraph* (PTT) entities. Proposals[8] into the WCIT would have applied the treaty to a wider range of organizations and companies. In the end, the treaty developed a new term, *Authorized Operating Agencies* (AOA). The proponents of this new term argued that it does not broaden the scope of the ITRs in terms of the organizations to which it applies. This interpretation of the new term should be supported, but monitored.

Internet-Specific Proposals and Resolutions (Resolutions Plen/3 and Plen/5)

Proposals[8] were submitted to the WCIT to define the term "Internet" and to encode into the treaty the right of countries to regulate the "national segment" of the Internet. At the end of the first week of WCIT, Algeria, Saudi Arabia, Bahrain, China, United Arab Emirates, Iraq, Sudan, and Russia announced development of a new draft set of Resolutions that contained provisions that Member States shall have the right to manage the Internet, including Internet numbering, naming, addressing, and identification resources.

Although the United States, United Kingdom, and others were successful in removing any mention of the Internet from the treaty text, Internet-related language was moved into a nonbinding resolution *(Resolution Plen/3)* proposed by Russia "to foster an enabling environment for the greater growth of the Internet." Resolution Plen/3 instructs the ITU Secretary-General "to continue to take the necessary steps for ITU to play an active and constructive role in the development of broadband and the multistakeholder model of the Internet as expressed in § 35 of the *Tunis Agenda*." It also invites Member States to elaborate their positions on Internet-related concerns in the relevant ITU-related fora (something they could have done anyway).

This does not look too bad until one reads Paragraph 35 of the Tunis Agenda[9]. This paragraph lays out the roles of each type of stakeholder (private industry, civil society, *Intergovernmental Organizations* [IGOs], governments, etc.). It reserves an explicit role in "Internet-related public policy issues" for governments and intergovernmental organizations. It does not provide for any role in this area for the private sector or civil society. So although the Resolution seems to support the multistakeholder model of the Internet, it really restricts the roles of several of the main stakeholders.

Several countries pushed for inclusion of Paragraph 55 of the Tunis Agenda, recognizing that the existing arrangements have worked effectively, to balance the inclusion of Paragraph 35, but it was not included in the final Resolution.

Resolution Plen/3 may be used by some governments to reinforce the ITU's role in Internet Governance, including at future ITU conferences in 2013 and 2014.

On the other hand, the Resolution also instructs the Secretary-General "to support the participation of Member States and *all* other stakeholders, as applicable, in the activities of ITU in this regard." This statement supports participation of all stakeholders in the activities of the ITU, not restricted just to ITU Members, or in the case of ITU Council or some Council Working Groups just to Member States.

In signing the Final Acts, Russia added a Declaration/Reservation that it views the Internet as a new global telecommunication infrastructure and reserves the right to implement public policy, including international policy, on matters of Internet Governance. This reservation could signal that Russia plans to apply the telecommunications provisions in the ITRs to the Internet and to further regulate the Internet.

In addition to Resolution Plen/3, some of the proposals on the Internet were part of the discussion on Resolution Plen/5. This Resolution began as a basic resolution on invoicing for international telecommunication services, but ended up including numerous other provisions that did not make it into the main text of the treaty. Although the final text does not contain provisions explicitly mentioning the Internet, the introductory text of the Resolution mentions the transition of phone and data networks to IP-based networks. Also, the proposal that evolved into "resolves" originally applied to the relationship between network operators and application providers. During the discussions this proposal was modified to refer to "providers of international services" instead of application providers. Even with this modification, the application of this provision is ambiguous and could be applied to over-the-top providers.

Resolution Plen/5 is likely to reinforce work in Study Group 3 on accounting, fraud and charges for international telecommunications service traffic termination and exchange, etc.

Telecommunications Traffic Exchange Points

A proposal[8] concerning "telecommunication traffic exchange points" was included as an Article in the ITRs. The term "telecommunication traffic exchange point" was left undefined. This article does not mention the Internet or Internet Exchange Points, but the discussion of this Article included discussion on how it related to Internet Exchange Points. At least one delegation indicated that the Article was intended to help enable development of regional Internet Exchange Points.

Although this provision raised concerns over possible regulation of Internet Exchange Points, it focuses on creating an enabling environment for creation of regional telecommunication traffic exchange points. This environment could provide support for development of trans-border telecommunications and connectivity.

Route-Related Factors

Prior to the conference, there were several proposals [8] to require transparency into the international routes used for a Member States' traffic and to allow Member States to control what routes were used between them. Note that the definition of "route" in the ITRs is different from the concept of a "route" on the Internet. In the ITRs, a route is defined as the technical facilities used for telecommunications traffic between two telecommunication terminal exchanges or offices.

Coming into the WCIT, the proposal to control routes by Member States was dropped from the proposal, so the debate centered over whether Member States should have the right to know what routes were being used. After much discussion, the final result was a provision allowing "authorized operating agencies" (not Member States) to determine which routes are to be used between them and allowing the originating operator to determine the outbound route for traffic. This provision is not much different from how network operators manage their networks today.

Quality of Service Proposals

Several proposals[8] were made to WCIT to require QoS to be negotiated between network providers including Internet providers. Some proposals also allowed network providers to charge over-the-top providers for QoS.

The final provisions did not add any new requirements for QoS other than a nonspecific requirement related to mobile roaming. Although no new provisions were added specific to the Internet, it does not mean that countries could not try to impose the current QoS provisions to VoIP services. The debate over QoS on the Internet will continue outside the ITRs.

Naming, Numbering, and Addressing Proposals

Several countries and regions proposed[8] to extend provisions on telephone numbering to include naming, addressing, and origin identifiers. Several proposals were made to require delivery of calling party number and to cooperate in preventing the misuse ("misuse" not defined) of numbering, naming, and addressing resources. Although the Internet was not explicitly mentioned, these proposals were intended to apply to VoIP based on comments at pre-WCIT preparatory meetings[10].

In the end, several provisions were added related to delivery of calling party number and prevention of misuse of telecommunications numbering resources as defined in ITU-T Recommendations. Provisions to include naming, addressing, and more general "origin identifiers" were not accepted.

Even though there were no provisions specifically on the Internet, some countries could apply these provisions to VoIP services that use E.164 telephone numbers and that provide for bypass of the international telephony accounting system.

However, it is not clear that these provisions add any more authority than what these countries have today.

Content and Spam

Proposals[8] to include spam in the treaty caused a lot of contentious discussion, in ad hoc groups, plenary, and in consultations. Some countries took a strong position that spam is a content topic that was out of scope of the ITRs. There was a concern that adding a provision on spam would legitimize content filtering by governments. Some African countries insisted on including a provision on spam, claiming that it consumed a large percentage of their international bandwidth. In the end to address concern about content, a statement was added to Article 1.1:

> "These Regulations do not address the content-related aspects of telecommunications."

To address the proposals on spam, Article 5B was added on unsolicited bulk electronic communication:

> "Member States should endeavour to take necessary measures to prevent the propagation of unsolicited bulk electronic communications and minimize its impact on international telecommunication services. Member States are encouraged to cooperate in that sense."

As written the final text, it is fairly vague and could have implications beyond spam; for example, there are no exemptions for broadcasters or for emergency alert systems (for example, tsunami alerts). It is also not clear how Article 5B can be implemented consistent with the statement on content in Article 1.1.

It was clear from the discussion that many of the delegates from countries supporting this provision do not understand spam or spam-mitigation techniques and their usage (or not) in their own countries. It is clear that many of the delegates were not aware of basic best practices from the *Messaging Anti-Abuse Working Group* (MAAWG) and other organizations. These discussions highlighted the need for capacity building for developing countries on spam-mitigation techniques.

Human Rights and Member State Access to International Telecommunications

In a plenary session on the penultimate night of the WCIT, a provision on human rights was added to the final draft of the ITRs. This discussion led to a debate concerning the right of Member States to access international telecommunication services, originating from a proposal from Sudan and Cuba creating a right of Member States to access Internet websites. This provision was targeted at U.S. and European actions taken in response to UN sanctions against Sudan due to Darfur and U.S. sanctions on Cuba.

The provision provides a right for Member States, not its citizens. Thus it did not provide any rights for citizens to access international telecommunication services. In addition, it is not clear what or whose international telecommunication service Member States have a right to. The implications of the provision were unclear, and delegations did not have time to consult their home countries before the end of the conference.

Several times during the debate the Chair of the WCIT and the Secretary-General of the ITU both tried to dissuade the proponents from pushing their proposal, to no avail. After extended debate, Iran called for a point of order and then called for a vote, the only official vote of the conference. After the text passed by majority vote, the Chair of the WCIT declared the ITRs approved. At that point the United States, followed by the United Kingdom, Sweden, and other countries, made statements that they would not sign the treaty. Supporters of the treaty read their statements in favor of the treaty. The conference was effectively over[11].

The uncertainty caused by the addition of this text at such a late date and the way it was added created a situation in which many countries that might have signed the treaty ended up not signing. This provision more than any other disagreement in the conference caused the conference to split to the extent that it did.

Looking Forward

Much of the long-term impact of the treaty will not be felt until the signing governments ratify the treaty and start enacting provisions into either law or regulation. It is likely that some of the countries that did not sign in Dubai will accede to the treaty at a later time, including countries that did not attend the WCIT.

WCIT is only one step (though an important one) in the long-term debate over Internet Governance and the appropriate role of governments (and intergovernmental organizations) in the Internet. The debate will continue in numerous international fora going forward such as:

- World Telecommunications Policy Forum (May 2013)
- World Summit on the Information Society Action Line Forum (May 2013)
- ITU Council Working Group on Internet Public Policy (ongoing)
- ITU-T Study Group meetings (ongoing)
- ITU Plenipotentiary Conference (2014)
- WSIS+10 Review (2013–2015)

It has already been seen that many of the same topics debated at WCIT will be debated in these venues; for example, IP addressing, naming, spam, and cybersecurity. The WCIT Resolutions (especially Res. Plen/3) will likely be used to promote a larger role of the ITU in the Internet Governance debate.

The ITU's Plenipotentiary Conference in 2014 will be the next important treaty conference where the ITU's Constitution and Convention (both treaty instruments) can be revised. In the hierarchy of treaties at ITU, the ITU Constitution takes precedence over the ITRs, and many of the terms used in the ITRs are defined in the Constitution. Therefore, changes to the ITU Constitution could affect the meaning of the ITRs. The ITU Plenipotentiary will provide an opportunity for the ITU Member States to come together and heal some of the differences coming out of the WCIT, but it is also an opportunity to widen the rift.

The WSIS+10 Review will be an important process because it is likely to set the agenda for the discussion of Internet Governance for the 5–10 years after 2015, much as the Tunis Agenda from 2005 set the agenda for the last 8 years. An important aspect of the WSIS+10 Review is that it involves other UN agencies (for example, UNESCO) in addition to the ITU. Many of the events involve stakeholders whose voices are not normally heard at ITU conferences.

Some of the disagreements exhibited at WCIT brought to light opportunities for the Internet community to engage with governments and other stakeholders by providing technical and thought leadership. Capacity building with many of the developing country governments will be an important part of the preparation leading up to the major international conferences such as the ITU Plenipotentiary and WSIS+10.

Much of the growth of the Internet going forward is likely to come in the countries that signed the ITRs. Many of these countries have started to develop multistakeholder consultations and processes when dealing with Internet topics. The fact that a government signed the ITRs does not mean that the country is somehow against the Internet. On the contrary, many of these countries are looking for ways to accelerate the Internet's development within their borders and to accelerate their international connectivity to the Internet. As the Internet grows and develops in these countries, the Internet communities in these countries will likely look to play a larger role in a consultative process regarding government positions on issues related to Internet Governance. Future growth of the Internet across ITR boundaries (signatories and non-signatories) will depend on cooperation amongst all stakeholders.

ROBERT PEPPER leads Cisco's Global Technology Policy team working with governments across the world in areas such as broadband, IP enabled services, wireless and spectrum policy, security, privacy, Internet governance and ICT development. He joined Cisco in July 2005 from the FCC where he served as Chief of the Office of Plans and Policy and Chief of Policy Development beginning in 1989 where he led teams developing policies promoting the development of the Internet, implementing telecommunications legislation, planning for the transition to digital television, and designing and implementing the first U.S. spectrum auctions. He serves on the board of the U.S. Telecommunications Training Institute (USTTI) and advisory boards for Columbia University and Michigan State University, and is a Communications Program Fellow at the Aspen Institute. He is a member of the U.S. Department of Commerce's Spectrum Management Advisory Committee, the UK's Ofcom Spectrum Advisory Board and the U.S. Department of State's Advisory Committee on International Communications and Information Policy. Pepper received his BA. and Ph.D. from the University of Wisconsin-Madison. E-mail: **rmpepper@cisco.com**

CHIP SHARP has 30 years in the communications industry and currently is a Director in the Research and Advanced Development Department at Cisco Systems, Inc. His current role is in Technology Policy focusing on Internet Governance issues. He participated in the US preparatory process for WCIT from 2010 including as Private Sector Advisor to the US Delegation to the ITU's Council Working Group to Prepare for the 2012 WCIT (CWG-WCIT12), mainly analyzing the impact of proposals on the Internet and Internet Governance. He helped develop many of the talking points and position papers related to the Internet for the US Delegation. He served in the same capacity on the US Delegation to WCIT. He continues to be active in many follow-on activities preparing for the World Telecommunication Policy Forum (WTPF), World Summit on the Information Society 10 year review (WSIS+10), ITU Plenipotentiary Conference 2014 and Internet Governance Forum. He also currently service on the FCC's Open Internet Advisory Committee. Prior to this role, he led a multinational, multidisciplinary team at Cisco helping drive various technologies such as LISP, DNSSEC, BGPSEC, ENUM, Lawful Intercept etc. He has also supported capacity building and development programs for developing countries, for example, deployment of Internet Exchange Points (IXPs). He started at Cisco in 1996 helping design dialup Internet access products to interface with legacy telco signaling systems. Prior to Cisco, Chip worked at Teleos Communications, AT&T Consumer Product Labs and NASA's Communications Division. E-mail: **chsharp@cisco.com**

Letters to the Editor

Dear Ole,
I am sorry that there is some delay (more than 1 second) between the arrival of *The Internet Protocol Journal* at my desk and this e-mail. In the December 2012 issue (Volume 15, No. 4), Geoff Houston discusses the extra second on the last minute of the 31st of June. There is no 31st of June in the calendar, at least not in old Europe, but maybe in the United States. It is funny to discuss the problem of a second at the end of a nonexistent day, isn't it?

Nevertheless I could take some new knowledge from this article.

Best regards,

—Richard Schuerger
richard.schuerger@gmx.de

Hi Geoff (and Ole)!
I am sitting comfortably in a chair on the terrace in a Tenerife house, reading the December 2012 issue of IPJ, which I received by mail today. Since I have been working many years with the *Network Time Protocol* (NTP), I started reading your article on the subject with great interest. Having read only a few sentences I jumped in my chair:

> "Back at the end of June 2012 there was a brief IT hiccup as the world adjusted the *Coordinated Universal Time* (UTC) standard by adding an extra second to the last minute of the 31st [!!] of June."

Of course you may have received numerous notices of this hiccup [ha, ha], but still I couldn't resist writing to you. Thank you for an [otherwise] well-written and clarifying article (as always).

—Truls Hjelle
truls@sund-hjelle.org

PS: Thanks to Ole for this anachronism on paper still available to us oldies who prefer sitting with a paper magazine in the sun instead of gazing at a poorly lit screen and struggling with the tiny letters.

The author responds:

Back in 45 BC, Julius Caesar made same revolutionary changes to the Roman calendar, and the changes included adding one extra day to June (well not quite, as the letter "J" was not around until the 16th Century, and the letter "u" was also yet to makes its debut, so it is probably less of an anachronism to record that Gaivs Ivlivs Caesar added an extra day to the month of Ivnivs). Either way, this change brought the total number of days in the month of June to 30, which is where it has remained for 2058 years.

It is often said that Australia operates on a calendar all of its own, but while our isolation on a largish rock at the southern end of the Pacific Ocean has led to a number of revolutionary innovations that are easily on a par with fire and the wheel, including the world-renowned stump-jump plough and the sheep-shearing machine, we Australians have not yet turned our collective national genius to the calendar. Despite a pretty sensible suggestion from the latest meeting of the Grong Grong Shire Council for a year to be made up of 10 months of 30 days followed by a decent 65-day session at the pub, we have yet to get the blokes back from the pub after their last 65-day bender, so that plan needs some more work back at the shed before it gets another airing! Thus it looks like Australia uses the same calendar as everyone else, making the reference to the 31st of June one of those pesky brain-fade errors! Oops. Yes, it was meant to say 30th of June. Well spotted!

—Geoff Huston

Book Review

On Internet Freedom

On Internet Freedom, by Marvin Ammori, Elkat Books, January 2013, sold by: Amazon Digital Services, Inc., ASIN: B00B1MQZNW.

Marvin Ammori has written an important book about the threats to free speech and expression that we are not only privileged to conduct on the Internet today but have come to treat as basic human rights.

On Internet Freedom looks at the past, present, and future of the Internet as a speech technology. Ammori examines how the coordinated and determined efforts by Big Content to protect content and increasing efforts by governments to censor content threaten Internet use as we embrace it today. Ammori also explains how these acts were in fact anticipated by Clark, Sollins, Wroclawski, and Braden in a paper entitled "Tussle in Cyberspace: Defining Tomorrow's Internet,"[1] where the authors assert:

> "User empowerment, to many, is a basic Internet principle, but for this paper, it is the manifestation of the right to choose—to drive competition, and thus drive change."

Ammori cites only the first clause of this sentence—as a technologist, I believe the second is extremely important as well—but he makes clear that the end-to-end design of the Internet establishes a fundamental thesis:

> "If user choice is our design principle, then users should have the final say."

Unfortunately, Ammori explains that users do not have the final say but are increasingly challenged by lawyers, bureaucrats, commissioners, and others who are motivated to constrain their freedoms and who want to do so by altering the fundamental design of the Internet. Ammori's response, admittedly U.S.-centric, is simple: the Internet is a speech technology, and:

> "... the ultimate design principle for any speech technology, at least in the United States: the First Amendment, which protects freedom of speech. The *First Amendment* is not generally thought of as a design principle, but, by definition, it limits what Congress or any other government actor may or may not adopt in shaping the Internet's future."

This statement sets the context for the remainder of the book. In Part II, Ammori looks at events leading to the 18 January 2012 Internet Blackout in protest of the *Stop Online Piracy Act* (SOPA) and *PROTECT IP Act* (PIPA) and how these and possibly future legislation threaten "...the speech tools of the many while reshaping our speech environment for the benefit of the few."

Conveniently, Part II is largely about how the few benefit. Before judging whether you believe this theory is even-handed or not, remember that the litmus test throughout this book is the First Amendment of the U.S. Constitution. This part ought to make every Internet user or free speech advocate pause, or shiver. One of the most worrisome speculations Ammori offers is the extent to which legislation could stilt adoption of emerging technologies such as *three-dimensional* (3D) printing or stifle future innovations of this kind.

Part III looks at how the Internet as speech technology influences governments, how governments have attempted to exert influence, and how Internet users and dominant Internet forces (Google, Amazon, Facebook, and Twitter) respond. This part will probably be illuminating for most readers, because it explains situations where a *private conversation* between a government official and an *Internet Service Provider* (ISP) or hosting company can circumvent the First Amendment, and why *Terms of Service* are often more speech-restricting than the First Amendment as well.

Part IV focuses on net neutrality concerns. Ammori draws the lines of conflict: ISPs seek to differentiate, rate-control, block, or charge users differently for content that is transmitted on their networks. However, content includes speech, and if the Internet is speech technology, then ISPs should not be able to decide what you say or see, or they do so in violation of your First Amendment rights. Ammori also explains that net neutrality is not only a First Amendment concern but also an economic one: net neutrality violations can influence investments in or creation of new technology.

I began by saying that Marvin Ammori has written an important book. It is also an extremely readable book. Ammori does a commendable job explaining constitutional law and technology in easy to understand terms. I highly recommend the book not only for people who are interested in law or technology but for anyone who advocates freedom of expression.

On Internet Freedom is currently available as a Kindle download.

Nominations Sought for 2013 Jonathan B. Postel Service Award

The Internet Society is soliciting nominations of qualified candidates for the 2013 *Jonathan B. Postel Service Award* by May 31, 2013. This annual award is presented to an individual or organization that has made outstanding contributions in service to the data communications community. The award is scheduled to be presented during the 87th IETF meeting in Berlin, Germany, July 28–August 2.

The award was established by the Internet Society to honor a person who has made outstanding contributions in service to the data communications community. The award is focused on sustained and substantial technical contributions, service to the community, and leadership. With respect to leadership, the award committee places particular emphasis on candidates who have supported and enabled others in addition to their own specific actions.

The award is named for Dr. Jonathan B. Postel to recognize and commemorate the extraordinary stewardship exercised by Jon over the course of a thirty-year career in networking. He served as the editor of the RFC series of notes from its inception in 1969 until 1998. He also served as the ARPANET "Numbers Czar" and *Internet Assigned Numbers Authority* (IANA) over the same period of time. He was a founding member of the Internet Architecture (nee Activities) Board and the first individual member of the Internet Society, which he also served as a Trustee.

For more information, see: **http://www.internetsociety.org/**

Upcoming Events

The *Internet Corporation for Assigned Names and Numbers* (ICANN) will meet in Beijing, China, April 7–11, 2013 and in Durban, South Africa, July 14–18, 2013. For more information, see: **http://icann.org/**

The *North American Network Operators' Group* (NANOG) will meet in New Orleans, Louisiana, June 3–5, 2013 and in Phoenix, Arizona, October 7–9, 2013. For more information see: **http://nanog.org**

The *Internet Engineering Task Force* (IETF) will meet in Berlin, Germany, July 28–August 2, 2013 and in Vancouver, Canada, November 3–8, 2013. For more information see: **http://www.ietf.org/meeting/**

The *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT) will meet in Bangkok, Thailand, February 18–28, 2014. For more information see: **http://www.apricot.net**

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ contains standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

From The Editor

Fifteen years ago we published the first edition of *The Internet Protocol Journal* (IPJ). This seems like a good time to reflect on where the Internet is today and where it might be going in the future, instead of looking back at earlier developments the way we did in the tenth anniversary issue of IPJ.

In our first article, Geoff Huston discusses network service models, comparing the Internet to the traditional *Public Switched Telephone Network* (PSTN) in both technical and business terms, and asks if the fundamental architectural differences between these networks might explain the rather slow deployment of IPv6. Although the number of IPv6-connected users has doubled in the last year (see page 35), IPv6 still represents a small percentage of total Internet traffic.

The mobile device dominates today's Internet landscape. Smartphones and tablets are starting to replace more traditional computers for Internet access. Many technical developments have made this possible, including high-resolution screens; powerful processors; and compact, long-lasting batteries. Combine such developments with numerous radio-based technologies (GPS, cellular, Wi-Fi, and Bluetooth) and you end up with a handheld device that is always connected to the network and can perform almost any task, using an appropriate "app." Improvements to communications technologies such as the deployment of *Long-Term Evolution* (LTE) cellular data networks and *Gigabit Wi-Fi* (IEEE 802.11ac) are already underway.

We asked Vint Cerf, known to many as one of the "Fathers of the Internet," to look beyond what is possible with today's Internet and today's devices and predict what the future might look like in a world where every imaginable appliance is "smart," connected to the network, and location-aware. His article takes us through some history and current trends, and then describes how the future Internet might shape many aspects of society such as business, science, and education.

According to Wikipedia, a *Data Center* is "a facility used to house computer systems and associated components, such as telecommunications and storage systems." In our final article, Alvaro Retana and Russ White discuss how developments in link-state protocols, usually associated with wide-area networks, can be applied to data center networks.

Network Service Models and the Internet

by Geoff Huston, APNIC

In recent times we've covered a lot of ground in terms of the evolution of telecommunications services, riding on the back of the runaway success of the Internet. We have taken the computer and applied a series of transformational changes in computing power and size, battery technology, and added radio capabilities to create a surprising result. We've managed to put advanced computation power in a form factor that fits in the palms of our hands, and have coupled it with a communications capability that can manage data flows of tens if not hundreds of megabits per second—all in devices that have as few as two physical buttons! And we have created these devices at such scale that their manufacturing cost is now down to just tens of dollars per unit. The Internet is not just at the center of today's mass market consumer service enterprise, it is now at the heart of many aspects of our lives. It's not just the current fads of the social networking tools, but so much more. How we work; how we buy and sell, even what we buy and sell; how we are entertained; how democracies function, even how our societies are structured; and so much more—all of these activities are mediated by the Internet.

But a few clouds have strayed into this otherwise sunny story of technological wonder. Perhaps the largest of these clouds is that the underlying fabric of the Internet, the numbering plan of the network, is now fracturing. We have run out of IP addresses in the Asia Pacific region, Europe, and the Middle East. At the same time, the intended solution, namely the transition to a version of the IP protocol with a massively larger number space, IPv6, is still progressing at an uncomfortably slow pace. Although the numbers look like a typical "up and to the right" Internet data series, the vertical axis tells a somewhat different story. The overall deployment of IPv6 in today's Internet currently encompasses around 1.3 percent[0] of the total user base of the Internet, and it is possible that the actions of the open competitive market in Internet-based service provision will not necessarily add any significant further impetus to this necessary transition.

We have gone through numerous phases of explanation for this apparently anomalous success-disaster situation for the Internet. Initially, we formed the idea that the slow adoption of IPv6 was due to a lack of widely appreciated knowledge about the imminent demise of IPv4 and the need to transition the network to IPv6. We thought that the appropriate response would be a concerted effort at information dissemination and awareness rising across the industry, and that is exactly what we did. But the response, as measured in terms of additional impetus for the uptake of IPv6 in the Internet, was not exactly overwhelming.

We then searched for a different reason as to why this IPv6 transition appeared to be stalling. There was the thought that this problem was not so much a technical one as a business or a market-based one, and there was the idea that a better understanding of the operation of markets and the interplay between markets and various forms of public sector initiatives could assist in creating a stronger impetus for IPv6 in the service market. The efforts at stimulation of the market to supply IPv6 goods and services through public sector IPv6 purchase programs have not managed to create a "tipping point" for adoption of IPv6.

Some have offered the idea that the realization of IPv4 exhaustion would focus our thinking and bring some collective urgency to our actions. But although IPv4 address exhaustion in the Asia Pacific region in 2011 has created some immediate interest in IPv4 address extension mechanisms, the overall numbers on IPv6 adoption have stubbornly remained under 1.5 percent of the 2 billion user base of the Internet.

Why has this situation occurred? How can we deliberately lead this prodigious network into the somewhat perverse outcomes that break to basic end-to-end IP architecture by attempting to continue to overload the IPv4 network with more and more connected devices? What strange perversity allows us to refuse to embrace a transition to a technology than can easily sustain the connection needs of the entire silicon industry for many decades to come and instead choose a path that represents the general imposition of additional cost and inefficiency?

Perhaps something more fundamental is going on here that reaches into the architectural foundations of the Internet and may explain, to some extent, this evident reluctance of critical parts of this industry to truly engage with this IPv6 transition and move forward.

Telephony Network Intelligence

Compared to today's "smart" phone, a basic telephone handset was a remarkably basic instrument. The entire telephone service was constructed with a model of a generic interface device that was little more than a speaker, a microphone, a bell, and a pulse generator. The service model of the telephone, including the call-initiation function of dialing and ringing, the real-time synchronous channel provision to support bidirectional speech, all forms of digital and analogue conversion, and of course the call-accounting function, were essentially all functions of the network itself, not the handset. Although the network was constructed as a real-time switching network, essentially supporting a model of switching time slots within each of the network switching elements, the service model of the network was a "full-service" model.

The capital investment in the telecommunications service was therefore an investment in the network—in the transmission, switching, and accounting functions.

Building these networks was an expensive undertaking in terms of the magnitude of capital required. By the end of the 20th century the equipment required to support synchronous time switching included high-precision atomic time sources, a hierarchy of time-division switches to support the dynamic creation of edge-to-edge synchronous virtual circuits, and a network of transmission resources that supported synchronous digital signaling. Of course although these switching units were highly sophisticated items of technology, most of this investment capital in the telephone network was absorbed by the last mile of the network, or the so-called "local loop."

Although the financial models to operate these networks varied from operator to operator, it could be argued that there was little in the way of direct incremental cost in supporting a "call" across such a network, but there is a significant opportunity or displacement cost. These networks have a fixed capacity, and the requirements for supporting a "call" are inelastic. When a time slot is being used by one call, this slot is unavailable for use by any other call.

Telephony Tariffs

Numerous models were used when a retail tariff structure for telephony was constructed. One model was a "subscription model," where, for a fixed fee, a subscriber could make an unlimited number of calls. In other words the operator's costs in constructing and operating the network were recouped equally from all the subscribers to the network, and no transaction-based charges were levied upon the subscriber. This model works exceptionally well where the capacity of the network to service calls is of the same order as the peak call demand that is placed on the network. In other words, where the capacity of the network is such that the marginal opportunity or displacement cost to support each call is negligible, there is no efficiency gain in imposing a transactional tariff on the user. In the United States' telephone network, for example, a common tariff structure was that the monthly telephone service charge also allowed the subscriber to make an unlimited number of local calls.

Another model in widespread use in telephony was of a smaller, fixed service charge and a per-transaction charge for each call made. Here a subscriber was charged a fee for each call (or "transaction") that the subscriber initiated. The components to determine the charge for an individual transaction included the duration of the call, the distance between the two end parties of the call, the time of day, and the day of the week. This model allowed a network operator to create an economically efficient model of exploitation of an underlying common resource of fixed capacity. This model of per-call accounting was widespread, used by some operators in local call zones, and more widely by telephone service operators in long distance and international calls.

This model allowed the operator to generate revenue and recoup its costs from those subscribers who used the service, and, by using the pricing function, the network operator could moderate peak demand for the resource to match available capacity.

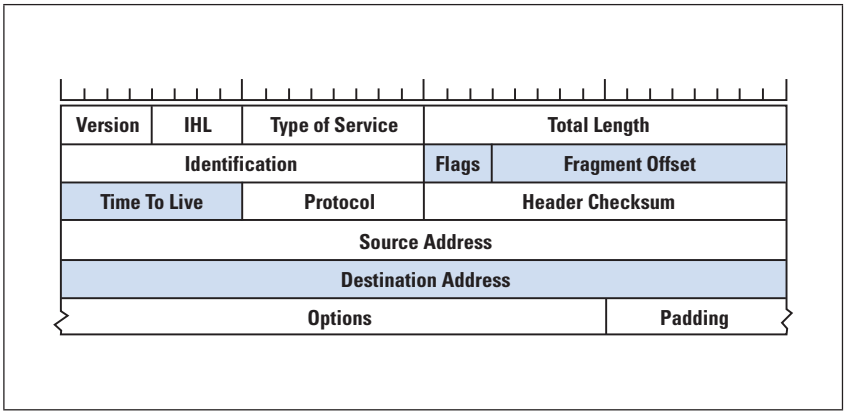
This per-transaction service model of telephony was available to the operator of the telephone service simply because the entire function of providing the telephone service was a network-based service. The network was aware of who initiated the transaction, who "terminated" the transaction, how long the transaction lasted, and what carriers were involved in supporting it. Initially this transactional service model was seen as a fair way to allocate the not inconsiderable costs of the construction and operation of the network to those who actually used it, and allocate these costs in proportion to the relative level of use. I suspect, though, that this fair cost allocation model disappeared many decades ago because these per-transaction service tariffs became less cost-based and more based on monopoly rentals.

IP Network Minimalism

The Internet is different. Indeed, the Internet is about as different from telephony as one could possibly imagine. The architecture of the Internet assumes that a network transaction is a transaction between computers. In this architecture the computers are highly capable signal processors and the network is essentially a simple packet conduit. The network is handed "datagrams," which the network is expected to deliver most of the time. However, within this architecture the network may fail to deliver the packets, may reorder the packets, or may even corrupt the content of the packets. The network is under no constraint as to the amount of time it takes to deliver the packet. In essence, the expectations that the architecture imposes on the network are about as minimal as possible. Similarly, the information that the edge-connected computers now expose to the network is also very limited. To illustrate this concept, it is useful to look at the fields that the Internet Protocol exposes to the network.

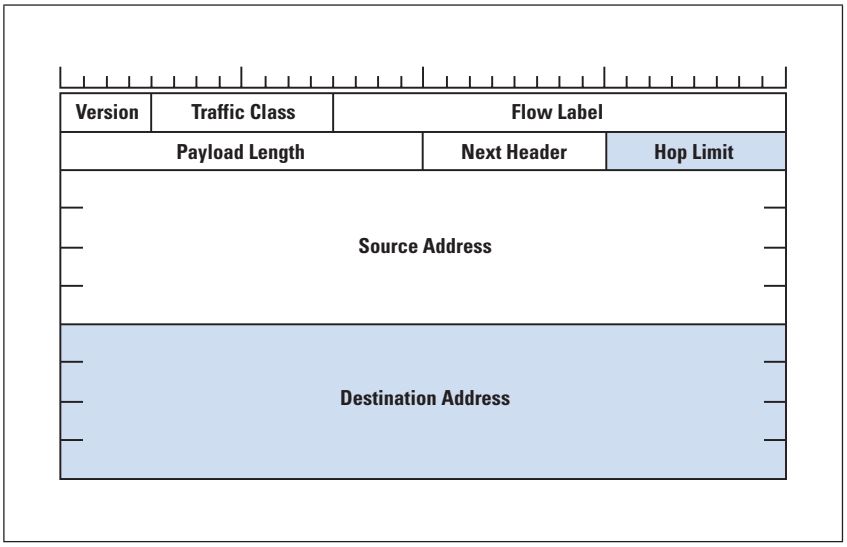
In IPv4 the fields of the Internet Protocol header are a small set, as shown in Figure 1. An IP packet header exposes the protocol *Version, Header Length* (IHL), *Total Length* of the IP packet, packet *Fragmentation Offset,* and *Type of Service* fields, a hop counter (*Time To Live* field), a *Header Checksum* field, and the *Source and Destination Address* fields. In practice, the Type of Service field is unused, and the Length and Checksum fields have information that is also contained in the data link frame header. What is left is the protocol Version field, packet length (Total Length field), the Fragmentation Offset field, a hop counter, and the Source and Destination Address fields. Of these fields, the Packet Length, Fragmentation Offset, hop counter, and Destination Address are the fields used by the network to forward the packet to its ultimate destination.

Figure 1: The IPv4 Packet Header



In IPv6 this minimal approach was further exercised with the removal of the Fragmentation Control fields and the Checksum fields (Figure 2). Arguably, the *Traffic Class* and *Flow Label* are unused, leaving only the *Protocol Version*, *Payload Length*, a *Hop Counter*, and the source and destination addresses exposed to the network. In IPv6 the minimal network-level information is now reduced to the packet length, the hop counter, and the destination address.

Figure 2: The IPv6 Packet Header



These fields represent the totality of the amount of information that the Internet Protocol intentionally exposes to the network. There are no transaction identifiers, no call initiation or call teardown signals, or even any reliable indication of relative priority of the packets. All the network needs to "see" in each carried packet is a hop counter, a packet length, and a destination address.

Within this model the actions of each of the network's switching elements are extremely simple, as shown in Figure 3.

Figure 3: IPv4 and IPv6 Packet Processing

```
for each received packet:
      decrement the hop counter
          if the counter value is zero then discard the packet, otherwise…
      look up the packet's destination address in a local table
          if the lookup fails then discard the packet, otherwise…
      look up the output queue from the located table entry
          if the queue is full discard the packet, otherwise…
          if the packet is too large for the outbound interface then
                 fragment the packet to fit, if permitted (IPv4)
                 or discard the packet (IPv6), otherwise…
      queue the packet for onward transmission
```

The Internet Service Model

What happened to "transactions" in this service model? What happened to network state? What happened to resource management within the network? What happened to all the elements of network-based communications services? The simple answer is that within the architecture of the Internet it is not necessary to expose such a detailed view of transactional state to the underlying network just to have the network deliver a packet. From a network perspective, IP has thrown all of that network level function away!

In the context of the Internet service architecture, a "transaction" is now merely an attribute of the application that is run on the end systems, and the underlying network is simply unaware of these transactions. All the network "sees" is IP packets, and each packet does not identify to the network any form of compound or multi-packet transaction.

Because a transaction is not directly visible to the IP network operator, the implication is that any effort for an IP service provider to use a transactional service tariff model becomes an exercise in frustration, given that there are no such network-visible interactions that could be used to create a transactional service model. In the absence of a network-based transactional service model, the *Internet Service Provider* (ISP) has typically used an access-based model as the basis of the IP tariff. Rather than paying a tariff per "call" the ISP typically charges a single flat fee independent of the number or nature of individual service transactions. Some basic differentiation is provided by the ability to apply price differentials to different access bandwidths or different volume caps, but this form of market segmentation is a relatively coarse one. Finer levels of transactional-based prices, such as pricing each individual video stream—or even pricing every individual webpage fetch—are not an inherent feature of such an access-based tariff structure.

The consequence for ISPs here is that within a single network access bandwidth class, this service model does not differentiate between heavy and light users, and is insensitive to the services operated across the network and to the average and peak loads imposed by these services. Like the flat-rate local telephone access model, the Internet pricing model is typically a flat-rate model that takes no account of individual network transactions. The ISP's service-delivery costs are, in effect, equally apportioned across the ISP's user base.

Interestingly, this feature has been a positive one for the Internet. With no marginal incremental costs for network usage, users are basically incented to use the Internet. In the same vein suppliers are also incented to use the Internet, because they can deliver goods and services to their customer base without imposing additional transaction costs to either themselves or their customers. For example, we have seen Microsoft and Apple move toward a software distribution model that is retiring the use of physical media, and moving to an all-digital Internet-based service model to support their user base. We have also seen other forms of service provision where the access-based tariff model has enabled services that would otherwise not be viable—here Netflix is a good example of such services that have been enabled by this flat-rate tariff structure. The attraction of cloud-based services in today's online world is another outcome of this form of incentive.

The other side effect of this shift in the architecture of the Internet is that it has placed the carriage provider—the network operator—into the role of a commodity utility. Without any ability to distinguish between various transactions, because the packets themselves give away little in terms of reliable information about the nature of the end-to-end service transaction, the carriage role is an undistinguished commodity utility function. The consequent set of competitive pressures in a market that is not strongly differentiated ultimately weans out all but the most efficient of providers from the service provider market—as long as competitive interests can be brought to bear on these market segments.

Invariably, consumers value the services that a network enables, rather than the network itself. In pushing the transaction out of the network and into the application, the architecture of the Internet also pushed value out of the network. Given that a service in the Internet model is an interaction between applications running on a content service provider's platform and on their clients' systems, it is clear that the network operator is not a direct party to the service transaction. An ISP may also provide services to users, but it is by no means an exclusive role, and others are also able to interact directly with customers and generate value through the provision of goods and services, without the involvement of the underlying network operators. It is not necessary to operate a network in order to offer a service on the Internet. Indeed, such a confusion of roles could well be a liability for such a carriage and content service provider.

The Content Business Model of the Internet

This unbundling of the service provision function from the network has had some rather unexpected outcomes. Those who made the initial forays of providing content to users believed that this function was no different from that of many retail models, where the content provider formed a set of relationships with a set of users. The direct translation of this model encountered numerous problems, not the least of which was reluctance on the part of individual users to enter into a panoply of service and content relationships. When coupled with considerations of control of secondary redistribution of the original service, this situation created some formidable barriers to the emergence of a highly valuable market for content and services on the Internet.

However, as with many forms of mass market media, the advertising market provides some strong motivation. With a traditional print newspaper, the full cost of the production of the newspaper is often borne largely by advertisers rather than by the newspaper readers. But newspaper advertising is a relatively crude exercise, in that the advertisement is visible to all readers, but it is of interest to a much smaller subset. The Internet provided the potential to customize the advertisement.

The greatest market value for advertisements is generated by those operations that gain the most information about their customers. These days it has a lot to do with knowledge of the consumer. It could be argued that Facebook's $1B purchase of Instagram was based on the observation that the combination of an individual's pictures and updates forms an amazingly rich set of real-time information about the behavior and preferences of individual consumers. It could also be argued that Google's business model is similarly based on forming a comprehensive and accurate picture of individual users' preferences, which is then sold to advertisers at a significant premium simply because of its tailored accuracy. And the mobile services are trying to merge users' current locations with the knowledge of their preferences to gain even greater value.

These developments are heading in the direction of a multiparty service model, where the relationship between a content provider and a set of users allows the content provider to resell names of these users to third parties through advertising. This on-selling of users' profiles and preferences is now a very sophisticated and significant market. As reported in [1], some 90 percent of Google's $37.9B income was derived from advertising revenue. The cost per click for "cheap car insurance" is reported in the same source to be $33.97!

The Plight of the Carrier

Although the content market with its associated service plane is now an extraordinarily valuable activity, the same is not true for the network operator—whose carriage function has been reduced from complete service-delivery management to a simple packet carrier without any residual visibility into the service plane of the network.

Obviously, network carriers look at these developments with dismay. Their own traditional value-added market has been destroyed, and the former model where the telcos owned everything from the handset onward has now been replaced by a new model that relegates them to a role similar to electricity or water reticulation—with no prospect of adding unique value to the content and service market. The highly valuable service-level transactions are effectively invisible to the carriage service providers of the Internet.

There is an evident line of thought in the carriage industry that appears to say: "If we could capture the notion of a service-level transaction in IP we could recast our service profile into a per-transaction profile, and if we can do that, then we could have the opportunity to capture some proportion of the value of each transaction."

Short of traffic interception, could the network operators working at the internet level of the network protocol stack have a means to identify these service-level transactions? The generic answer is "no," as we have already seen, but there are some other possibilities that could expose service-level transactions to the network operator.

QoS to the Rescue?

The recent calls by the The *European Telecommunications Network Operators' Association* (ETNO) advocating the widespread adoption of IP *Quality of Service* (QoS) appear to have some context from this perspective of restoring transaction visibility to the IP carriage provider. In the QoS model an application undertakes a QoS "reservation" with the network. The network is supposed to respond with a commitment to reserve the necessary resources for use by this transaction. The application then uses this QoS channel for its transaction, and releases the reservation when the transaction is complete.

From the network operator's perspective, the QoS-enabled network is now being informed of individual transactions, identifying the end parties for the transaction, the nature of the transaction and its duration, as well as the resource consumption associated with the transaction. From this information comes the possibility for the QoS IP network operator to move away from a now commonplace one-sided flat access tariff structure for IP services, and instead use a transactional service model that enables the network operator to impose transaction-based service fees on both parties to a network service if it so chooses. It also interposes the network operator between the content provider and the consumer, permitting the network operator to mediate the content service and potentially convert this gateway role into a revenue stream.

Of course the major problem in this QoS model is that it is based on a critical item of Internet mythology—the myth that inter-provider QoS exists on the Internet. QoS is not part of today's Internet, and there is no visible prospect that it will be part of tomorrow's Internet either!

Knotting up NATs

But QoS is not the only possible approach to exposing service-level transactions to the carriage-level IP network operator. Interestingly, the twin factors of the exhaustion of IPv4 addresses and the lack of uptake of IPv6 offers the IP network operator another window into what the user is doing, and, potentially, another means of controlling the quality of the user's experience by isolating individual user-level transactions at the network level.

When there are not enough addresses to assign each customer a unique IP address, the ISP is forced to use private addresses and operate a *Network Address Translator* (NAT)[2] within the carriage network.

However, NATs are not stateless passive devices. A NAT records every TCP and *User Datagram Protocol* (UDP) session from the user, as well as the port addresses the application uses when it creates a binding from an internal IP address and port to an external IP address and port. A new NAT binding is created for every user transaction: every conversation, every website, every streamed video, and literally everything else. If you were to look at the NAT logs that record this binding information, you would find a rich stream of real-time user data that shows precisely what each user is doing on the network. Every service transaction is now visible at the network level. How big is the temptation for the IP network operator to peek at this carrier-operated NAT log and analyze what it means?

Potentially, this transaction data could be monetized, because it forms a real-time data feed of every customer's use of the network. At the moment carriers think that they are being compelled to purchase and install this NAT function because of the IPv4 address situation. NATs offer a method for the carriage operator to obtain real-time feeds of customer behavior without actively intruding themselves into the packet stream. The NAT neatly segments the customer's traffic into distinct transactions that are directly visible to the NAT operator. I suspect that when they look at the business case for purchasing and deploying these *Carrier-Grade NAT* devices, they will notice a parallel business case that can be made to inspect the NAT logs and perhaps to either on-sell the data stream or analyze it themselves to learn about their customers' behavior.[3] And, as noted, there is already market evidence that such detailed real-time flows of information about individual users' activities can be worth significant sums.

But it need not necessarily be limited to a passive operation of stalking the user's online behavior. If the carriage provider were adventurous enough, it could bias the NAT port-binding function to even make some content work "better" than other content, by either slowing down the binding function for certain external sites or rationing available ports to certain less-preferred external sites. In effect, NATs provide many exploitable levers of control for the carriage operator, bundled with a convenient excuse of "we had no choice but to deploy these NATs!"

Where Now?

In contrast, what does an investment in IPv6 offer the carriage provider? An admittedly very bleak response from the limited perspective of the carriage service provider sector is that what is on offer with IPv6 is more of what has happened to the telecommunications carriage sector over the past 10 years, with not even the remote possibility of ever altering this situation. IPv6 certainly looks like forever, so if the carriers head down this path then the future looks awfully bleak for those who are entirely unused to, and uncomfortable with, a commodity utility provider role.

So should we just throw up our hands at this juncture and allow the carriage providers free rein? Are NATs inevitable? Should we view the introduction of transactional service models in the Internet as a necessary part of its evolution? I would like to think that these developments are not inevitable for the Internet, and that there are other paths that could be followed here. The true value for the end consumer is not in the carriage of bits through the network, but in the access to communication and services that such bit carriage enables. What does that reality imply for the future for the carriage role? I suspect that despite some evident misgivings, the carriage role is inexorably heading to that of a commodity utility operation.

This is not the first time an industry sector has transitioned from production of a small volume of highly valuable units to production of a massively larger volume of commodity goods, each of which has a far lower unit value, but generates an aggregate total that is much larger. The computing industry's transition from mainframe computers to mass market consumer electronics is a good example of such a transformation. As many IT sector enterprises have shown, it is possible to make such transitions. IBM is perhaps a classic example of an enterprise that has managed numerous successful transformations that have enabled it to maintain relevance and value in a rapidly changing environment.

The models for electricity distribution have seen a similar form of evolution in the last century. In the 1920s in the United Kingdom, electricity was a low-volume premium product. The prices for electricity were such that to keep just 5 light bulbs running for 1 day in a household cost the equivalent of an average week's wages. The consequent years saw public intervention in the form of nationalization of power generation and distribution that transformed electricity supply into a commonly available and generally affordable commodity.

The challenge the Internet has posed for the carriage sector is not all that different from these examples. The old carriage business models of relatively low-volume, high-value, transaction-based telecommunication services of telephony and faxes find no resonance within the service model of the Internet.

In the architecture of the Internet, it is the applications that define the services, while the demands from the underlying carriage network have been reduced to a simple stateless datagram-delivery service. Necessarily, the business models of carriage have to also change to adapt to this altered role, and one of the more fundamental changes is the dropping of the transaction-based model of the provision of telecommunications services for the carriage provider. What this situation implies for the carriage sector of the Internet is perhaps as radical as the transformation of the electricity supply industry during the period of the construction of the national grid systems in the first half of the 20th century.

The necessary change implied here is from a high-value premium service provider dealing in individual transactions across the network to that of a high-volume undistinguished commodity utility operator. The architectural concepts of a minimal undistinguished network carriage role and the repositioning of service management into end-to-end applications is an intrinsic part of the architecture of the Internet itself. It is not a universally acclaimed step—and certainly not one that is particularly popular in today's carriage industry—but if we want to see long-term benefits from the use of the Internet in terms of positive economic outcomes and efficient exploitation of this technology in delivering goods and services, then it is a necessary step in the broader long-term public interest.

The Internet: Looking Forward

by Vint Cerf, Google

As I write, it is 2013 and 40 years have passed since the first drafts of the Internet design were written. The first published paper appeared in 1974[1] and the first implementations began in 1975. Much has happened since that time, but this essay is not focused on the past but, rather, on the future. Although the past is plainly prologue, our ability to see ahead is hampered by the unpredictable and the unknown unknowns that cloud and bedevil our vision. The exercise is nonetheless worth the effort, if only to imagine what might be possible.

Current trends reveal some directions. Mobile devices are accelerating access and applications. The economics of mobile devices have increased the footprint of affordable access to the Internet and the World Wide Web. Mobile infrastructure continues to expand on all inhabited continents. Speeds and functions are increasing as faster processors, more memory, and improved display technologies enhance the functions of these platforms. Cameras, microphones, speakers, sensors, multiple radios, touch-sensitive displays, and location and motion detection continue to evolve and open up new application possibilities. Standards and open source software facilitate widespread interoperability and adoption of applications. What is perhaps most significant is that these smart devices derive much of their power from access to and use of the extraordinary computing and memory capacity of the Internet. The Internet, cloud computing, and mobile devices have become hypergolic in their capacity to ignite new businesses and create new economic opportunities.

In the near term, the Internet is evolving. The *Domain Name System* (DNS) is expanding dramatically at the top level. Domain names can be written in non-Latin characters. The Internet address space is being expanded through the introduction of the IPv6 packet format, although the implementation rate among *Internet Service Providers* (ISPs) continues to be unsatisfactorily slow. This latter phenomenon may change as the so-called *Internet of Things*[2] emerges from its long incubation. Sensor networks, Internet-enabled appliances, and increasing application of artificial intelligence will transform the Internet landscape in ways that seem impossible to imagine. The introduction of IPv6 and the exhaustion of the older IPv4 address space have generated demand for application of the so-called *Network Address Translation* (NAT)[3] system. Geoff Huston has written and lectured extensively on this topic[4] and the potential futures involving their use. In some ways, these systems simultaneously interfere with the motivation to implement IPv6 and act as a bridge to allow both network address formats to be used concurrently.

Ironically, although most edge devices on the Internet today are probably IPv6-capable, as are the routers, firewalls, DNS servers, and other application servers, this advanced version of the Internet Protocol may not have been "turned on" by the ISP community. This situation is changing, but more slowly than many of us would like.

As the applications on the Internet continue to make demands on its capacity to transport data and to deliver low-latency services, conventional Internet technologies are challenged and new ideas are finding purchase in the infrastructure. The *OpenFlow*[5, 6] concept has emerged as a fresh look at packet switching in which control flow is segregated from data flow and routing is not confined to the use of address bits in packet headers for the formation and use of forwarding tables. Originally implemented with a central routing scheme to improve efficient use of network resources, the system has the flexibility to be made more distributed. It remains to be seen whether OpenFlow networks can be interconnected by using an extended form of the *Border Gateway Protocol* (BGP) so as to achieve end-to-end performance comparable to what has already been achieved in single networks.

Business models for Internet service play an important role here because end-to-end differential classes of service have not been realized, generally, for the current Internet implementations. Inter-ISP or edge-to-core commercial models also have not generally been perfected to achieve multiple classes of service. These aspirations remain for the Internet of the present day. Although it might be argued that increasing capacity in the core and at the edge of the Internet eliminates the need for differential service, it is fair to say that some applications definitely need lower delay, others need high capacity, and some need both (for example, for interactive video). Whether these requirements can be met simply through higher speeds or whether differential services must be realized at the edges and the core of the network is the source of substantial debate in the community. Vigorous experimentation and research continue to explore these topics.

Ubiquitous Computing

Mark Weiser[7] coined the term and concept of *Ubiquitous Computing*. He meant several things by this term, but among them was the notion that computers would eventually fade into the environment, becoming ever-present, performing useful functions, and operating for our convenience. Many devices would host computing capacity but would not be viewed as "computers" or even "computing platforms." Entertainment devices; cooking appliances; automobiles; medical, environmental, and security monitoring systems; our clothing; and our homes and offices would house many computing engines of various sizes and capacities. Many, if not all, would be interconnected in communication webs, responding to requirements and policies set by users or by their authorized representatives.

To this idyllic characterization, he implied there would be challenges: configurations of hundreds of thousands of appliances and platforms, privacy, safety, access control, information confidentiality, stability, resilience, and a host of other properties.

Even modest thought produces an awareness of the need for strong authentication to assure that only the appropriate devices and authorized parties are interacting, issuing instructions, taking data, etc. It is clear that multifactor authentication and some form of public key cryptography could play an important role in assuring limitations on the use and operation of these systems. Privacy of the information generated by these systems can be understood to be necessary to protect users from potential harm.

The scale of such systems can easily reach tens to hundreds of billions of devices. Managing complex interactions at such magnitudes will require powerful hierarchical and abstracting mechanisms. When it is also understood that our mobile society will lead to a constant background churn of combinations of devices forming subsets in homes, offices, automobiles, and on our persons, the challenge becomes all the more daunting. (By this I do not mean the use of mobile smartphones but rather a society that is geographically mobile and that moves some but not all its possessions from place to place, mixing them with new ones.) Self-organizing mechanisms, hierarchically structured systems, and systems that allow remote management and reporting will play a role in managing the rapidly proliferating network we call the Internet.

For further insight into this evolution, we should consider the position location capability of the *Global Positioning System* (GPS)[8]. Even small, low-powered devices (for example, mobile devices) have the ability to locate themselves if they have access to the proper satellite transmissions. Adding to this capability is geo-location using mobile cell towers and even known public Wi-Fi locations. In addition, we are starting to see appliances such as *Google Glass*[9] enter the environment. These appliances are portable, wearable computers that hear what we hear and see what we see and can respond to spoken commands and gestures. The Google self-driving cars[10] offer yet another glimpse into the future of computing, communication, and artificial intelligence in which computers become our partners in a common sensory environment—one that is not limited to the normal human senses. All of these systems have the potential to draw upon networked information and computing power that rivals anything available in history. The systems are potentially self-learning and thus capable of improvement over time. Moreover, because these devices may be able to communicate among themselves, they may be able to cooperate on a scale never before possible.

Even now we can see the outlines of a potential future in which virtually all knowledge can be found for the asking; in which the applications of the Internet continue to evolve; in which devices and appliances of all kinds respond and adapt to our needs, communicate with each other, learn from each other, and become part of an integrated and global environment.

Indeed, our day-to-day environment is very likely to be filled with information and data gathered from many sources and subject to deep analysis benefitting individuals, businesses, families, and governments at all levels. Public health and safety are sure to be influenced and affected by these trends.

Education

It is often noted that a teacher from the mid-19th century would not feel out of place in the classroom of the 21st, except, perhaps, for subject matter. There is every indication that this situation may be about to change. In 2012, two of my colleagues from Google, Peter Norvig and Sebastian Thrun, decided to use the Internet to teach an online class in artificial intelligence under the auspices of Stanford University. They expected about 500 students, but 160,000 people signed up for the course! There ensued a scramble to write or revise software to cope with the unexpectedly large scale of the online class. This phenomenon has been a long time in coming. Today we call such classes "MOOCs" (*Massive, Open, OnLine Classes*). Of the 160,000 who signed up, something like 23,000 actually completed the class. How many professors of computer science can say they have successfully taught 23,000 students?

The economics of this form of classroom are also very intriguing. Imagine a class of 100,000 students, each paying $10 per class. Even one class would produce $1,000,000 in revenue. I cannot think of any university that regularly has million dollar classes! There are costs, but they are borne in part by students (Internet access, equipment with which to reach the Internet, etc., for example) and in part by the university (Internet access, multicast or similar capability, and salaries of professors and teaching assistants). In some cases, the professors prepare online lectures that students can watch as many times as they want to—whenever they want to because the lectures can be streamed. The professors then hold classroom hours that are devoted to solving problems, in an inversion of the more typical classroom usage. Obviously this idea could expand to include nonlocal teaching assistants. Indeed, earlier experiments with video-taped lectures and remote teaching assistants were carried out with some success at Stanford University when I served on the faculty in the early 1970s.

What is potentially different about MOOCs is *scale*. Interaction and examinations are feasible in this online environment, although the form of exams is somewhat limited by the capabilities of the online platform used. Start-ups are experimenting with and pursuing these ideas (refer to **www.udacity.com** and **www.coursera.org**).

People who are currently employed also can take these courses to improve their skills, learn new ones, and position themselves for new careers or career paths. From young students to retired workers, such courses offer opportunities for personal expansion, and they provide a much larger customer base than is usually associated with a 2- or 4-year university or college program. These classes can be seen as re-invention of the university, the short course, the certificate program, and other forms of educational practice. It is my sense that this state of affairs has the potential to change the face of education at all levels and provide new options for those who want or need to learn new things.

The Information Universe

It is becoming common to speak of "big data" and "cloud computing" as indicators of a paradigm shift in our view of information. This view is not unwarranted. We have the ability to absorb, process, and analyze quantities of data beyond anything remotely possible in the past. The functional possibilities are almost impossible to fully fathom. For example, our ability to translate text and spoken language is unprecedented. With combinations of statistical methods, hierarchical hidden Markov models, formal grammars, and Bayesian techniques, the fidelity of translation between some language pairs approaches native language speaker quality. It is readily predictable that during the next decade, real-time, spoken language translation will be a reality.

One of my favorite scenarios: A blind German speaker and a deaf *American Sign Language* (ASL) signer meet, each wearing Google Glass. The deaf signer's microphone picks up the German speaker's words, translates them into English, and displays them as captions for the deaf participant. The blind man's Glass video camera sees the deaf signer's signs, translates the signs from ASL to English and then to German, and then speaks them through the bone conduction speaker of the Google Glass. We can do all of this now except for the correct interpretation of ASL. This challenge is not a trivial one, but it might be possible in the next 10 to 15 years.

The World Wide Web continues to grow in size and diversity. In addition, large databases of information are being accumulated, especially from scientific disciplines such as physics, astronomy, and biology. Telescopes (ground and space-based), particle colliders such as the Large Hadron Collider[11], and DNA sequencers are producing petabytes and more—in some cases on a daily basis!

We seem to be entering a time when much of the information produced by human endeavor will be accessible to everyone on the planet. Google's motto: "To organize the world's information and make it universally accessible and useful," might be nearly fulfilled in the decades ahead. Some tough problems lie ahead, however. One I call "bit rot."

By using this term, I do not mean the degradation of digital recordings on various media, although this is a very real problem. The more typical problem is that the readers of the media fall into disuse and disrepair. One has only to think about 8-inch Wang disks for the early Wang word processor, or 3.5-inch floppy disks or their 5 ¼-inch predecessors. Now we have CDs, DVDs, and Blu-Ray disks, but some computer makers—Apple for example—have ceased to build in readers for these media.

Another, more tricky problem is that much of the digital information produced requires software to correctly interpret the digital bits. If the software is not available to interpret the bits, the bits might as well be rotten or unreadable. Software applications run over operating systems that, themselves, run on computer hardware. If the applications do not work on new versions of the operating systems, or the applications are upgraded but are not backward-compatible with earlier file and storage formats, or the maker of the application software goes out of business and the source code is lost, then the ability to interpret the files created by this software may be lost. Even when open source software is used, it is not clear it will be maintained in operating condition for thousands of years. We already see backward-compatibility failures in proprietary software emerging after only years or decades.

Getting access to source code for preservation may involve revising notions of copyright or patent to allow archivists to save and make usable older application software. We can imagine that "cloud computing" might allow us to emulate hardware, run older operating systems, and thus support older applications, but there is also the problem of basic input/output and the ability to emulate earlier media, even if the physical media or their readers are no longer available. This challenge is a huge but important one.

Archiving of important physical data has to be accompanied by archiving of metadata describing the conditions of collections, calibration of instruments, formatting of the data, and other hints at how to interpret it. All of this work is extra, but necessary to make information longevity a reality.

The Dark Side

To the generally optimistic and positive picture of Internet service must be added a realistic view of its darker side. The online environment and the devices we use to exercise it are filled with software. It is an unfortunate fact that programmers have not succeeded in discovering how to write software of any complexity that is free of mistakes and vulnerabilities.

Despite the truly remarkable and positive benefits already delivered to us through the Internet, we must cope with the fact that the Internet is not always a safe place.

The software upon which we rely in our access devices, in the application servers, and in the devices that realize the Internet itself (routers, firewalls, gateways, switches, etc.) is a major vulnerability, given the apparently inescapable presence of bugs.

Not everyone with access to the Internet has other users' best interests at heart. Some see the increasing dependence of our societies on the Internet as an opportunity for exploitation and harm. Some are motivated by a desire to benefit themselves at the expense of others, some by a desire to hurt others, some by nationalistic sentiments, some by international politics. That Shakespeare's plays are still popular after 500 years suggests that human frailties have not changed in the past half millennium! The weaknesses and vulnerabilities of the Internet software environment are exploited regularly. What might the future hold in terms of making the Internet a safer and more secure place in which to operate?

It is clear that simple usernames and passwords are inadequate to the task of protecting against unauthorized access and that multifactor and perhaps also biometric means are going to be needed to accomplish the desired effect. We may anticipate that such features might become a part of reaching adulthood or perhaps a rite of passage at an earlier age. Purely software attempts to cope with confidentiality, privacy, access control, and the like will give way to hardware-reinforced security. Digitally signed *Basic Input/Output System* (BIOS), for example, is already a feature of some new chipsets. Some form of trusted computing platform will be needed as the future unfolds and as online and offline hazards proliferate.

Governments are formed that are, in principle, kinds of social contracts. Citizens give up some freedoms in exchange for safety from harm. Not all regimes have their citizens' best interests at heart, of course. There are authoritarian regimes whose primary interest is staying in power. Setting these examples aside, however, it is becoming clear that the hazards of using computers and being online have come to the attention of democratic as well as authoritarian regimes. There is tension between law enforcement (and even determination of what the law should be) and the desire of citizens for privacy and freedom of action. Balancing these tensions is a nontrivial exercise. The private sector is pressed into becoming an enforcer of the law when this role is not necessarily an appropriate one. The private sector is also coerced into breaching privacy in the name of the law.

"Internet Governance" is a broad term that is frequently interpreted in various ways depending on the interest of the party desiring to define it for particular purposes. In a general sense, Internet Governance has to do with the policies, procedures, and conventions adopted domestically and internationally for the use of the Internet. It has not only to do with the technical ways in which the Internet is operated, implemented, and evolved but also with the ways in which it is used or abused.

In some cases it has to do with the content of the Internet and the applications to which the Internet is put. It is evident that abuse is undertaken through the Internet. Fraud, stalking, misinformation, incitement, theft, operational interference, and a host of other abuses have been identified. Efforts to defend against them are often stymied by lack of jurisdiction, particularly in cases where international borders are involved. Ultimately, we will have to reach some conclusions domestically and internationally as to which behaviors will be tolerated and which will not, and what the consequences of abusive behavior will be. We will continue to debate these problems well into the future.

Our societies have evolved various mechanisms for protecting citizens. One of these mechanisms is the Fire Department. Sometimes volunteer, this institution is intended to put out building or forest fires to minimize risks to the population. We do not have a similar institution for dealing with various forms of "cyberfires" in which our machines are under attack or are otherwise malfunctioning, risking others by propagation of viruses, worms, and Trojan horses or participation in botnet denial-of-service or other forms of attacks. Although some of these matters may deserve national-level responses, many are really local problems that would benefit from a "Cyber Fire Department" that individuals and businesses could call upon for assistance. When the cyber fire is put out, the question of cause and origin could be investigated as is done with real fires. If deliberately set, the problem would become one of law enforcement.

Intellectual property is a concept that has evolved over time but is often protected by copyright or patent practices that may be internationally adopted and accepted. These notions, especially copyright, had origins in the physical reproduction of content in the form of books, films, photographs, CDs, and other physical things containing content. As the digital and online environment penetrates more deeply into all societies, these concepts become more and more difficult to enforce. Reproduction and distribution of digital content gets easier and less expensive every day. It may be that new models of compensation and access control will be needed in decades ahead.

Conclusion

If there can be any conclusion to these ramblings, it must be that the world that lies ahead will be immersed in information that admits of extremely deep analysis and management. Artificial intelligence methods will permeate the environment, aiding us with smart digital assistants that empower our thought and our ability to absorb, understand, and gain insight from massive amounts of information.

It will be a world that is also at risk for lack of security, safety, and privacy—a world in which demands will be made of us to think more deeply about what we see, hear, and learn. While we have new tools with which to think, it will be demanded of us that we use them to distinguish sound information from unsound, propaganda from truth, and wisdom from folly.

Optimizing Link-State Protocols for Data Center Networks

by Alvaro Retana, Cisco Systems, and Russ White, Verisign

With the advent of cloud computing[6, 7], the pendulum has swung from focusing on wide-area or global network design toward a focus on *Data Center* network design. Many of the lessons we have learned in the global design space will be relearned in the data center space before the pendulum returns and wide-area design comes back to the fore.

This article examines three extensions to the *Open Shortest Path First* (OSPF) protocol that did not originate in the data center field but have direct applicability to efficient and scalable network operation in highly meshed environments. Specifically, the application extensions to OSPF to reduce flooding in *Mobile Ad Hoc Networks* (MANET)[1], demand circuits designed to support on-demand links in wide-area networks[2], and OSPF stub router advertisements designed to support large-scale *hub and spoke* networks[3] are considered in a typical data center network design to show how these sorts of protocol improvements could affect the scaling of data center environments.

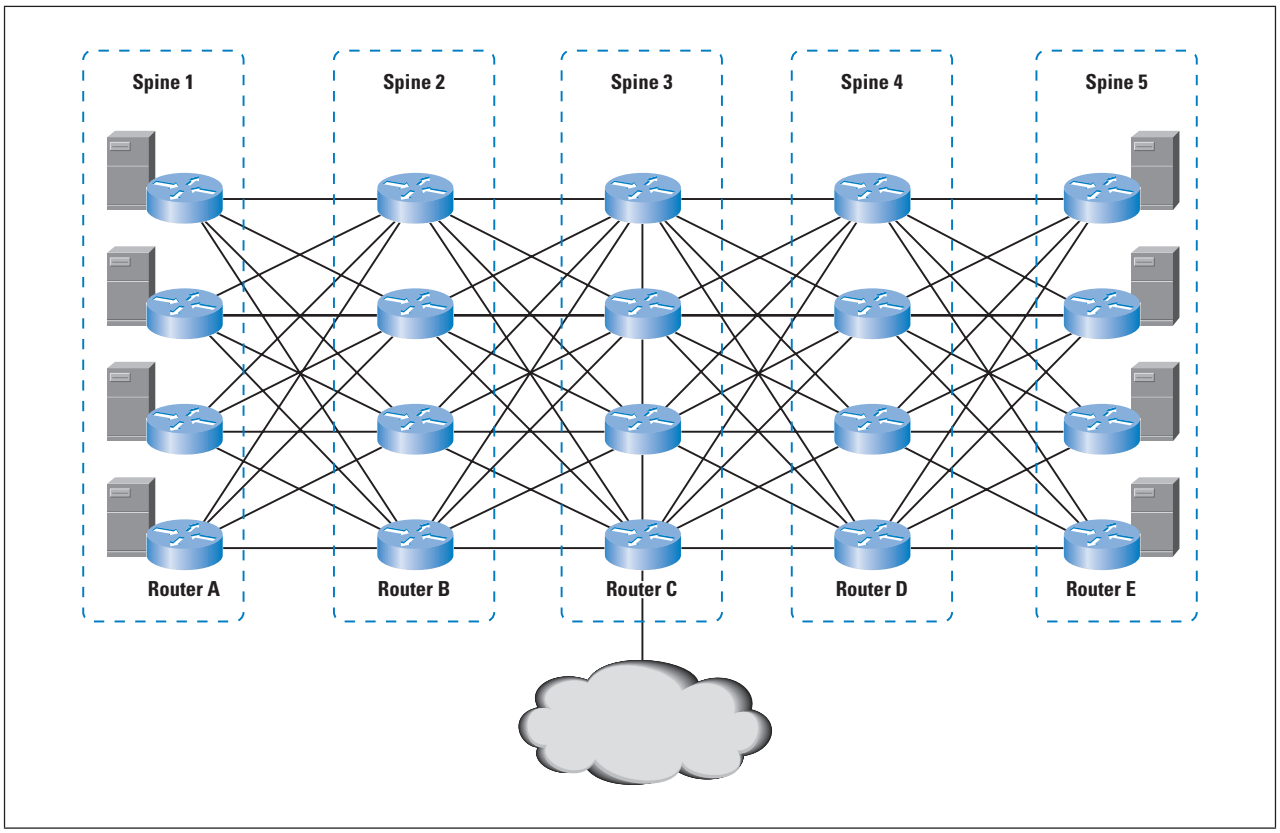
Each of the improvements examined has the advantage of being available in shipping code from at least one major vendor. All of them have been deployed and tested in real-world networks, and have proven effective for solving the problems they were originally designed to address. Note, as well, that OSPF is used throughout this article, but each of these improvements is also applicable to *Intermediate System-to-Intermediate System* (IS-IS), or any other link-state protocol.

Defining the Problem

Figure 1 illustrates a small Clos[0] fabric, what might be a piece of a much larger network design. Although full-mesh fabrics have fallen out of favor with data center designers, Clos and other styles of fabrics are in widespread use. A Clos fabric configured with edge-to-edge Layer 3 routing has three easily identifiable problems.

The flooding rate is the first problem a link-state protocol used in this configuration must deal with. Router B (and the other routers in spine 2), for instance, will receive four type 1 *Link State Advertisements* (LSAs) from the four routers in spine 1. Each of the routers in spine 2 will reflood each of these type 1 LSAs into spine 3, so the other routers in spines 3, 4, and 5 will each receive four copies of each type 1 LSA originated by routers in spine 1, a total of 16 type 1 LSAs in all.

Figure 1: A Clos Fabric with Layer 3 to the Top of Rack



To make matters worse, OSPF is designed to time out every LSA originated in the network once every 20 to 30 minutes. This feature was originally put in OSPF to provide for recovery from bit and other transmission errors in older transport mechanisms with little or no error correction. So a router in spine 5 will receive 16 copies of each type 1 LSA generated by routers in spine 1 every 20 minutes. A single link failure and recovery can also cause massive reflooding. The process of bringing the OSPF adjacency back into full operation requires a complete exchange of local link-state databases. If the link between router A and router B fails and then is recovered, the entire database must be transferred between the two routers, even though router B clearly has a complete copy of the database from other sources.

Finally, the design of this network produces some challenges for the *Shortest Path First* (SPF) algorithm, which link-state protocols use to determine the best path to each reachable destination in the network. Every router in spine 1 appears to be a transit path to every other destination in the network. This outcome might not be the intent of the network designer, but SPF calculations deal with available paths, not intent.

This set of problems has typically swayed network designers away from using link-state protocols in such large-scale environments. Some large cloud service providers use the *Border Gateway Protocol* (BGP) (see [4]), with each spine being a separate Autonomous System, so they can provide scalable Layer 3 connectivity edge-to-edge in large Clos network topologies. Others have opted for simple controls, such as removing all control-plane protocols and relying on reverse-path-forwarding filters to prevent loops.

The modifications to OSPF discussed in this article, however, make it possible for a link-state protocol to not only scale in this type of environment, but also to be a better choice.

Reducing Flooding Through MANET Extensions

MANET networks are designed to be "throw and forget;" a collection of devices is deployed into a quickly fluid situation on the ground, where they connect over short- and long-haul wireless links, and "just work." One of the primary scaling (and operational) factors in these environments is an absolute reduction of link usage wherever possible, including for the control plane.

The "Extensions to OSPF to Support Mobile Ad Hoc Networking,"[1] were developed to reduce flooding in single-area OSPF networks to the minimal necessary, while providing fast recovery and guaranteed delivery of control-plane information. The idea revolves around the concept of an overlapping relay, which reduces flooding by accounting for the network topology, specifically groups of overlapping nodes.

Let's examine the process from the perspective of router A shown in Figure 2.

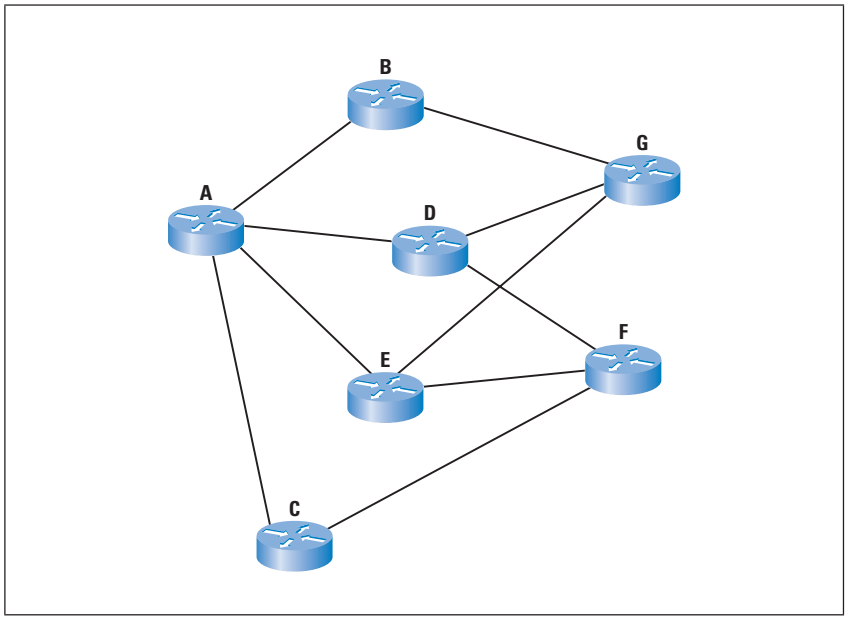


Figure 2: Ad Hoc Extensions to OSPF

Router A begins the process by not only discovering that it is connected to routers B, C, D, and E, but also that its *two-hop neighborhood* contains routers F and G. By examining the list of two-hop neighbors, and the directly connected neighbors that can reach each of those two-hop neighbors, router A can determine that if router D refloods any LSAs router A floods, every router in the network will receive the changes. Given this information, router A notifies routers B, C, and E to delay the reflooding of any LSAs received from router A itself.

When router A floods an LSA, router D will reflood the LSA to routers F and G, which will then acknowledge receiving the LSA to routers B, C, D, and E. On receiving this acknowledgement, routers B, C, and E will remove the changed LSA from their reflood lists.

Routers F and G, then, will receive only one copy of the changed LSA, rather than four.

Applying this process to the Clos design in Figure 1 and using this extension would dramatically reduce the number of LSAs flooded through the network in the case of a topology change. If router A, for instance, flooded a new type 1 LSA, the routers in spine 2 would each receive one copy. The routers in spines 3, 4, and 5 would also receive only one copy each, rather than 4 or 16.

Reducing Flooding Through Demand Circuits

Network engineers have long had to consider links that are connected only when traffic is flowing in their network and protocol designs. Dial-up links, for instance, or dynamically configured *IP Security* (IPsec) tunnels, have always been a part of the networking landscape. Part of the problem with such links is that the network needs to draw traffic to destinations reachable through the link even though the link is not currently operational.

With protocols that rely on neighbor adjacencies to maintain database freshness, such as OSPF, links that can be disconnected in the control plane and yet still remain valid in the data plane pose a unique set of difficulties. The link must appear to be available in the network topology even when it is, in fact, not available.

To overcome this challenge, the OSPF working group in the IETF extended the protocol to support demand links. Rather than attacking the problem at the adjacency level, OSPF attacks the problem at the database level. Any LSA learned over a link configured as a demand link is marked with the *Do Not Age* (DNA) bit; such LSAs are exempt from the normal aging process, causing LSAs to be removed from the link-state database periodically.

How does this situation relate to scaling OSPF in data center network design?

Every 20 minutes or so, an OSPF implementation will time out all the locally generated LSAs, replacing them with newly generated (and identical) LSAs. These newly generated LSAs will be flooded throughout the network, replacing the timed-out copy of the LSA throughout the network. In a data center network, these refloods are simply redundant; there is no reason to refresh the entire link-state database periodically.

To reduce flooding, then, data center network designers can configure all the links in the data center as demand circuits. Although these links are, in reality, always available, configuring them as demand circuits causes the DNA bit to be set on all the LSAs generated in the network. This process, in turn, disables periodic reflooding of this information, reducing control-plane overhead.

Reducing Control-Plane Overhead by Incremental Database Synchronization

When a link fails and then recovers, the OSPF protocol specifies a lengthy procedure through which the two newly adjacent OSPF processes must pass to ensure their databases are exactly synchronized. In the case of data center networks, however, there is little likelihood that a single link failure (or even multiple link failures) will cause two adjacent OSPF processes to have desynchronized databases.

For instance, in Figure 1, if the link between routers A and B fails, routers A and B will still receive any and all link-state database updates from some other neighbor they are still fully adjacent with. When the link between routers A and B is restored, there is little reason for routers A and B to exchange their entire databases again.

This situation is addressed through another extension suggested through the MANET extensions to OSPF called *Unsynchronized Adjacencies*. Rather than sending an entire copy of the database on restart and waiting until this exchange is complete to begin forwarding traffic on link recovery, this extension states that OSPF processes do not need to synchronize their databases if they are already synchronized with other nodes in the network. If needed, the adjacency can be synchronized out of band at a later time.

The application of the MANET OSPF extensions[1] to a data center network means links can be pressed into service very quickly on recovery, and it provides a reduction in the amount of control-plane traffic required for OSPF to recover.

Reducing Processing Overhead Through Stub Routers

The SPF calculation that link-state protocols use to determine the best path to any given destination in the network treats all nodes and all edges on the graph as equal. Returning to Figure 2, router B will calculate a path through router A to routers D, E, and C, even if router A is not designed to be a transit node in the network. This failure to differentiate between transit and nontransit nodes in the network graph increases the number of paths SPF must explore when calculating the shortest-path tree to all reachable destinations.

Although modern implementations of SPF do not suffer from problems with calculation overhead or processor usage, in large-scale environments, such as a data center network with tens of thousands of nodes in the shortest-path tree and virtualization requirements that cause a single node to run SPF hundreds or thousands of times, small savings in processing power can add up.

The "OSPF Stub Router Advertisement"[3] mechanism allows network administrators to mark an OSPF router as nontransit in the shortest-path tree. This mechanism would, for instance, prevent router A in Figure 1 from being considered a transit path between router B and some other router in spine 2. You would normally want to consider this option only for any actual edge routers in the network, such as the top-of-rack routers shown here. Preventing these routers from being used for transit can reduce the amount of redundancy available in the network, and, if used anyplace other than a true edge, prevent the network from fully forming a shortest-path tree.

Advantages and Disadvantages of Link-State Protocols in the Data Center

Beyond the obvious concerns of convergence speed and simplicity, there is one other advantage to using a link-state protocol in data center designs: equal-cost load sharing. OSPF and IS-IS both load share across all available equal-cost links automatically (subject to the limitations of the forwarding table in any given implementation). No complex extensions (such as [5]), are required to enable load sharing across multiple paths.

One potential downside to using a link-state protocol in a data center environment must be mentioned, however—although BGP allows route filtering at any point in the network (because it is a path vector–based protocol)—link-state protocols can filter or aggregate reachability information only at flooding domain boundaries. This limitation makes it more difficult to manage traffic flows through a data center network using OSPF or IS-IS to advertise routing information. This problem has possible solutions, but this area is one of future, rather than current, work.

Conclusion

Many improvements have been made to link-state protocols over the years to improve their performance in specific situations, such as MANETs, and when interacting with dynamically created links or circuits. Many of these improvements are already deployed and tested in real network environments, so using them in a data center environment is a matter of application rather than new work. All of these improvements are applicable to link-state control planes used for Layer 2 forwarding, as well as Layer 3 forwarding, and they are applicable to OSPF and IS-IS.

These improvements, when properly applied, can make link-state protocols a viable choice for use in large-scale, strongly meshed data center networks.

ALVARO RETANA is a Distinguished Engineer in Cisco Technical Services, where he works on strategic customer enablement. Alvaro is widely recognized for his expertise in routing protocols and network design and architecture; he has CCIE® and CCDE® certifications, and he is one of a handful of people who have achieved the CCAR® certification. Alvaro is an active participant in the IETF, where he co-chairs the Routing Area Working Group (rtgwg), is a member of the Routing Area Directorate, and has authored several RFCs on routing technology. Alvaro has published 4 technical books and has been awarded more than 35 patents by the U.S. Patent and Trademark Office. His current interests include software-defined networking, energy efficiency, infrastructure security, routing protocols, and other related topics. E-mail: **aretana@cisco.com**

Letter to the Editor

Dear Editor,

I enjoyed reading the article on "Address Authentication" in the March 2013 edition of *The Internet Protocol Journal* (Volume 16, No. 1), but I couldn't help thinking to myself how the widespread adoption of the use of *IPv6 Privacy Addresses* (RFC 4941) would affect some of the assertions in the article about the relative merits of using IPv6 addresses for authentication. With both Microsoft and Apple operating systems now implementing IPv6 Privacy Addresses, it is now effectively impossible for any user authentication service to assume that a presented IPv6 address is going to remain constant over time. It is probably safer to assume that such IPv6 addresses are in fact not constant at all, and not to use them in any context of authentication. Given that the widespread use of NATs in IPv4 leads one to the same basic conclusion about using IPv4 addresses for authentication, isn't the best advice these days to avoid "Address Authentication" as it is applied to Internet end users?

Regards,

—*Geoff Huston*
gih@apnic.net

The author responds:

I agree with Geoff's comments. My article explores the idea that IPv6 may be more "trustworthy," but it concludes by recommending against using any IP address as a form of authentication.

IPv4 addresses will be far less "trustworthy" with the introduction of *Carrier-Grade NATs* or *Large-Scale NATs*. We will not be able to trust IPv6 addresses if the interface identifier changes frequently. My expectation is that most enterprises would prefer *Dynamic Host Configuration Protocol for IPv6* (DHCPv6) with randomized interface identifiers, but most broadband Internet access subscribers will use a *Customer Premises Equipment* (CPE) that uses *Stateless Address Autoconfiguration* (SLAAC) and Stateless DHCPv6. IPv6 offers the ability to perform traceback to the /64 subnet level. That feature is only slightly better than IPv4 traceback.

Book Review

Network Geeks

Network Geeks: How They Built the Internet, by Brian E. Carpenter, Copernicus Books, ISBN 978-1-4471-5024-4, 2013.

The movie opens on a familiar scene, toward the end of a congenial dinner party at the plush home of an august personage. Conversation has been casual and wide-ranging. The group retires to the library for brandy, cigars, and more conversation. Because you are new to your profession and the august personage was involved in its early years, you ask him what it was like. As he begins his recitation, the scene fades to an earlier time... "My great-grandfather, John Winnard, was born in Wigan..."

Such is the style of Brian Carpenter's book, *Network Geeks: How They Built the Internet*. Although indeed many other people are cited, the book really is Brian's personal memoir, complete with his own photographs. It explores his background and work, providing a fascinating travelogue of one person's arc through recent history. Given the breadth and scale of the 50-year process of invention and development of the global Internet, we need perhaps a thousand more such reminiscences to provide sufficiently rich detail about the many actors and acts that contributed to its success.

Brian's experiences within that global history are certainly worthy of note. His writing paints pictures of places and topics such as the forces and attractions that drew him to computer networking; in those days, it was an outlier technical topic and people often happened into it, rather than setting out with a plan. Indeed, Brian's doctoral work was in computer speech understanding—not networking. However, he has played a key role in many significant Internet activities. His frequent employer, the Swiss CERN[0], was a focal point for much of the early European networking activity—as well as being the birthplace of the World Wide Web—and Brian's various leadership roles in the *Internet Engineering Task Force* (IETF) came at pivotal times. Other popular references to Internet history tend to emphasize its American basis, making Brian's primarily European perspective refreshing and helpful.

The book is short, just 150 pages. Although Brian makes some terse references early in the book, he does not get fully into gear talking about the Internet until a third of the way through it. He started in physics, coming fully to computer science only in graduate school. Over the course of the memoir, we hear quite a bit about his physics work at CERN and elsewhere, as well as his activities with the early European deployment of Internet services, his eventual work with Internet standards, and the like.

The IETF

Brian's reference to his great-grandfather does appear, but not until page 10 in a chapter that extensively details his family history and his own upbringing—how many other books on Internet history are likely to include an inset distinguishing the English Baptist church from the American Southern Baptist? Rather, the book begins with a description of a prototypical IETF plenary session at the thrice-annual standards meeting, and he paints the picture well enough to have prompted a guessing game about the person he was describing. IETF meetings, including the plenaries, have a great deal of audience participation, because these meetings are working meetings, not conferences. I particularly enjoyed Brian's turn of phrase when describing one participant, "...who had given several articulate but incomprehensible arguments at the microphone." Later in the book he also equitably describes a colleague as "a wise leader, decisive or even pig-headed, but willing to listen..."

After its opening sequences, the book follows Brian's life chronology, including extended periods in England, Switzerland, the United States, and New Zealand, most recently landing at the last. His employment has variously been university, research, and corporate, including roles as researcher, manager, chair, and teacher.

This book is a memoir, so Brian casually and regularly moves between discussion of personal and professional developments. From one paragraph to the next, he might describe structural aspects of an Internet organization, insulation of housing in New Zealand, the next effort at particle physics, optimizing travel when flying out of southeast England, the nature of a computer networking technology, or the personal style of a co-worker.

In particular, this work is not a tutorial on Internet technology or on its invention. Although Brian does discuss many aspects of the technologies, the pedagogy suits an after-dinner evening's reminiscences, not a classroom lecture. Some concepts are explained in great detail, while others are merely cited. For example, his early discussion of computer networking references the fact that it enables mesh topologies, in contrast to then-common star configurations, but he doesn't give much sense of what "mesh" means in technical terms. Also, the core technology of networking is *packet-switching* and although his discussion on the page after the mesh reference cites queuing theory, he never introduces the motivating design construct of "store and forward."

His discussion of addressing suggests his hardware background, and misses the essence that a name at one level of architecture is often an address at the next level up. So although `www.example.com` is the "name" of a host system attached to the Internet, it has the role of "address" in a URL, because it specifies where to go to resolve the remainder of the URL.

That said, quibbling with such an issue in a tutorial might be reasonable, but it is entirely inappropriate for a memoir. These are Brian's recollections. If they prompt the reader to explore things later, so much the better; but arguing his view will not do. Perhaps reflexively, it is convenient that the Internet makes such exploration quite easy...

NATs

Except that I remain sorry to see that Brian still has such a strikingly purist view about *Network Address Translation* (NAT)[1, 2] devices, which map between internal (private) IP addresses and public ones. The purist view is that they are an abomination that breaks the elegance of the "end-to-end" design principle of the Internet. The principle is powerful, because it tends to greatly simplify the communications infrastructure and greatly enable innovation at the endpoints. The problem is that the real world imposes organizational and operational models that are more complex than easily supported by the basic end-to-end construct, at the least needing to include enterprise-level policies. NATs do cause problems, by replacing one IP address for another, and some mechanisms do cease to work because of these replacements. However, the operational world views NATs as being useful against multiple problems. One is address space constraints, which is the formal justification for creating the mechanism: an enterprise uses far fewer public IP addresses—a reality that is now essential as IPv4 addresses have grown scarce. Another justification is the misguided view that they improve enterprise security, and the other is the legitimate view that they simplify enterprise network administration. After more than 20 years of extensive deployment, these devices might be expected to have become tolerable to a pragmatist, possibly even forcing consideration of a more elaborate architectural model for the Internet. Yet Brian suffers no such weakness; NATs are evil.

One of the technical points that intrigued me was Brian's repeated discussion of the *Remote Procedure Call* (RPC). This mechanism makes network interaction for an application look like little more than a subroutine invocation. It was hoped that it would greatly simplify network-oriented programming and make it accessible to any software developer, rather than requiring the developer to have a deep understanding of networking interfaces and dynamics. Brian cites the mechanism as having been "invented by the ARPANET community in the mid-1970s..." and used at CERN in a programming language shortly after that. But my own recollection is of hearing a Xerox *Palo Alto Research Center* (PARC) manager in 1980 proudly announce that one of his summer interns had just developed the idea. Indeed, Wikipedia credits the late Bruce Jay Nelson, a Carnegie Mellon University graduate student who was working at PARC.[3]

And that is the essence of a memoir. It is the remembrances of the speaker, not the formal work of a historian or journalist. It is not the diligent unfolding of a researched history, such as in *Where Wizards Stay up Late*[4], nor the tourist approach of *Exploring the Internet: A Technical Travelogue*[5] that seeks to name every possible person active at the time—although Brian does sometimes invoke that latter template. Instead it shares one person's sense of what happened—what he remembers doing and seeing.

Railing against architectural biases or historical nuances is essential when evaluating formal professional writing, and we do need such judicious efforts to capture the history of the Internet. But had Brian sought to produce such a tome, it would not have been as rich or as personal.

Number of IPv6-Connected Internet Users Doubles

The *Internet Society* (ISOC) recently reported that the number of IPv6-connected users has doubled since *World IPv6 Launch* began on June 6, 2012, when thousands of *Internet Service Providers* (ISPs), home networking equipment manufacturers, and Web companies around the world came together to permanently enable the next generation of *Internet Protocol Version 6* (IPv6) for their products and services. This marks the third straight year IPv6 use on the global Internet has doubled. If current trends continue, more than half of Internet users around the world will be IPv6-connected in less than 6 years.

"The year since World IPv6 Launch began has cemented what we know will be an increasing reality on the Internet: IPv6 is ready for business," said Leslie Daigle, the Internet Society's Chief Internet Technology Officer. "Forward-looking network operators are successfully using IPv6 to reduce their dependency on expensive, complex network address translation systems (*Carrier Grade Network Address Translators*) to deal with a shortage of IPv4 addresses. Leaders of organizations that aspire to reach all Internet users must accelerate their IPv6 deployment plans now, or lose an important competitive edge."

As IPv6 adoption continues to grow, members of the worldwide Internet community are contributing to its deployment. Statistics reported by World IPv6 Launch participants underscore the increasing deployment of IPv6 worldwide:

- Google reports the number of visitors to its sites using IPv6 has more than doubled in the past year.
- The number of networks that have deployed IPv6 continues to grow, with more than 100 worldwide reporting significant IPv6 traffic.
- Australian ISP Internode reports that 10 percent of its customers now use IPv6 to access the Internet.
- Akamai reports that it is currently delivering approximately 10 billion requests per day over IPv6, which represents a 250 percent growth rate since June of last year.
- KDDI measurement shows that the number of IPv6 users of KDDI has doubled and that IPv6 traffic has increased approximately three times from last year.

World IPv6 Launch participants have worked together to help drive adoption, leading to the creation of *World IPv6 Day* in 2011, in which hundreds of websites joined together for a successful global 24-hour test flight of IPv6.

This was followed by World IPv6 Launch in 2012, in which more than a thousand participants permanently enabled IPv6 for their products and services, including four of the most visited websites: Google, Facebook, YouTube, and Yahoo!.

As a platform for innovation and economic development, the Internet plays a critical role in the daily lives of billions. This momentum has not slowed—IPv6 adoption continues to skyrocket, fast establishing itself as the "new normal" and a must-have for any business with an eye towards the future.

For more information about companies that have deployed IPv6, as well as links to useful information for users and how other companies can participate in the continued deployment of IPv6, please visit: **http://www.worldipv6launch.org**

IPv4 has approximately four billion IP addresses (the sequence of numbers assigned to each Internet-connected device). The explosion in the number of people, devices, and web services on the Internet means that IPv4 is running out of space. IPv6, the next-generation Internet protocol which provides more than 340 trillion, trillion, trillion addresses, will connect the billions of people not connected today and will help ensure the Internet can continue its current growth rate indefinitely.

The Internet Society is the trusted independent source for Internet information and thought leadership from around the world. With its principled vision and substantial technological foundation, the Internet Society promotes open dialogue on Internet policy, technology, and future development among users, companies, governments, and other organizations. Working with its members and Chapters around the world, the Internet Society enables the continued evolution and growth of the Internet for everyone. For more information, visit: **http://www.internetsociety.org**

RIPE NCC Report on ITU WTPF-13

The RIPE NCC has published a report on the recent *ITU World Telecommunications/ICT Policy Forum* (WTPF-13). The report is available from the following URL:

https://www.ripe.net/internet-coordination/news/ripe-ncc-report-on-the-itu-wtpf-13

Google.org Awards Grant to ISOC to Advance IXPs in Emerging Markets

The *Internet Society* (ISOC) recently announced that it has been awarded a grant by Google.org to extend its *Internet Exchange Point* (IXP) activities in emerging markets. The grant will build on the Internet Society's previous efforts and will establish a methodology to assess IXPs, provide training for people to operate the IXPs, and build a more robust local Internet infrastructure in emerging markets.

IXPs play an important role in Internet infrastructure that allows *Internet Service Providers* (ISPs) and other network operators to exchange traffic locally and more cost effectively, which can help lower end-user costs, speed-up transmissions, increase Internet performance, and decrease international Internet connectivity costs. The Internet Society and Internet technical experts have been working for several years to bring IXPs to emerging markets. These efforts have resulted in locally trained experts and facilitated the development of local and regional technical infrastructures. An additional benefit of IXP development is the expansion of community governance models as well as building local Internet expertise.

Google.org, a team within Google focused on social impact, develops and supports technology solutions that can address global challenges, such as expanding Internet access to more of the world's seven billion people.

"The Internet Society has proved to be one of the most effective institutions in the Internet community," said Vint Cerf, vice president and Chief Internet Evangelist at Google. "I am confident that they will apply their grant wisely to extend their work to increase Internet access for everyone, including those in emerging markets."

Lynn St. Amour, President and CEO of the Internet Society, stated, "We are very excited to receive this grant from Google.org. With support to extend our IXP development and improvement projects, we can more quickly bring core Internet infrastructure to underserved countries and assist in building key human and governance capabilities. We will also be able to extend the Internet Society's mission to ensure the open development, evolution, and use of the Internet for the benefit of people everywhere. We look forward to working with Google.org, and we are committed to collaborating with Internet community partners around the world on this important project."

IPJ Subscription FAQ

What is my "Subscription ID" for The Internet Protocol Journal (IPJ) and where do I find it?

Your Subscription ID is a unique combination of letters and numbers used to locate your subscription in our database. It is printed on the back of your IPJ issue or on the envelope. You will also find information about your subscription expiration date near your Subscription ID. Here is an example:

How do I renew or update my subscription?

From the IPJ homepage (**www.cisco.com/ipj**) click "Subscriber Service" and then enter your Subscription ID and your e-mail address in the boxes. After you click "Login" the system will send you an e-mail message with a unique URL that allows access to your subscription record. You can then update your postal and e-mail details, change delivery options, and of course *renew* your subscription.

What will you use my e-mail address and postal address for?

This information is used *only* to communicate with you regarding your subscription. You will receive renewal reminders as well as other information about your subscription. We will never use your address for any form of marketing or unsolicited e-mail.

I didn't receive the special URL that allows me to renew or update my Subscription. Why?

This is likely due to some form of spam filtering. Just send an e-mail message to **ipj@cisco.com** with your Subscription ID and any necessary changes and we will make the changes for you.

Do I need my Subscription ID to read IPJ online? What is my username and password?

Your Subscription ID is used *only* for access to your subscription record. No username or password is required to read IPJ. All back issues are available for online browsing or for download at **www.cisco.com/ipj**

I can't find my Subscription ID and I have since changed e-mail address anyway; what do I do now?

Just send a message to **ipj@cisco.com** and we will take care of it for you.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ contains standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`
