We have some options for Inter-AS traffic engineering: we can prepend additional AS numbers onto a prefix path, use *Multi-Exit Discriminators* (if the provider supports this), announce more specific prefixes or not announce prefixes at all, modify the origin type, or use communities designed by the other service provider. Communities are clean and consistent with regard to the method of signaling to an adjacent AS how each prefix should be treated.

Of most concern to downstream customers is controlling their primary and backup circuits. Small service providers and enterprises may negotiate different rates on different circuits. Customers purchasing transit with a commitment to send a high amount of traffic with a lower cost per megabit on one circuit, and on a second circuit purchase transit with a very low commitment but at a higher cost per megabit can save some money, assuming they use only the second circuit during outages on the first. Two simple communities can be used to effectively influence a service provider into using the appropriate primary and backup circuits: one value to lower and another to raise the preference of specific prefixes during the transit provider's best-path selection.

An example of adjusting Local Preference with communities can be found in RFC 1998, "An Application of the BGP Community Attribute in Multi-home Routing"[5].

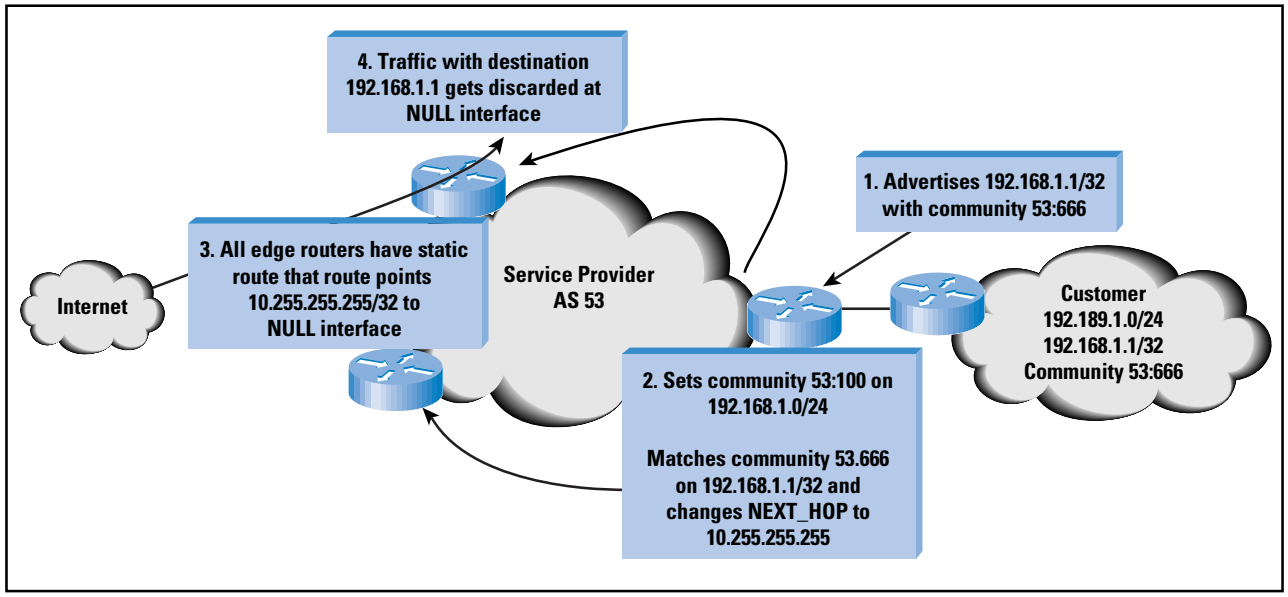
Some other traffic engineering signaling possibilities include:

- Force the adjacent AS to prepend its ASN a certain number of times to a prefix sent to customers or peers.
- Force the other side to selectively advertise a prefix to specific neighbors.
- Request that the neighbor drop all traffic to a prefix.

The last example may seem a little strange; if you are paying someone to deliver traffic, you expect to receive that traffic. Here is where communities can play a role in network security. *Denial-of-Service* (DoS) attacks may take out an entire customer's service, but the attack may be

focused on one or several hosts and not an entire network, as illustrated in Figure 3, allowing customers to tag individual host routes (a subnet consisting of a single address), the customer can signal to the provider to drop all traffic (black hole) for that specific address. To achieve this, the provider selects a single IP address and routes all traffic destined for it to the NULL interfaces on every BGP-speaking router. When a customer signals for a prefix to be blackholed, the service provider replaces the NEXT_HOP information in the BGP advertisement (which under normal circumstances is the edge router IP address) with the specific address that all other routers have statically routed to the NULL interface. When a packet arrives destined for the host under attack, the edge router performs a routing table lookup to find the BGP prefix; using the NEXT_HOP, it then performs a recursive lookup and ultimately sends the packet out the NULL interface. It is important to use other techniques such as prefix lists to prevent a third party from exploiting this technique to disrupt service for others in the Internet.

Figure 3: Customer-Initiated Black Hole to Defend Against a DoS Attack



A service provider may elect to send communities to its customers, leaving it up to the customers to decide for themselves which communities to act on. For a customer who is dual-homed to the same service provider in multiple states or countries, it may be helpful to know where a prefix was originated. A customer could use this community to prefer a connection in New York instead of a Los Angeles connection for European traffic. A single composite metric composed of all relevant geographical information is best, because this gives customers maximum flexibility in choosing the values that are meaningful to them.

Tagging the type of prefix may help other networks to selectively filter more specific addresses. Adding a community specifying if a block is a more specific part of a *Classless Inter-Domain Routing* (CIDR) block being advertised, the CIDR block itself, or if it is a more specific block but the CIDR block is not being advertised, can help the downstream network avoid incorrect filtering.

Example: Network A announces

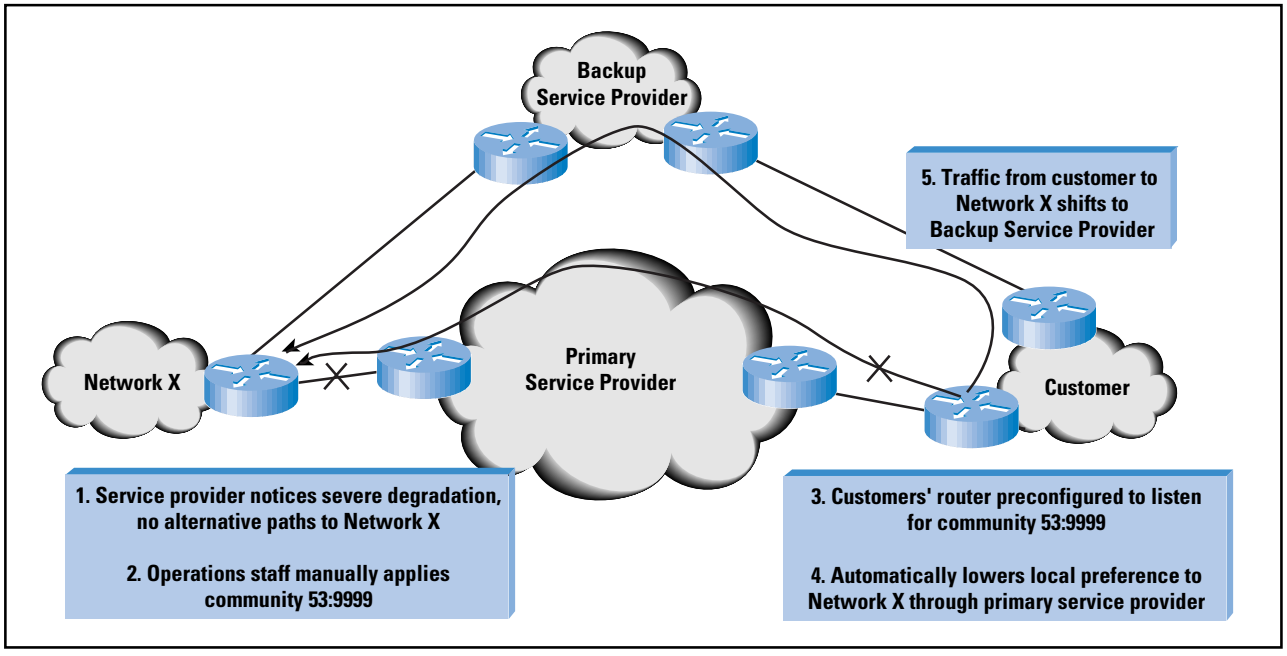
142.77.0.0/16 with a tag of **1:77**
142.77.1.0/24 with a tag of **1:88**
150.3.12.0/24 with a tag of **1:99**

1:77 means it is a CIDR block
1:88 means it is a more specific block within a CIDR block
1:99 means that the full CIDR block is not being announced

Network B then has the option of accepting the more specific **142.77.1.0/24**. It also knows that it must accept **150.3.12.0/24** because there is no other route to this network.

In extreme cases providers may find that a portion of their network has become severely degraded. Planned with customers in advance, the upstream provider manually sets a specific community on prefixes associated with the degradation to indicate that this path should be avoided. This could be helpful during natural disasters, fiber cuts, or other unanticipated network outages/degradation. The downstream customers' inbound filters would then match this community and lower the preference on the prefixes tagged with it, causing them to automatically shift traffic to an alternative source if it is available. The degradation signalling process can be seen in Figure 4.

Figure 4: Provided Initiated Signalling of Severe Route Degradation



Design Recommendations

The following are some suggestions if you are just starting out with using communities in your own network. Even the smallest network can benefit from starting early with a clean community design.

- Choose a set of internal communities that best reflects the topology and characteristics of your network. For external communities some service providers offer none, others offer only enough to allow for the tagging of primary and backup circuits, and others provide a seemingly endless list.
- Keep the set simple. Adding additional complexity typically requires changes to all the BGP-speaking edge routers. Router configurations can quickly grow to enormous proportions to accommodate the numerous community combinations. Troubleshooting a routing mess with a complex community structure can be difficult for those on the graveyard shift.
- Avoid transiting communities received from neighboring ASs blindly through your network. This could be abused intentionally or unintentionally to influence traffic to use your costly transit over settlement-free peering and revenue-generating customer circuits. Problems can be created farther out in the Internet and can be very difficult to locate. Depending on the support of your router software, you may be able to selectively add and remove communities, or failing that, you may need to remove all communities and re-add what is acceptable.
- Document your communities internally and externally. Your customers will appreciate the additional control, and your operations team will have an easier time troubleshooting.

Summary

Communities add power to BGP, changing it from a routing protocol to a tool for signaling and policy enforcement. If deployed correctly and consistently, communities can help make a network scale, easier to operate, easier to troubleshoot, and can give its customers what they want.

WAP: Broken Promises or Wrong Expectations?

by Edgar Danielyan, Danielyan Consulting LLP

The *Wireless Application Protocol* (WAP) was once hailed as the ultimate mobile Internet solution that would revolutionize how we use the Internet and mobile phones. As you may already know, it didn't. What is to blame? Is it bad technology, wrong time, or greedy network operators? Actually, is there a reason to blame anyone? This article introduces WAP with its related technologies and tries to answer these questions. Although WAP is available on a variety of wireless mobile networks, such as those employing *Code Division Multiple Access* (CDMA) IS-95, *Time Division Multiple Access* (TDMA) IS-136, *International Mobile Telecommunications* (IMT-2000), *Universal Mobile Telecommunication System* (UMTS), and *Wideband Code Division Multiple Access* (W-CDMA), in addition to GSM/GPRS this article covers WAP over GSM/GPRS networks only.

A Case for WAP

Before looking at WAP itself, let's first recall what sparked its idea and development. As we all know, most if not all *second-generation* (2G) mobile phones and networks suffer from numerous limitations that make it impossible or impractical to use standard Internet protocols and technologies on today's mobile phones. The most visible of these limitations include the following:

- Low bandwidth (usually 9.6 kbps)
- High network latency
- Small, mostly monochrome displays
- Numeric keypads
- Slow processors
- Limited memory

All these limitations meant that it was necessary to develop an alternative suite of protocols and technologies that would work on these mobiles phones but still provide functionality comparable to the standard Internet technologies used on wired networks and desktops. WAP was developed to address these issues[1].

WAP Forum and Open Mobile Alliance

The *WAP Forum* is the industry organization behind WAP and its associated protocols and technologies. In 2002, the WAP Forum and the Open Mobile Architecture Initiative merged, creating the *Open Mobile Alliance* (OMA), which will continue work on WAP 2 and develop new mobile and wireless solutions. Nearly 200 of the world's top network operators, vendors, and content providers are members of the Open Mobile Alliance[2]. Other organizations such as the *Location Interoperability Forum* (LIF)[3], *Multimedia Messaging (MMS) Interoperability Group* (MMS-IOP)[4], *SyncML Initiative*[5], and *Wireless Village Initiative*[6] have announced their support for the new organization.

Global System for Mobile Communications

GSM, or *Global System for Mobile Communications,* is used by more than 700 million people across 190 countries[7]. In less than ten years after its introduction, GSM became the most popular and widely used digital mobile wireless communications standard in the world. GSM networks use TDMA technology and are fully digital, employing a unique voice codec known as *GSM codec* to provide relatively good voice quality using narrow bandwidth (usually 9.6 kbps). However, GSM is not as secure as many may think. Although it does use encryption and smartcard technology, this didn't result in strong security. As a result, it is possible to intercept and decrypt GSM communications, fake short text messages (*Short Message Service* [SMS]), and clone *Subscriber Identification Modules* (SIMs), miniature smartcards used to identify subscribers to the GSM network. GSM security is not the subject of this article, but it deserves attention and I hope to cover it in a separate article in this journal.

Wireless Application Environment

Before proceeding further, we should clarify one point. The term "WAP" is usually used to refer to the entire suite of protocols and technologies that are actually called the *Wireless Application Environment* (WAE)[8]. However, "WAP" is used everywhere to refer to WAE (which includes WAP). Because WAP is the commonly used term, we shall continue to use it as well.

Wireless Application Protocol

WAP protocols were expected to satisfy the following criteria in order to implement the objectives set by the WAP Forum:

- Independent of wireless network standard (bearer technology)
- Open to all
- Will be proposed to the appropriate standards bodies
- Applications scale across transport options
- Applications scale across device types
- Extensible to new networks and transports

The objectives of the WAP as defined by the WAP Forum follow:

- To bring Internet content and advanced data services to digital cellular phones and other wireless terminals
- To create a global wireless protocol specification that will work across differing wireless network technologies
- To enable the creation of content and applications that scale across a very wide range of bearer networks and device types
- To embrace and extend existing standards and technology wherever appropriate

Two major versions of WAP exist—Versions 1 and 2. WAP Version 2 is backward compatible with WAP Version 1 and tends to be more integrated with the newest Internet and Web standards than WAP 1. Although WAP uses many technologies and concepts from the Internet and Web worlds, because of their inherent limitations, WAP devices are unable to directly access Web resources on the Internet[9]. To do so, they must use a WAP gateway. The following table shows the relationship between the WAP client device, WAP gateway, and Web servers on the Internet, with their protocol layers side by side:

Web Client	WAP Gateway	Web Server
WSP	WSP/HTTP	HTTP
WTP	WTP/HTTP	HTTP
WTLS	WTLS/SSL/TLS	SSL/TLS
WDP	WDP/TCP/UDP	TCP/UDP
Bearer	Bearer/IP	IP

The table shows that the main function of the WAP gateway is to translate between WAP and Web/Internet protocols, conventions, and encodings. In some cases the WAP gateway and the Web server may be the same system, eliminating the need for a separate WAP gateway and possibly improving performance—however, for this setup to work the combined WAP/Web server has to be integrated into the mobile/wireless network provider's infrastructure. In practice, network operators provide the WAP gateway services and content providers offer WAP content on separate Web servers configured for WAP access (any standards-compliant Web server can do this).

Wireless Session Protocol

The *Wireless Session Protocol* (WSP) is the WAP session-layer protocol for remote operations between a wireless (WAP) client and proxies, gateways, and servers[10]. It functions above the *Wireless Transaction Protocol* (WTP) and the *Wireless Datagram Protocol* (WDP), and optionally, the *Wireless Transport Layer Security* (WTLS). The WSP provides a way for an organized exchange of data between client/server applications in a wireless environment. It provides such features as establishment and release of sessions between client and server; agreement on common functionality by way of negotiation; and exchange of data between client and server using compact encoding. WSP defines two subprotocols—a connection-oriented session service protocol over WTP and a connectionless service protocol over the WDP.

Wireless Transaction Protocol

WTP runs on top of the WDP and optionally, the WTLS protocol, and provides the request/response protocol used by WAP browsers to request and receive content[11]. WTP is a reliable transaction-oriented protocol specially designed for wireless networks—in WTP there are no connection setup or release phases.

Reliability in WTP is achieved using transaction IDs, retransmissions, acknowledgments, and removal of duplicates.

Wireless Datagram Protocol

WDP is the transport protocol of WAP[12]. It operates directly above the bearer technology (such as GSM CSD or GPRS) and directly below WTP described previously. WDP provides a consistent, bearer-independent interface for the upper-level protocols to the transport service provided by WDP. In addition to the GSM *Circuit Switched Data* (CSD) and the *General Packet Radio Service* (GPRS), WDP supports the following wireless bearer technologies:

GSM SMS	IDEN Packet Data
GSM USSD	FLEX
GSM Cell Broadcast	REFLEX
ANSI-I36	PHS CSD
CDPD	DataTAC
CDMA CSD	TETRA Short Data Service
CDMA Packet Data	TETRA Packed Data
CDMA SMS	DECT SMS
PDC Circut Switched Data	DECT Connection-oriented Service
PDC CSD	DECT Packed Switched Service
PDC Pacet Data	Mobitex
IDEN CSD	

When used over GSM CSD, WDP actually uses the *User Datagram Protocol* (UDP) in the following way:

Layer 4: UDP
Layer 3: Internet Protocol (IP)
Layer 2: Point-to-Point Protocol (PPP)
Layer 1: GSM CSD

When used over the GPRS, PPP at Layer 2 is not necessary, because GPRS works at Layers 1 and 2:

Layer 4: UDP
Layer 3: IP
Layers 1 and 2: GSM and GPRS

In all cases when IP is supported over a given bearer, UDP is used by WDP—actually, UDP is the WDP in these cases.

Wireless Control Message Protocol

Not surprisingly, *Wireless Control Message Protocol* (WCMP) resembles and corresponds to the *Internet Control Message Protocol* (ICMP) of TCP/IP networks[13]. WCMP is used by WDP nodes to report errors and provide network information and diagnostics. However, WCMP is not necessary and is not used with bearers that support IP—the function of WCMP in these circumstances is carried out by ICMP. In particular, this is the case with GSM CSD and GPRS bearers.

Wireless Transport Layer Security

WTLS is the transport layer security protocol of the WAE that provides privacy, integrity, and authentication services[14]. It is heavily influenced by the *Transport Level Security* (TLS) protocol Version 1 and includes additional support for optimized handshake, connectionless transport, and dynamic key refresh. WTLS, like other WAP protocols, is optimized for low-bandwidth, high-latency wireless networks and supports server and client certificates for mutual authentication. WTLS includes the following three subprotocols:

- Cipher protocol
- Alert protocol
- Handshake protocol

The following cryptographic algorithms are used by the Wireless TLS protocol:

- RSA
- SHA-1
- Diffie-Hellman (DH)
- Elliptic Curve Diffie-Hellman (EC-DH)
- DSA
- Elliptic Curve DSA (EC-DSA)
- MD5
- RC5
- DES
- IDEA

WTLS is tightly linked to and works in conjunction with the *Wireless Public Key Infrastructure* (WPKI).

Wireless Public Key Infrastructure

WPKI tries to reuse the existing *Public Key Infrastructure* (PKI) standards as much as practical to provide an adequate PKI framework for the WAE. Both X.509 and WTLS certificates can be used by WTLS[15].

Wireless Markup Language Version 1

The *Wireless Markup Language* (WML) Version 1[16] is used in WAP/WAE 1 and supported in WAE 2. Unlike usual HTML, it is a strict application of the *Extensible Markup Language* (XML), specially designed for use on narrowband devices. Also unlike HTML, WML has a metaphor of *decks* and *cards*. A deck contains one or more cards, and cards in turn contain one or more screens of user interaction. This metaphor helps increase efficiency on low-speed, high-latency wireless networks by bundling several screens into a single WML file (deck). WML supports all basic text display options, such as *italic*, **boldface**, and underlined text, as well as inter-card and inter-deck navigation using hyperlinks. The most apparent difference between HTML and WML noted by HTML developers is the fact that WML is a strict markup language and does not tolerate even seemingly little errors—an incorrectly written WML file will not display at all. Some would say this is an overkill but it is not—this feature of WML is important because compiled versions of WML files are sent to WAP clients by the WAP gateway instead of the source WML text files. This compiled bytecode is known as *WMLC*, and it considerably lessens the time it takes to download a WML document.

WML Version 2

WML version 2 is based on XHTML Basic with additional modules for support of features specific to wireless devices—this extended XHTML is called *XHTML Mobile Profile* (XHTML-MP)[17]. WML Version 2 is backward compatible with WML Version 1, so devices able to display WML 2 will also display WML 1 content. Use of XHTML shows that WAP in Version 2 is moving toward even closer integration with Internet and Web standards.

WMLScript

WMLScript is a lightweight scripting language based on ECMAScript, which is in turn based on JavaScript[18]. It is well integrated with WML and has a defined set of standard libraries, including support for cryptographic functions. Like WML, WMLScript files are also compiled into bytecode and only then sent to the requesting WAP device. Another difference between JavaScript and WMLScript is that WMLScript content is not embedded in WML pages but instead is requested separately—the necessary WMLScript functions are only referenced in WML pages. The main use of WMLScript is the client-side validation of user input—accepting only valid input is more crucial for WAP than for Web applications because of the low-speed and usually expensive nature of WAP transport.

Wireless bitmaps

The *Wireless Bitmaps* (WBMP) file format (`.wbmp`) is used by WAP devices to transmit and display small and simple monochrome bitmap images[19].

GSM CSD

CSD is the traditional data service provided by GSM networks. Also known as a *data call service*, it provides either a 9.6- or 14.4-kbps dialup facility and is supported by all GSM networks. Data calls are possible both from and to a GSM network. When used as a bearer for WAP, it serves at the physical layer of the *Open System Interconnection* (OSI) model, with PPP used in the usual way.

High-Speed Circuit Switched Data

The *High-Speed Circuit Switched Data* (HSCSD) service is similar in nature to CSD, but provides 28.8 or 43.2 kbps of bandwidth. It is not as widespread as the regular CSD, nor it is as asked-for as GPRS.

General Packet Radio Service

GPRS is an always-on, higher-speed alternative to the CSD service of GSM networks. It solves two of the most annoying issues of GSM data users—connection delay (the time it takes to set up a data call before data may be sent or received) and the bandwidth limitation, increasing the supported data rates to 48 kbps, with theoretical maximum of 171.2 kbps. Because GPRS is a connectionless packet service, GPRS terminals are always connected and may send and receive IP packets at any time. This makes possible applications such as instant messaging previously impossible or impractical with GSM CSD. Eight time slots are available for GPRS in GSM networks, but only five may be used simultaneously. The GPRS class supported by the GPRS terminal dictates what data rates are possible:

Class 2:	Uplink 8–12 kbps, downlink 16–24 kbps
Class 4:	Uplink 8–12 kbps, downlink 24–36 kbps
Class 6:	Uplink 16–24 kbps, downlink 24–36 kbps, or Uplink 24–36 kbps, downlink 16–24 kbps
Class 8:	Uplink 8–12 kbps, downlink 32–40 kbps
Class 10:	Uplink 8–12 kbps, downlink 32–48 kbps, or Uplink 16–24 kbps, downlink 24–36 kbps
Class 12:	Uplink 8–12 kbps, downlink 32-48 kbps, or Uplink 16–24 kbps, downlink 24–36 kbps, or Uplink 24–36 kbps, downlink 16–24 kbps, or Uplink 32–48 kbps, downlink 8–12 kbps

In addition to the classes of GPRS service, there are three classes of GPRS terminals:

- Class A terminals can be connected to GSM and GPRS services simultaneously.
- Class B terminals can be connected to both GSM and GPRS services, but can use only one service at a time.
- Class C terminals can be connected to either GSM or GPRS services but the user has to switch between two modes of operation.

When used as a bearer for WAP, GPRS works at the physical and data link layers of the OSI reference model. Because GPRS is connectionless and always on, there is no need for PPP—so IP works directly over GPRS.

So Why Aren't We Happy with WAP?

Many surveys of customer opinion show that the end users of WAP are not as happy as WAP developers and content providers wanted them to be. WAP service and content providers discovered that sign-up and usage rates of WAP services have not reached two-thirds of the total customer base once predicted. In short, WAP didn't change the world, and people still use their mobile phones mainly to talk to each other and send a text message or two. If you have used WAP, you probably know the reasons: the data transfer rate is slow, screens are small, charges are high, and it is tiring to type even a short URL or an e-mail message using the ten keys of a phone.

But wait a moment—are these limitations of WAP or the handsets and networks they use? Remember, WAP was required to work on devices with many limitations? So it does. Is WAP to blame that these devices have these limitations? No, that wouldn't be just. But of course it is not only the today's technology restrictions that stood in the way of the widespread usage and popularity of WAP. Scarcity of WAP content and services also contributed to this. Relatively high charges for WAP/data usage by network operators didn't help either, so the combination of these issues resulted in the situation we have today—most networks support WAP but most users don't use it anyway.

Is the technology dead, as some think? Definitely not—there are millions of WAP handsets and most wireless users will not have 3G for the foreseeable future because of both technical and economic issues, so the only available solution for these users is WAP. On the other side, 3G networks and handsets are coming and will be upon us sooner or later (they are already available in some countries), and only time will show whether tomorrow's WAP will be more popular or less relevant when 3G finally arrives. And, of course, fundamental limits of mobile phones—screen sizes, power consumption, and input methods—will still remain relevant. Other issues, such as the time it takes to set up a CSD connection, are solved by newer technologies such as GPRS, and are not really faults of WAP. You may say that if GRPS is available why would you need WAP? Why not run trusted IP? Well, this is true if you are using GPRS with a laptop or a palmtop computer, but a large majority of mobile phones don't have the resources necessary to run IP, UDP, TCP, HTTP/HTTPS, POP, and SMTP—so even if GPRS is available but your equipment cannot run the full TCP/IP suite, your only choice is still WAP.

Although WAP is clearly not as popular as its proponents and developers hoped, it is still used and developed, and handsets that support only WAP are still sold. But the hype and excitement built up by the media and the industry didn't match the reality, and it is these unrealistic expectations that have broken the promise of WAP.

Additional Acronyms

DataTAC:	*Motorola wireless data system*

The IETF IPv6 Operations Group and the Development of a Framework for Deployment of IPv6 into IPv4 Networks

by Bob Fink,
Margaret Wasserman, Wind River,
Jun-ichiro Itojun Hagino, IIJ

During 2002, the *Internet Engineering Task Force* (IETF) determined that it was best to focus the introduction of IPv6 into the IPv4 Internet by developing deployment scenarios before further development of transition mechanisms without any clearly identified framework for their place in an IPv6 deployment.

Previously the IPv6 Transition working group of the IETF, called *ngtrans* (for IP next-generation transition), was chartered to develop mechanisms and tools to support an IPv6 transition. This work initially focused, in 1995–1996, on the development of the original IPv6 standards, and it led to the basic Transition Mechanism RFC 1933[1] and later RFC 2893[2] that defined dual IPv4 and IPv6 protocol stack operation as well as IPv6-over-IPv4 tunnels.

Subsequent attempts to define a framework for transition in 1998–1999 were not successful because there did not appear to be a single vision for a transition to IPv6. Indeed the focus became one of how to have IPv4 and IPv6 coexist for a long period of time, because most felt that a full transition could take well over 10–15 years, with many believing that it would never completely obsolete IPv4. This led to the development of many transition mechanisms and tools, some of which might possibly be more useful than others, that never fit into a coherent framework for operation of a *dual protocol,* that is, IPv4 and IPv6, network.

v6ops

Thus in 2002 the ngtrans working group was disbanded, and the IPv6 Operations working group, *v6ops,* created. The v6ops working group was chartered to:

- Solicit input from network operators and users to identify operational or security issues with the IPv4/IPv6 Internet, and determine solutions or workarounds to those issues. This includes identifying standards work that is needed in other IETF working groups or areas and working with those groups or areas to begin appropriate work. These issues will be documented in Informational or *Best Current Practice* (BCP) RFCs, or in Internet-Drafts. For example, important pieces of the Internet infrastructure such as the *Domain Name System* (DNS), the *Simple Mail Transfer Protocol* (SMTP), and the *Session Initiation Protocol* (SIP) have specific operational issues when they operate in a shared IPv4/IPv6 network. The v6ops working group will cooperate with the relevant areas and working groups to document those issues, and find protocol or operational solutions to those problems.

- Provide feedback to the IPv6 working group regarding portions of the IPv6 specifications that cause, or are likely to cause, operational or security concerns, and work with the IPv6 working group to resolve those concerns. This feedback will be published in Internet-Drafts or RFCs.
- Publish Informational RFCs that help application developers (within and outside the IETF) understand how to develop IP version-independent applications. Work with the Applications area, and other areas, to ensure that these documents answer the real-world concerns of application developers. This includes helping to identify IPv4 dependencies in existing IETF application protocols and working with other areas or groups within the IETF to resolve them.
- Publish informational or BCP RFCs that identify potential security risks in the operation of shared IPv4/IPv6 networks, and document operational practices to eliminate or mitigate those risks. This work will be done in cooperation with the Security area and other relevant areas or working groups.
- Publish Informational or BCP RFCs that identify and analyze solutions for deploying IPv6 within common network environments, such as *Internet Service Provider* (ISP) networks (including core, *Hybrid Fiber-Coaxial* [HFC] or cable, DSL, and dialup networks), enterprise networks, unmanaged networks (home or small office), and cellular networks. These documents should serve as useful guides to network operators and users on how to deploy IPv6 within their existing IPv4 networks, as well as in new network installations.
- Identify open operational or security issues with the deployment scenarios documented in the previous bullet point and fully document those open issues in Internet-Drafts or informational RFCs. Try to find workarounds or solutions to basic, IP-level operational or security issues that can be solved using widely applicable transition mechanisms, such as dual-stack, tunneling, or translation. If the satisfactory resolution of an operational or security issue requires the standardization of a new, widely applicable transition mechanism that does not properly fit into any other IETF working group or area, the v6ops working group will standardize a transition mechanism to meet that need.
- Assume responsibility for advancing the basic IPv6 transition mechanism RFCs along the standards track, if their applicability to common deployment scenarios is demonstrated.

v6ops has started by creating four efforts to define transition scenarios and subsequently to analyze them for potential solutions to the deployment scenarios. These four efforts follow:

- *Third Generation Partnership Project* (3GPP) defined packet networks, that is, *General Packet Radio Service* (GPRS) that would need IP Version 6 deployment into the IPv4 Internet.

- "Unmanaged networks," which typically correspond to home networks or small office networks.
- ISP networks, including core, HFC or coaxial, DSL, dialup, public wireless, broadband Ethernet, and Internet exchange points.
- Enterprise networks, which are networks that have multiple links and a router connection to an ISP, and are actively managed by a network operations entity.

During 2003 and 2004 it is expected that these deployment scenario efforts will lead to further analysis and identification of deployment solutions and development of appropriate mechanisms to support them.

In addition to this work, serious efforts are under way to engage the entire IETF standards process in the identification and development of appropriate solutions for an IPv6 deployment. One such effort is the *IPv4 Survey* project, which has reviewed the entire IETF RFC catalog of standards to identify what work might need to be done and to disseminate this information to the appropriate area within the IETF.

As progress is made in v6ops, follow-up articles in IPJ will inform you of these efforts.

Opinion: The Mythology of IP Version 6

by Geoff Huston, Telstra

Disclaimer: This is an opinion piece and, therefore, the author takes some liberties in making his points. I hope you as the reader take this in the spirit in which it is intended—a gentle poke at ourselves that sometimes we oversell ourselves and our technology.

In January 1983, the *Advanced Research Projects Agency Network* (ARPANET) experienced a "flag day," and the Network Control Protocol, NCP, was turned off, and TCP/IP was turned on. Although there are, no doubt, some who would like to see a similar flag day where the world turns off its use of IPv4 and switches over to IPv6, such a scenario is a wild-eyed fantasy. Obviously, the Internet is now way too big for coordinated flag days. The transition of IPv6 into a mainstream deployed technology for the global Internet will take some years, and for many there is still a lingering doubt that will happen at all.

Let's look more closely at how IPv6 came about, and then look at IPv6 itself in some detail to try to separate the myth from the underlying reality about the timeline for the deployment of IPv6. Maybe then we can suggest some answers to these questions.

IPv6

The effort that has led to the specification of IPv6 is by no means a recently started initiative. A workshop hosted by the then *Internet Activities Board* (IAB) in January 1991 identified the two major scaling issues for the Internet: a sharply increasing rate of consumption of address space and a similar, unconstrained growth of the interdomain routing table. The conclusion reached at the time was that "if we assume that the Internet architecture will continue in use indefinitely, then we need additional [address] flexibility."

These issues were considered later that year by the *Internet Engineering Task Force* (IETF) with the establishment of the ROAD (*ROuting and ADdressing*) effort. This effort was intended to examine the issues associated with the scaling of IP routing and addressing, looking at the rate of consumption of addresses and the rate of growth of the interdomain routing table. The ultimate objective was to propose some measures to mitigate the worst of the effects of these growth trends. Given the exponential consumption rates then at play, the prospect of exhaustion of the IPv4 Class B space within two or three years was a very real one at the time. The major outcome of the IETF ROAD effort was the recommendation to deprecate the implicit network/host boundaries that were associated with the Class A, B, and C address blocks. In their place the IETF proposed the adoption of an address and routing architecture where the network/host boundary was explicitly configured for each network, and proposed that this boundary could be altered such that two or more network address blocks may be aggregated into a common, single block.

Side Note:

Some would argue that although CIDR was important, it was not the only reason why IPv4 has been able to defy the earlier predictions of its imminent demise. Dynamic *Network Address Translation*, or NAT, allows a network to use a local private address pool to uniquely number its devices, and then translate these private addresses into public addresses to support transactions involving local and external end points. This way, a small pool of public addresses, or even a single address, is used to service a very much larger local private network. It is difficult to estimate the number of devices that are positioned behind NATs, but a highly conservative estimate would see the Internet being at least three times as large as the directly visible part of the Internet.

Side Note:

At an IETF plenary session from that time, the OSI protocol suite was termed the "Road-kill of the Information Superhighway." It was not completely clear that the presenter made the comment in jest!

This approach was termed *Classless Interdomain Routing*, or CIDR. This was a short-term measure that was intended to buy some time, and it was acknowledged that it did not address the major issue of defining a longer-term, scalable network architecture. But as a short-term measure it has been amazingly successful, given that almost ten years and one Internet boom later, the CIDR address and routing architecture for IPv4 is still holding out.

The IAB, by then renamed the Internet *Architecture* Board, considered the ROAD progress in June 1992, still with its eye on the longer-term strategy for Internet growth. The board's proposal was that the starting point for the development of the next version of IP would be *Connectionless Network Layer Protocol* (CLNP). This protocol was an element of the *Open System Interconnection* (OSI) protocol suite, with CLNP being defined by the ISO 8473 standard. It used a variable-length address architecture, where network level addresses could be up to 160 bits long. RFC 1347 contained an initial description of how CLNP could be used for this purpose within the IPv4 TCP/IP architecture and with the existing Internet applications. For the IAB this was a bold step, and considering that the IETF community at the time regarded the OSI protocol suite as a very inferior competitor to its own efforts with IP, it could even be termed a highly courageous step. Predictably, one month later in July 1992, at the IETF meeting this IAB proposal was not well received.

The IETF outcome was not just a restatement of architectural direction for IP, but a sweeping redefinition of the respective roles and membership of the various IETF bodies, including that of the IAB.

Of course such a structural change in the composition, roles, and responsibilities of the bodies that collectively make up the IETF could be regarded as upheaval without definite progress. But perhaps this is an unkind view, because the IAB position also pushed the IETF into a strenuous burst of technical activity. The IETF immediately embarked on an effort to undertake a fundamental revision of the Internet Protocol that was intended to result in a protocol that had highly efficient scaling properties in both addressing and routing. There was no shortage of protocols offered to the IETF during 1992 and 1993, including the fancifully named TUBA, as well as PIP, SIPP and NAT.

This effort was part of a process intended to understand the necessary attributes of such a next-generation protocol.

The IETF formed an *Internet Protocol Next Generation (IPng) Directorate* in 1994, and canvassed various industry sectors to understand the broad dimensions of the requirements of such a protocol. This group selected the IPv6 Protocol from a set of proposals, largely basing its selection on the so-called "Simple Internet Protocol," or SIP proposal. The essential characteristic of the protocol was that of an evolutionary refinement of the Version 4 protocol, rather than a revolutionary departure from Version 4 to an entirely different architectural approach.

Side Note:

IPv6 has had a variety of names—the original IAB documents refer to IP Version 7, working on the assumption that the protocol numbers 5 and 6 were already in use in research networks. It was renamed IPng, for "next generation."

The final word from the *Internet Assigned Numbers Authority* (IANA) was that protocol number 6 was unused, and the final specification was named Version 6 of the Internet Protocol.

The major strength of IPv6 is the use of fixed-length, 128-bit address fields. Other packet header changes include the dropping of the fragmentation control fields from the IP header, dropping the header checksum and length, and altering the structure of packet options within the header and adding a flow label. But it is the extended address length that is the critical change with IPv6. A 128-bit address field allows an addressable range of 2 to the 128th power, and 2 to the power of 128 is an exceptionally large number. On the other hand, if we are talking about a world that is currently capable of manufacturing more than a billion silicon chips every year, and recognizing that even a one in one thousand address utilization rate would be a real achievement, then maybe it is not all that large a number after all. There is no doubt that such a protocol has the ability to encompass a network that spans billions of devices, which is a network attribute that is looking more and more necessary in the coming years.

Its not just the larger address fields per se, but also the ability for IPv6 to offer an answer to the address scarcity workarounds being used in IPv4 that is of value here. The side effect of these larger address fields is that there is then no forced need to use NAT as a means of increasing the address scaling factor. NAT has always presented operational issues to both the network and the application. NAT distorts the implicit binding of IP address and IP identity and allows only certain types of application interaction to occur across the NAT boundary. Because the "interior" to "exterior" address binding is dynamic, the only forms of applications that can traverse a NAT are those that are initiated on the "inside" of the NAT boundary. The exterior cannot initiate a transaction with an interior end point simply because it has no way of addressing this remote device. IPv6 allows all devices to be uniquely addressed from a single address pool, allowing for coherent end-to-end packet delivery by the network. This in turn allows for the deployment of end-to-end security tools for authentication and encryption and also allows for true peer-to-peer applications.

IPv6, as a protocol architecture, is not a radical departure from the architecture of IPv4. The same datagram delivery model is used, with the same minimal set of assumptions about the underlying network capabilities, and the same decoupling of the routing and forwarding capabilities. The use of an address field in the IP header to contain the semantics of both location and identity was not altered in any fundamental way. The changes made by IPv6 could be seen as conservative set of decisions, based on falling back to the IPv4 protocol model for guidance, on the principle that IPv4 is an operating proof of concept for this architectural approach.

In such a light, IPv6 can be seen as an attempt to regain the advantage of the original IP network architecture: that of a simple and uniform network service that allows maximal flexibility for the operation of the end-to-end application.

It is often the case that complex architectures scale very poorly, and from this perspective the core of IPv6 appears to be a readily scalable architecture.

The Mythology of IPv6

Good as all this is, these attributes alone have not been enough so far to propel IPv6 into broad-scale deployment, and consequently there has been considerable enthusiasm to discover additional reasons to deploy IPv6. Unfortunately, most of these reasons fall into the category of myth, and in looking at IPv6 it is probably a good idea, as well as fair sport, to expose some of these myths as well.

"IPv6 Is More Secure"

A common claim is that IPv6 is more "secure" than IPv4. It is more accurate to indicate that IPv6 is no more or less secure than IPv4. Both IPv4 and IPv6 offer the potential to undertake secure transactions across the network, and both protocols are potentially highly capable in attempting to undertake highly secure transactions. Yes, the IPv6 specification includes as mandatory support for *Authentication and Encapsulating Security Payload* extension headers, but no, there is no "mandatory to use" sticker associated with these extension headers, and, like IPv4 *IP Security* (IPSec), it is left to the application and the user to determine whether to deploy security measures at the network transport level. So, to claim that IPv6 is somehow implicitly superior to IPv4 is an overly enthusiastic claim that falls into the category of "IPv6 myth."

Now I should qualify this, because there is a distinction between the protocol and its environment of deployment. In the case of IPv4, this protocol capability is compromised in many environments in the face of various forms of deployed active middleware such as NAT. It's too early to tell with IPv6, but the line of argument is that NAT-based active middleware has been deployed as a means of address extension, and in a IPv6 world such devices are no longer necessary, and will not be deployed. So perhaps one could say that IPv6 enables a path toward widespread peer-to-peer authentication and transport security at the protocol level, but whether the deployment models faithfully follow along such a path remains an open question.

"IPv6 Is Required for Mobility"

It is also claimed that only IPv6 supports mobility. If one is talking about a world of tens of billions of mobile devices, then the larger IPv6 address fields are entirely appropriate for such large-scale deployments. IPv6 includes a developing concept of stateless autoconfiguration and *Neighbor Discovery* mechanisms.

But if the claim is more about the technology to support mobility than the number of mobile devices, then this claim also falls short. The key issue with mobility is that mobility at a network layer requires the network to separate the functions of providing a unique identity for each connected device, and identifying the location within the network for each device.

As a device "moves" within the network its identity remains constant while its location is changing. IPv4 overloaded the semantics of an address to include both identity and locality within an address, and IPv6 did not alter this architectural decision. In this respect, IPv4 and IPv6 offer the same levels of support for mobility. Both protocols require an additional header field to support a decoupled network identity, commonly referred to as the "home address," and then concentrate on the manner of the way in which the home agent maintains a trustable and accurate copy of the mobile node or current location of the network. This topic remains the subject of activity within the IETF in both IPv4 and IPv6.

"IPv6 Is Better for Wireless Networks"

Mobility is often associated with wireless, and again there has been the claim that somehow IPv6 is better suited for wireless environments than IPv4. Again this is well in the realm of myth.

Wireless environments differ from wireline environments in numerous ways. One of the more critical differences is that a wireless environment may experience bursts of significant levels of bit error corruption, which in turn will lead to periods of non-congestion-based packet loss within the network. A TCP transport session is prone to interpreting such packet loss as being the outcome of network level congestion. The TCP response is not only retransmission of the corrupted packets, but also an unnecessary reduction of the sending rate at the same time. Neither IPv4 nor IPv6 have explicit signaling mechanisms to detect corruption-based packet loss, and in this respect the protocols are similarly equipped, or ill-equipped as in this case, to optimize the carriage efficiency and performance of a wireless communications subnet.

"IPv6 Offers Better QoS"

Another consistent assertion is that IPv6 offers "bundled" support for differentiated *Quality of Service* (QoS), whereas IPv4 does not. The justification for this claim often points to the 20-bit flow label in the IPv6 header as some kind of instant solution to QoS. This claim conveniently omits to note that the flow identification field in the IPv6 header still has no practical application in large-scale network environments. Both IPv4 and IPv6 support an 8-bit traffic class field, which includes the same 6-bit field for differentiated service code points, and both protocols offer the same fields to an *Integrated Services* packet classifier. From this perspective, QoS deployment issues are neither helped nor hindered by the use of IPv4 or IPv6. Here, again, it is a case of nothing has changed.

"Only IPv6 Supports Auto-Configuration"

Another common claim is that only IPv6 offers "plug-and-play" auto-configuration. Again this is an overenthusiastic statement, given the widespread use of the *Dynamic Host Configuration Protocol* (DHCP) in IPv4 networks these days. Both protocol environments support some level of "plug-and-play" auto-configuration capability, and in this respect the situation is pretty much the same for both IPv4 and IPv6.

"IPv6 Solves Routing Scaling"

It would be good if IPv6 included some novel approach that solved, or even mitigated to some extent, the routing scaling issues. Unfortunately, this is simply not the case, and the same techniques of address aggregation using provider hierarchies apply as much to IPv6 as they do to IPv4. The complexity of routing is an expression of the product of the topology of the network, the policies used by routing entities, and the dynamic behavior of the network—not the protocol being routed. The larger address space does little to improve on capability to structure the address space in order to decrease the routing load. In this respect IPv6 does not make IP routing any easier, nor any more scalable.

"IPv6 Provides Better Support for Rapid Prefix Renumbering"

If provider-based addressing is to remain an aspect of the deployed IPv6 network, then one way to undertake provider switching for multi-homed end networks is to allow rapid renumbering of a network common prefix. Again, it has been claimed that IPv6 offers the capability to undertake rapid renumbering within a network to switch to a new common address prefix. Again IPv6 performs no differently from IPv4 in this regard. As long as "rapid" refers to a period of hours or days, then yes, IPv4 and IPv6 both support "rapid" local renumbering. For a shorter time frame for "rapid," such as a few seconds or even a few milliseconds, this is not really the case.

"IPv6 Provides Better Support for Multihomed Sites"

This leads on to the more general claim that IPv6 supports multi-homing and dynamic provider selection. Again this is an optimistic claim, and the reality is a little more tempered. Multihoming is relatively easy if you are allowed to globally announce the network address prefix without recourse to any form of provider-based address aggregation. But this is a case of achieving a local objective at a common cost of the scalability of the entire global routing system, and this is not a supportable cost. The objective here is to support some form of multihoming of local networks where any incremental routing load is strictly limited in its radius of propagation. This remains an active area of consideration for the IETF and clear answers, in IPv4 or IPv6, are not available at present. So at best this claim is premature, and more likely the claim will again fall into the category of myth rather than firm reality.

"IPv4 Has Run Out of Addresses"

Again, this is in the category of myth rather than reality. Of the total IPv4 space, some 6 percent is reserved and another 6 percent is used for multicast. Forty-one percent of the space has already been allocated, and the remaining 37 percent (or some 1.5 billion addresses) is yet to be allocated. Prior to 1994, some 36 percent of the address space had been allocated. Since that time, and this includes the entire Internet boom period, a further 15 percent of the available address space was allocated. With a continuation of current policies it would appear that IPv4 address space will be available for many years yet.

So Why IPv6 Anyway ?

The general observation is that IPv6 is not a "feature-based" revision of IPv4—there is no outstanding capability of IPv6 that does not have a fully functional counterpart in IPv4. Nor is there a pressing urgency to deploy IPv6 because we are about to run out of available IPv4 address space in the next few months or even years within what we regard as the "conventional" Internet.

It would appear that the real drivers for network evolution lurk in the device world. We are seeing the various wireless technologies, ranging from Bluetooth for personal networking through the increasingly pervasive IEEE 802.11 "hot-spot" networking to the expectations arising from various forms of *third-generation* (3G) large radius services being combined with consumer devices, control systems, identification systems, and various other forms of embedded dedicated function devices. The silicon industry achieves its greatest advantage through sheer volume of production, and it is in the combination of Internet utility with the production volumes of the silicon industry that we will see demands for networking that encompasses tens, if not hundreds, of billions of devices. This is the world where IPv6 can and will come into its own, and I suspect that it is in this device and utility mode of communications that we will see the fundamental drivers that will lead to widespread deployment of IPv6 support networks.

GEOFF HUSTON holds a B.Sc. and a M.Sc. from the Australian National University. He has been closely involved with the development of the Internet for the past decade, particularly within Australia, where he was responsible for the initial build of the Internet within the Australian academic and research sector. Huston is currently the Chief Scientist in the Internet area for Telstra. He is also the Executive Director of the Internet Architecture Board, and is a member of the APNIC Executive Committee. He is author of *The ISP Survival Guide,* ISBN 0-471-31499-4, *Internet Performance Survival Guide: QoS Strategies for Multiservice Networks,* ISBN 0471-378089, and coauthor of *Quality of Service: Delivering QoS on the Internet and in Corporate Networks,* ISBN 0-471-24358-2, a collaboration with Paul Ferguson. Letters to the Editor

SIP Typos

Dear Mr. Stallings, and Mr. Jacobsen,

The *Session Initiation Protocol* article by Mr. Stallings in the *Internet Protocol Journal,* Volume 6, Number 1, March 2003, provides an excellent tutorial on the subject, IMHO.

The article does an extraordinary job at presenting what is quite a complicated protocol (SIP) in simple terms. However, there seem to be some typographical errors in the article, which I wanted to bring to your attention:

- In Figure 2, message number 10 should be "180 Ringing" as opposed to "100 Ringing."
- In Figure 2, the line under message number 14 should be pointing in the opposite direction (that is *from* Bob's proxy *to* Alice's proxy).
- In Figure 2, message number 16 should read only "ACK" not "180 ACK."
- In Figure 2, message number 15 should perhaps read as "200 OK" as opposed to just "OK"
- In Figure 3, message number 5 should read "200 OK" as opposed to "200 Trying"
- Figure 4 message number 5 and 7 should perhaps read as "NOTIFY <Signed In>" as opposed to "<Not Signed-In>"
- Figure 4 "User Agent Bob" should be labelled as "(signed in)" as opposed to "(not signed in)"
- There are missing closing angular brackets in the SIP INVITE message listing on page 27:

  To: Bob **<sip:bob@biloxi.com>**
  From: Alice **<sip:alice@atlanta.com>;tag=...**
- There are missing closing angular brackets in the SIP 200 OK message listing on page 28:

  To: Bob **<sip:bob@biloxi.com>;tag=....**
  From: Alice **<sip:alice@atlanta.com>;tag=...**

Sincerely,

—Rajnish Jain, Excel Switching Corp.
rajnishjain@xl.com

The author responds:

Rajnish,

Thanks for the comments. I am embarrassed that so many errors slipped through, even though I and several reviewers for Ole checked the paper.

—Bill Stallings
ws@shore.net

DoD and IPv6

Dear Geoff,

After reading your article, I couldn't help but notice the U.S. Department of Defense's announcement concerning their intentions to adopt IPv6 in the coming years (see "Fragments," page 38). Given that you've made some strong statements about the value of IPv6 in your article, would you care to offer some views about this announcement?

—Ole

Dear Editor,

As I said in the article, the true value of IP v6 lies in the massive amount of coherent address space that allows literally billions of devices to be uniquely addressed. Address uniqueness is a strong value proposition when you want an identifier space to cover a very large deployment space. As an example of this, one of the two properties of the original Digital-Intel-Xerox Ethernet II specification that remains in today's 10 Gigabit Ethernet specification is unique MAC addresses. All of that highly innovative CSMA/CD thinking that at the time we thought was the fundamental property of Ethernet has been dispensed with.

The general observation is that any communications systems requires any party to be able to uniquely identify any other party in order to initiate a private communication session. If you cannot perform that most basic of communications functions, then you simply do not have a functional peer-to-peer communications network.

But doesn't that mean that the stories of IPv4 address exhaustion have some substance? With the large amount of addressable devices hidden behind NATs, and the associated move to using domain names as the underlying identifier space for many communications applications, the pressure on consumption of IPv4 address space has been reduced considerably. This has implied that in a world of human-driven screens and keyboards we see some considerable lifetime left in the admittedly comfortable world of IPv4 as we know it. To support this model we've actually moved away from the IP address as the unique identifier token for many applications, and substituted an application model that is driven from domain names. As an example, consider the virtual hosting mechanism as implemented in Apache Web servers to see this shift in communications identifiers from address to domain name. And both as consumers of the technology and as an industry we can live with this for some time yet, because we appear to concentrate our use IP addresses as a routing and forwarding framework and increasingly use the DNS as the identifier realm of an application.

But our world is a world where the device is subservient to the user, and the applications we associate with the Internet of today are applications that are essentially human pastimes, such as e-mail, Web browsing, or high-value automated transactions, such as those commonly bracketed into the e-commerce area. And we've now established a highly valuable global industry upon these foundations.

But in so doing we should recognize the emergence of a second set of communications realms populated by uniquely identified devices that number in their billions, where the inter-device traffic is not human mediated, and the value of the device transactions are, on an individual transactions value level, far lower than the value of the human-driven realm of IPv4. In other words, in a device rich communications realm, it's likely that the human value we'd ascribe on average to each packet is far lower than our current Internet IPv4 world of human-mediated communications. And it's this extravagantly device-equipped world that we see the U.S. Department of Defense heading. If your stock in trade is one of quite astounding feats of logistical deployment of large numbers of people and large numbers of items of equipment, then the communications requirement is of a different order of scale to that of the retail Internet markets, and, yes, I'm sure that there are entirely effective arguments behind that decision to look forward to a communications realm with a uniform base protocol identifier domain in a scale that is 2 to the power 96 times larger than the entire IP address identifier domain of IPv4.

But I would be cautious about high levels of expectation that this immediately translates into an impetus in the market where you and I converse. My host here where I'm typing this message is already IPv6 capable, and if you are running a recent version of host software, then it's a reasonable assumption that yours is too. But I'll send this message over IPv4 and you'll receive it over IPv4, and between my mail sender and your mail receiver the transport channel will also be IPv4. Should we use IPv6 instead? Would I pay my provider additional money to compensate it for part of its additional expenditure to support a simultaneous IPv6 capable network between you and me? To send precisely the same message? In precisely the same time? Along the same path? Using the same transport TCP session? Obviously, to me, as a (hopefully) economically rational consumer of such services, and no doubt to you, in a similar role, there is no value in spending more money to achieve outcomes in IPv6 that are identical to what we can already do today in IPv4. And in the retail Internet world that remains the basic IPv6 conundrum. Why should any provider spend additional resources to service the same market with identical services, and in so doing be unable to raise additional revenue to offset their additional service costs? One interpretation is that there is no natural motivation for such activities in today's market, otherwise it would already be very widespread indeed.

What we've seen in the mainstream Internet world is an emerging mythology about IPv6 that somehow this additional expenditure, ultimately on the part of the consumer, provides some additional benefit for the consumer, motivating them to switch from IPv4-only services to some hybrid of mixed v4 and v6 and ultimately to a v6 world, and thereby funding the additional provider expenditure associated with such a massive transition.

The reality is more sobering in that in the retail Internet world there is so far nothing obvious in the "additional benefit" category. I'm using *Network Address Translation* (NAT) right now, using an *ssh* session back to my mail server that drives through NAT boxes to make a secure SMTP session, across a first step of 802.11 wireless in order to send this message to you.

I've auto-configured in the wireless world, and for me I'm living in a plug-and-play world that supports my level of roaming access. Would IPv6 make this session any more secure? Any different in terms of *Quality of Service* (QoS) ? In plug-and-play models of roaming? Would there be any visible difference in terms of my ability to communicate with you? To all of these questions the basic answer is still "no."

So, for you and I, we look inside the IPv6 technology box, and find nothing new there to motivate us to spend more money for our existing Internet-based communications services, and for some time to come it would appear that this will still hold.

On the other hand there are circumstances where there is a need to operate in a much larger base protocol address space. These include situations where one wants to take advantage of Internet applications that operate across a world of literally billions of devices, large and small. The application space may want to gather constant reports on the characteristics of the "thing" it is attached to, from a ration pack to a component of a large naval vessel. You may want to use supply channels for such devices such that the deployment is a plug-and-play world without a massive variety of detailed configuration processes. You may be looking to an architecture that would be stable for many years. In such circumstances you really want take advantage of a uniform set of Internet application technologies that potentially span massive numbers of addressable devices. Here a large base address space is a definite asset. And for such industry sectors in voicing such requirements where there is also a somewhat different ultimate value proposition for the supported communications activity, then it's quite understandable that there can be an attractive proposition offered by immediate adoption of IPv6.

But back in the communications realm where you and I currently exchange our messages, such requirements remain in a future framework that is still waiting for relevant value propositions that allow it to gain traction with you and me. And as I attempted to point out in the article, adding some elements of mythology and over-stating the IPv6 value case won't help here.

Maybe we just need to be patient. Steam ships did not halt operation the first day a diesel powered vessel appeared. It was a much slower process that lead to an outcome of the change of the maritime fleet—the next generation of mechanization offered cheaper services, and, as often happens, market price won in that commodity market.

Market price often wins in competitive commodity markets. And the Internet retail market is, in many parts of the world and in many sectors, a strongly competitive space with all the characteristics of a commodity offering. In addressing such initial specialized dedicated communications requirements with IPv6 technology as represented by the U.S. DoD, there is a distinct possibility that there may be some effective use of initial investment that translates into the retail world in some form of efficiency gain for IPv6-capable providers.

And there no doubt that if you and I could communicate in precisely the same fashion as we do today, with precisely the same applications and service environment, using precisely the same host devices and operating systems as we do today, but at some attractive fraction of today's price, then I'm sure that neither of us would care in the slightest that our data was encapsulated using a packet framing format and address tokens that used the IPv6 protocol specifications.

Kind regards,

—Geoff Huston, Telstra

Google Hacks

Google Hacks: 100 Industrial-Strength Tips & Tools, by Tara Calishain and Rael Dornfest, ISBN 0-596-00447-8, O'Reilly & Associates, 2003, 329 pages.

Hmm, this is a hard one. This is the second go at writing a review—the first one made me sound like a grumpy luddite and I don't want my secret identity to be revealed yet. So, put on some suitable music ("So What" from "Kind of Blue" by Miles Davis) and this time, to start with, "just the facts, ma'am" and we'll get back to the grumpiness later.

What we have here are "100 Industrial-Strength Tips & Tools" for using the Google search engine (or g**gling as we are not allowed to say). All the usual O'Reilly positives about layout and presentation apply so we can take those as read (and the usual negative about murky grey scale illustrations). The tips/tools are gathered into separate sections dealing with searching (surprise!), services, scraping, using the API, games and Web mastering. All the tips have some description, some have code and others have URLs that take you to the code or the service described. And indeed some of these are quite interesting and useful, but, and the grumpiness is starting to creep in again, many of them are really not. Tip #1 for instance—"Setting Preferences." Since when has a brief description of how what you can find on the Google preferences page been "Industrial-strength"? Too many of the tips are like this—simple stuff that you can get from many places on the Web (including Google itself) with little added value. Someone starting out using Google is not going to buy a book called *Google Hacks* because its title is off-putting, and someone who is a regular user of the service is going to know (or not be interested in) most of the content. Why do we need a 300 page paper copy of this information? Much of what is in here could be boiled down into a small, cheap guide just like those O'Reilly have for programming languages, and the rest of the stuff is irrelevant anyway (for instance the TouchGraph browser is fun and interesting, but it isn't really that useful—everyone I know has played with it for 5 minutes and then never returned).

I had better hopes of the API programming material, but it was not to be. I know I am in a tiny minority here, so don't complain, but most of the program examples provided in the book use *Perl*. "Hurrah" say you, "Boo" say I—I don't like Perl, never have and never will. Just like celery. I can put up with it, but I won't pick it when I have a choice.

Note, I am not knocking the Google APIs (though they are a bit baroque, and it would be nice to be able to get more than 10 results at time, and...). Being able to call up a search engine from within a program is a good thing, even if you do have to use Web Services (I'm not that keen on them either—are you surprised?). This book certainly tells you how to do that (at least from within Perl) but again you can pick that info up from the Web for free and it doesn't run to more than twenty pages tops. Most of the programming examples may have been fun to write and think up but are about as useful as a flowchart stencil.

Oh, and "Googlewhacking"[1] is not new—people were doing that on AltaVista long (in Internet terms) before Google appeared.

All things considered, I don't see this book being worth $25. If you know how to use Google even a little bit you ought to be able to use it to find all this information without it. And what of the stablemate book *Amazon Hacks* which is due to appear soon? I fear a miracle of padding there.

—Lindsay Marshall, University of Newcastle upon Tyne
Lindsay.Marshall@newcastle.ac.uk

[1] Googlewhacking is the art of finding a two-word query that has only one result. The two words may not be enclosed in quotes, and the words must be found in Google's own dictionary (no proper names, made-up words, etc).

Would You Like to Review a Book for IPJ?

We receive numerous books on computer networking from all the major publishers. If you've got a specific book you are interested in reviewing, please contact us and we will make sure a copy is mailed to you. The book is yours to keep if you send us a review. We accept reviews of new titles, as well as some of the "networking classics." Contact us at **ipj@cisco.com** for more information.

Fragments

Several Landmarks Define Push toward IPv6 Deployment in Japan

In April 1998, the KAME Project, **http://www.kame.net/**, an extension of the WIDE Project (**http://www.wide.ad.jp/**; representative Professor Jun Murai, Keio University), was established with eight core members from seven Japanese vendors. Work began under a two-year timeframe to provide free IPv6/IP Security (IPSec) reference code for UNIX BSD variants. The KAME Project remains active today.

The Japanese government's commitment to taking a leadership role in worldwide IPv6 research and deployment was outlined in a speech to open the September 2000 Diet session by then Prime Minister Mori. Mori identified IPv6 as a key discussion area for the national IT Strategy Council—a strategic pillar toward the "rebirth of the nation."

The *IPv6 Promotion Council of Japan* was established shortly thereafter, in Oct. 2000. Its founding members numbered only 18. As of March 2003 the Council's membership body consisted of 320 organizations from a variety of business fields; carriers, *Internet Service Providers* (ISPs), hardware vendors, software vendors, finance companies, general trading companies, automobile manufacturers, etc.

The Council is the most active and influential IPv6 organization in Japan, and is the formal contact point appointed by the Japanese government to handle requests from overseas private IPv6 promotion bodies, such as the various regional IPv6 Task Force bodies, for technical and deployment cooperation.

The Promotion Council is currently running the "IPv6 Appli-Contest 2003." The contest awards developers of applications and software who help to create new possibilities in the IPv6 Internet world, see: **http://www.v6pc.jp/apc/en/concept.html**

Supported by the Ministry of Public Management, Home Affairs, Posts and Telecommunications, and the WIDE Project, the contest is drawing on the cooperation of IPv6 bodies in the EU, North America, India, Korea, Taiwan, and China with the goal of creating a library of freely available IPv6 software.

Details on rules and regulations for entry can be found at the following URL: **http://www.v6pc.jp/apc/en/regulations.html**.
The deadline for entries is August 31, 2003.

Six entries will be selected as "Award of Excellence" winners and will share 1,500,000 JPY in prize money. Award of Excellence winners will also be eligible for the "Grand Prize" of 1,000,000 JPY to be presented at a ceremony during WPC EXPO 2003 to be held September 17–20, 2003, in Tokyo.

An excellent, up-to-date overview of the current status of IPv6 research and commercial service offerings in Japan, including IPv6 case studies and technology tutorials, can be found at IPv6style:

US Department of Defense adopts IPv6

Implementation of the next-generation Internet protocol that will bring the Department of Defense closer to its goal of net-centric warfare and operations was announced on June 13, 2003 by John P. Stenbit, assistant secretary of defense for networks and information integration and DoD chief information officer.

The new Internet protocol, known as IPv6, will facilitate integration of the essential elements of DoD's Global Information Grid—its sensors, weapons, platforms, information and people. Secretary Stenbit is directing the DoD-wide transition.

The current version of the Internet's operating system, IPv4, has been in use by DoD for almost 30 years. Its fundamental limitations, along with the world-wide explosion of Internet use, inhibit net-centric operations. IPv6 is designed to overcome those limitations by expanding available IP address space, improving end-to-end security, facilitating mobile communications, enhancing quality of service and easing system management burdens.

"Enterprise-wide deployment of IPv6 will keep the warfighter secure and connected in a fast-moving battlespace," Secretary Stenbit said. "Achievement of net-centric operations and warfare depends on effectively implementing the transition."

Secretary Stenbit signed a policy memorandum on June 9 that outlines a strategy to ensure an integrated, timely and effective transition. A key element of the transition minimizes future transition costs by requiring that, starting in October 2003, all network capabilities purchased by DoD be both IPv6-capable and interoperable with the department's extensive IPv4 installed base.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

The Internet Protocol Journal

September 2003 Volume 6, Number 3

A Quarterly Technical Publication for Internet and Intranet Professionals

In This Issue

From The Editor

The task of adding security to Internet protocols and applications is a large and complex one. From a user's point of view, the security-enhanced version of any given component should behave just like the old version, just be "better and more secure." In some cases this is simple. Many of us now use a *Secure Shell Protocol* (SSH) client in place of *Telnet*, and shop online using the secure version of HTTP. But there is still work to be done to ensure that *all* of our protocols and associated applications provide security. In this issue we will look at *routing*, specifically the *Border Gateway Protocol* (BGP) and efforts that are underway to provide security for this critical component of the Internet infrastructure. As is often the case with emerging Internet technologies, there exists more than one proposed solution for securing BGP. Two solutions, S-BGP and soBGP, are described by Steve Kent and Russ White, respectively.

The Internet gets attacked by various forms of viruses and worms with some regularity. Some of these attacks have been quite sophisticated and have caused a great deal of nuisance in recent months. The effects following the *Sobig.F* virus are still very much being felt as I write this. Tom Chen gives us an overview of the trends surrounding viruses and worms.

Closely related to the virus attacks is *spam*. Unfortunately, I know of no complete technical, or even legal, solutions to this growing problem, but I would love to hear your views and solutions. Send your comments to: **ipj@cisco.com**, but don't use the string "spam" in the subject field or it may get filtered out!

Following Geoff Huston's opinion piece "The Myth of IPv6" in our previous issue, we received a response from *The IPv6 Forum*. The article is entitled "IPv6 Behind the Wall" and is by Jim Bound.

I was very pleased to hear that professor Peter T. Kirstein of University College London had been awarded the Internet Society's *Jonathan B. Postel Service Award* for 2003. I have known Peter since about 1977, when we collaborated on SATNET packet voice conferences between Oslo, London, Boston, and Marina del Rey. Peter is truly an Internet pioneer. (See "Fragments," page 41).

Securing the Border Gateway Protocol

by Stephen T. Kent, BBN Technologies

Routing in the public Internet is based on a distributed system composed of many routers, grouped into management domains called *Autonomous Systems* (ASes). ASes are operated by *Internet Service Providers* (ISPs) and by multihomed subscribers. (Throughout the remainder of this article, for brevity, we will talk in terms of ISPs, usually omitting references to multihomed subscribers.) Routing information is exchanged between ASes using the *Border Gateway Protocol* (BGP)[1], via UPDATE messages.

BGP is used in two different contexts. *External BGP* (eBGP) propagates routes between ISPs. BGP also is used within an AS to propagate routes acquired from other ASes. This latter use is referred to as *internal BGP* (iBGP). eBGP is the primary focus of this article, because failures of eBGP can adversely affect large portions of the Internet, well beyond the administrative boundary of the source of the failure. Nonetheless, some ISPs have expressed interest in protecting the distribution of routes within an ISP. The security technology discussed in this article can be used to secure iBGP, but eBGP is the focus of this article. We use the term "BGP" to refer to eBGP throughout the article.

BGP is highly vulnerable to a variety of attacks[2]. In some cases, this vulnerability arises because of a lack of integrity and authentication for BGP messages. However, the more substantive and harder problem is the lack of a secure means of verifying that BGP traffic is authorized, a concept explored in more detail in this article. In April 1997, BBN began work on the security architecture described here, a system we refer to as *S-BGP,* to address the vulnerabilities of BGP. This article begins by reviewing the problem, discusses a model for correct operation of BGP, presents a threat model, and states the goals and assumptions that underlie our proposed security architecture.

Before we begin the discussion of BGP in more detail, a few definitions are in order. A *route* is defined as an *address prefix* and a set of *path attributes*. One of the path attributes is an AS path, and that is the primary focus of BGP security considerations. The AS path specifies the sequence of ASes that subscriber traffic should traverse if forwarded via this route. When propagating an UPDATE to a neighboring AS, the BGP router prepends its AS number to the sequence, and may update certain other path attributes. The first AS included in the path is referred to as the *origin AS*.

Each BGP router (other than at the edges of the Internet) maintains a complete routing table, capable of routing traffic to any reachable destination, and sends its best route for each prefix to each neighbor. In BGP, "best" is very locally defined. The BGP route selection algorithm has few criteria that are universal, thus limiting the extent to which any security mechanism can detect and reject "bad" routes emitted by a neighbor.

Each ISP makes use of local policies that it need not disclose, and this gives BGP route selection a "black box" flavor, which has significant adverse implications for security.

Correct Operation of BGP

Security for BGP should be defined as the correct operation of BGP routers. This definition is based on the observation that any successful attack against BGP will result in other than correct operation, presumably yielding degraded routing. Correct operation of BGP depends upon the integrity, authenticity, and timeliness of the routing information it distributes, as well as each BGP router processing, storing, and distributing this information in accordance with both the BGP specification and local routing policies. Many statements could be made in an effort to characterize correct operation, but they rest on two simple assumptions.

First, control (vs. subscriber traffic) communication between neighbor BGP routers must be authenticity and integrity secure. This is easily achieved through the use of a point-to-point security protocol capable of protecting BGP traffic; for example, *IP Security* (IPSec). Second, BGP routers must execute the route selection algorithm correctly and communicate the results. There are two parts to this assumption: processing received UPDATEs, and generation and transmission of UPDATEs. In terms of an AS trying to protect itself against external attacks, correct operation of its own BGP routers is mostly a local security issue, but not an Internet-wide security issue. However, an AS should not rely on other ASes to operate properly; such reliance permits a failure in one AS to propagate to others, a domino failure effect. Thus it is important for a BGP router to be able to verify that each UPDATE it receives from a peer is valid (authorized) and timely.

The validity of an UPDATE message is based on four primary criteria:

- The router that sent the UPDATE was authorized to act on behalf of the AS it claims to represent; that is, the AS at the front of the AS path.
- The AS from which the UPDATE emanates was authorized by the preceding AS in the AS path (in the UPDATE message) to advertise the prefixes in the UPDATE.
- The first AS in the AS path was authorized, by the owner of the set of prefixes that are represented in the UPDATE, to advertise those prefixes.
- If the UPDATE withdraws one or more routes (specified by the prefixes for the routes), then the sender must have advertised each route prior to withdrawing it.

There are some limitations to the ability of any practical security mechanism to detect all BGP security failures. The local policy feature of BGP allows each ISP considerable latitude in how UPDATEs are processed, making it difficult for an external observer—for example, a router in a neighboring AS—to determine if a router is operating properly.

This is because such behavior might be attributed to local policies not visible outside an AS. To address such attacks, the semantics of BGP itself would have to change. Moreover, because UPDATEs do not carry sequence numbers, a BGP router can emit an UPDATE based on authentic, but old, information; for example, withdrawing or reasserting a route based on outdated information. Thus the temporal accuracy of UPDATEs, in the face of Byzantine failures, is hard to enforce, except in a very coarse fashion. (Simply speaking, a *Byzantine failure* is one in which a nominally trusted or authorized entity misbehaves.)

Threat Model and BGP Vulnerabilities

Routers exhibit both architectural and implementation vulnerabilities. Implementation vulnerabilities are the result of errors that arise in developing design details or coding; for example, translating the BGP specs into software. Architectural vulnerabilities permit various forms of attack, independent of implementation details, and thus are potentially more damaging, because they persist across all implementations. To make Internet routing robust, both forms of vulnerabilities must be addressed. BGP vulnerabilities can be exploited to cause improper routing or nondelivery of subscriber traffic, network congestion, and traffic delays. Misrouting attacks can be used to facilitate both passive and active wiretapping of subscriber traffic. Often an attack against BGP may be part of a larger attack against subscriber computers. For example, there have been BGP attacks that seek to misroute queries to *Domain Name System* (DNS) root servers, as part of an attack against subscriber systems.

BGP can be attacked in many ways. Communication between BGP peers can be subjected to active or passive wiretapping. The BGP software, configuration information, or routing databases of a router may be modified or replaced via unauthorized access to a router, or to a server or management workstation from which router software is downloaded. These latter attacks transform routers into hostile insiders, so security measures must address such Byzantine failures.

Improved physical and procedural security for network management facilities, and routers, and cryptographic security for BGP traffic between routers would help reduce some of these vulnerabilities. However, physical and procedural security is expensive and imperfect, and these countermeasures would not protect the Internet against accidental or malicious misconfiguration by operators, nor against attacks that mimic such errors. Misconfiguration of this sort has been a source of Internet outages in the past and seems likely to persist. Any security approach that relies on ISPs to act properly violates the "principle of least privilege" and leaves the Internet routing system vulnerable at its weakest link. In contrast, the security approach described in this article satisfies this principle, so that any attack on any component of the routing system is limited in its impact on the Internet as a whole.

Routers also are susceptible to resource exhaustion attacks based on delivery of large quantities of management traffic, BGP or otherwise. This vulnerability arises because these devices are designed with the not unreasonable model that management traffic is a very tiny percentage of all the traffic that arrives at a router. Router interfaces can deliver traffic to the management processor at very high rates, because they are designed to accommodate subscriber traffic flows. Solutions to this problem need to be generic, to accommodate all types of router management traffic, and thus are outside the scope of the BGP security measures discussed in this article.

Goals, Constraints, and Assumptions

Any proposed security architecture must exhibit dynamics consistent with the existing BGP system; for example, responding automatically to topology changes, including the addition of new networks, routers, and ASes. These actions take place on different time scales and have different scopes. For example, in the current BGP system, if an ISP replaces a failed router, the action can take place fairly quickly and has only local impact, because ISPs are not aware of the identity of routers in other, non-neighboring, ISPs. The issuance of new AS numbers, representing new nets, is not a fast process, nor is the allocation of new blocks of address space (new prefixes). But both of these actions are globally visible. Changes in routes also may have global impact, and they may occur very quickly.

Solutions also must scale in a manner consistent with the growth of the Internet. The countermeasures must be consistent with the BGP protocol standards and with the likely evolution of these standards. This includes packet size limits and features such as path aggregation, communities, and multiprotocol support (for example, *Multiprotocol Label Switching* [MPLS]). The security measures must be incrementally deployable; there cannot be a "flag day" when all BGP routers suddenly begin executing a new security protocol. It is desirable to not create new organizational entities that must be accepted as authorities by ISPs and subscribers, in order to make routing secure.

S-BGP Architecture

S-BGP consists of four major elements:

- A *Public Key Infrastructure* (PKI) that represents the ownership and delegation of address prefixes and AS numbers
- *Address Attestations* that the owner of a prefix uses to authorize an AS to originate routes to the prefix
- *Route Attestations* that an AS creates to authorize a neighbor to advertise prefixes
- *IPSec* for point-to-point security of BGP traffic transmitted between routers

These elements are used by an S-BGP router to secure communication with neighbors, and to generate and validate UPDATE messages relative to the authorization model represented by the PKI and address attestations. Together, the combination of these security mechanisms prevents a compromised AS from propagating erroneous routing data to other, secured ASes. Each element is described in more detail in the following section.

S-BGP Public Key Infrastructure

S-BGP uses a PKI based on X.509 (v3) certificates to enable routers to validate the authorization of other routers to represent ASes (ISPs). The PKI also allows routers to verify the authorization of each ISP as the owner of one or more prefixes (contiguous blocks of address space). This PKI was described in[14], and the reader is referred to that paper for additional details. The PKI parallels the existing IP address and AS number assignment delegation system and takes advantage of this infrastructure. Because the PKI mirrors existing infrastructure, it avoids most of the "trust" issues that often complicate the creation of a PKI. This PKI is unusual in that it emphasizes authorization, not authentication. The names used in the certificates in this PKI are not employed to determine whether a given ISP or router is authorized to do anything, and the names are not even meaningful outside of S-BGP.

S-BGP calls for a certificate to be issued to each ISP (or subscriber) that owns (more properly, has a right to use) a portion of the IP address space. This certificate is issued through the same procedures employed for address allocation, starting with the *Internet Assigned Numbers Authority* (IANA) and continuing through a *Regional Internet Registry* (RIR), and, if applicable, an ISP. If an ISP owns multiple prefixes, we issue a single certificate containing a list of prefixes, to minimize the number of certificates in the system. The PKI represents address-space ownership by binding prefixes to a public key belonging to the ISP to which the prefixes have been assigned. Each certificate contains a private extension that specifies the set of prefixes that has been allocated to the ISP. Certificates issued under this PKI also represent the binding between an ISP and the AS numbers allocated to it. The PKI allows each ISP to issue certificates to its routers, certifying that these routers represent the ISP and hence, the ASes owned by the ISP. Here too, the PKI parallels the existing AS allocation system; that is, the IANA allocates AS numbers to RIRs, which in turn assign AS numbers to ISPs that run S-BGP.

Attestations

An *attestation* is a digitally signed datum asserting that its target (an AS) is authorized by the signer (an ISP) to advertise a path to one or more specified prefixes. There are two types of attestations, address and route, which share a common format. For an *Address Attestation* (AA), the signer is the ISP or subscriber that controls the prefixes in the AA, and the target is a set of ASes that the ISP/subscriber authorizes to originate a route to the prefixes. AAs are relatively static data items, because relationships between address-space owners and ISPs change relatively slowly.

For a *Route Attestation* (RA), the signer is an S-BGP router (operating on behalf of an ISP), and the target is an AS or set of ASes, representing the neighbors to which the UPDATE containing the RA will be sent. RAs, unlike AAs, are very dynamic, possibly changing for each transmitted UPDATE.

UPDATE Validation

Attestations and certificates are used by S-BGP routers to validate routes asserted in UPDATE messages; that is, to verify that the first AS in the route has been authorized to advertise the prefixes by the prefix owner(s), and that each subsequent AS has been authorized to advertise the route for the prefixes by the preceding AS in the route. To validate a route received from AS_n, AS_{n+1} requires:

- An AA for each organization owning a prefix represented in the UPDATE (not for prefixes in the UPDATE that represent routes being withdrawn)
- A certified public key for each organization owning a prefix in the UPDATE
- An RA corresponding to each AS along the path (AS_n to AS_1), where the RA generated and signed by the router in AS_n encompasses the *Network Layer Reachability Information* (NLRI) and the path from AS_{n+1} through AS_1
- A certified public key for each S-BGP router that signed an RA along the path (AS_n to AS_1), to check the signatures on the corresponding RAs

An S-BGP router verifies that the advertised prefixes and the origin AS are consistent with AA information. The router verifies the signature on each RA and verifies the correspondence between the signer of the RA and the authorization to represent the AS in question. There also must be a correspondence between each AS in the path and an appropriate RA. If all of these checks pass, the UPDATE is valid.

AAs are not used to check withdrawn routes in an UPDATE. Use of IPSec to secure communication between each pair of S-BGP routers, plus the fact that BGP uses a separate *Adjacency Routing Information Base* (Adj-RIB-In) for each neighbor, ensures that only the advertiser of a route can withdraw it.

Distribution of S-BGP Data

Each S-BGP router must have the public keys required to validate the RAs in UPDATEs, a scenario that translates into securely distributed keys for every router that implements S-BGP (and that is reachable via an S-BGP path). Each router also needs access to all AA information, to verify that the origin AS is authorized to originate a route to the prefixes in the UPDATE. S-BGP does not distribute certificates, *Certificate Revocation Lists* (CRLs), or AAs via UPDATE messages; transmission of these items via UPDATEs would be very wasteful of bandwidth, because each BGP router would receive many redundant copies from its neighbors.

Also, an UPDATE is limited to 4096 bytes and thus generally could not carry all of this data for the route represented by the UPDATE. Instead, S-BGP distributes this data to routers via out-of-band means. The data is relatively static and thus is a good candidate for caching and incremental update. Moreover, the certificates and AAs can be validated and reduced to a more compact format by ISP operation centers prior to distribution to routers. This avoids the need for each router to perform this processing, saving both bandwidth and storage space. It also means that routers do not need to be able to parse X.509 certificates and validate certificate paths for S-BGP purposes, although some capability in this area may be required for IPSec key management.

S-BGP uses *repositories* for distribution of this data. We initially described a model in which a few replicated, loosely synchronized repositories were operated by the RIRs. Discussions with ISPs suggest a model in which major ISPs and Internet exchanges operate repositories, and smaller ISPs and subscribers make use of these repositories. In either model, each ISP periodically, for example daily, uploads new/changed certificates, its current CRL, and AAs. Each ISP also downloads all of this data for all other ISPs that are running S-BGP. The repositories periodically transfer new data to one another to maintain loose synchronization. ISPs process the repository information to create more compact files that contain the AA data and the public keys and prefix and AS data from the certificates, but none of the certificate management information or CRLs. These resulting "extracted" files are transferred to the routers executing S-BGP under the control of the ISP.

Because certificates, AAs, and CRLs are signed and carry validity interval information, they require minimal additional security while in transit to or from a repository or while stored on a repository. Nonetheless, S-BGP employs the *Secure Sockets Layer* (SSL) protocol, with both client and server certificates, to protect access to the repositories, as a countermeasure to denial-of-service attacks. The simple, hierarchic structure of the PKI allows repositories to automatically effect access control checks on the uploaded data, for example, to prevent one ISP from accidentally or maliciously overwriting the certificates, CRLs, and AAs from another ISP.

Distribution of Route Attestations

S-BGP distributes RAs with BGP UPDATEs in a newly defined, optional, *transitive path attribute*. Because routes may change quickly, it is important that RAs accompany the UPDATEs that are validated using them. If any other means of distribution is employed for this data, there is a likelihood that the UPDATEs and the data will be out of synch, creating a conundrum for a router; that is, what should the router do when the UPDATE and the security data differ? RAs employ a compact encoding scheme to help ensure that they fit within the BGP packet size limits, even when route or address aggregation occurs. (S-BGP accommodates aggregation by explicitly including signed attribute data that otherwise would be lost when aggregation occurs.) An S-BGP router receiving an UPDATE from a peer caches the RAs with the route in the Adj-RIB for the peer, and in the *Local Routing Information Base* [Loc-RIB] (if the route is selected).

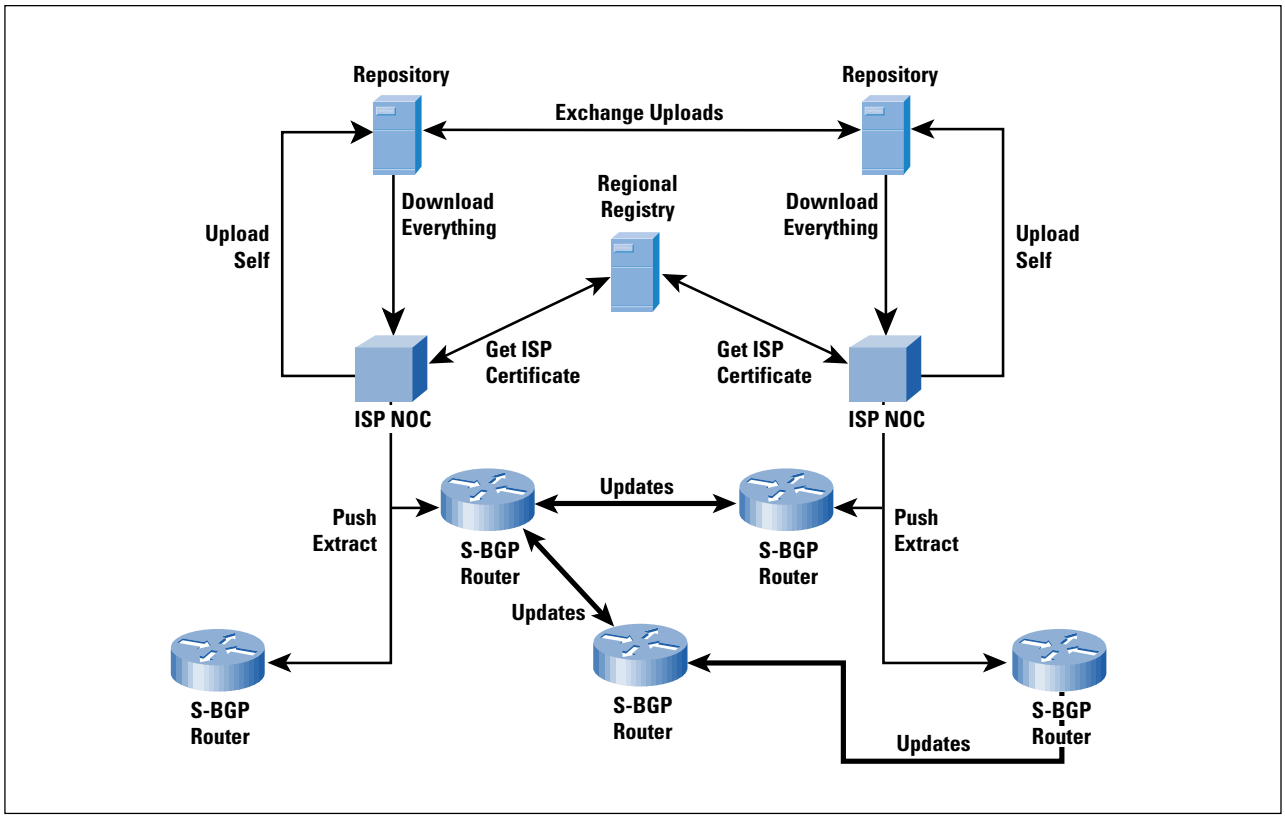
As noted in the following discussion, the bandwidth required to support in-band distribution of route attestations is negligible (compared to subscriber traffic).

Although the RA mechanism was designed to protect AS path data, it can also accommodate other new path attributes; for example, communities[11] and confederations[12]. Specifically, there is a provision to indicate what data, in addition to the AS path, is covered by the digital signature that is part of the RA.

Putting It All Together

Figure 1 illustrates how the major elements of S-BGP interact, using a simplified example. The figure shows two ISPs, each with a *Network Operations Center* (NOC), a repository, and three routers. A third ISP is represented by a single (S-BGP-enabled) router. Each ISP interacts with an RIR to acquire a certificate representing the prefixes and AS numbers assigned to the ISP. Each NOC interacts with a repository to upload data (certificates, CRLs, and AAs) from that ISP, and to download the same data acquired from all other ISPs. The repositories interact with one another to exchange uploaded ISP data, to make that data available to all other ISPs. Within an ISP, the NOC pushes a copy of the extracted certificate and AA data, produced from the downloads acquired from a repository, to each router. Routers exchange UPDATE messages, containing RAs, that enable validation of each received UPDATE.

Figure 1: S-BGP Element Interactions



IPSec and Router Authentication

S-BGP uses IPSec[6,7,8], specifically the *Encapsulating Security Payload* (ESP) protocol, to provide authentication, data integrity, and antireplay for all BGP traffic between neighboring routers. The *Internet Key Exchange* (IKE) protocol[9,10] is used for key management services in support of ESP. The S-BGP PKI includes certificates for IKE, separate from those used for RA processing.

The use of IPSec is preferable to the current option of the *Message Digest Algorithm 5* (MD5) TCP checksum option[15], in several respects. IPSec uses keyed hash functions in a way that is cryptographically more secure that the MD5 checksum option, and IKE provides automated key management, a feature sorely lacking in the option. Protecting BGP traffic at the IP layer, vs. the TCP layer, counters more vulnerabilities, because the TCP implementation is protected as well, for example, including SYN flooding and spoofed RSTs (resets), are rejected.

Residual Vulnerabilities in S-BGP

Despite the extensive security offered by S-BGP, architectural vulnerabilities exist that are not eliminated by its use. For example, an S-BGP router may reassert a route that was withdrawn earlier, even if the route has not been readvertised. The router also may suppress UPDATEs, including ones that withdraw routes. These vulnerabilities exist because BGP UPDATEs do not carry sequence numbers or time stamps that could be used to determine their timeliness. However, RAs do carry an expiration date and time, so there is a limit on how long an attestation can be misused this way. S-BGP restricts malicious behavior to the set of actions for which a router or AS is authorized, based on externally verifiable, authoritative constraints.

Performance and Operational Issues

In developing the S-BGP architecture, we paid close attention to the performance and operational impact of the proposed countermeasures, and reported our analysis in earlier papers. In preparing this article, we updated our data, utilizing a variety of sources; for example, the *Route Views* project. Although much data about BGP and associated infrastructure is available, other data is difficult to acquire in a fashion that is representative of a "typical" BGP router. This is because each AS in the Internet embodies a slightly different view of connectivity, as a result of local policy filters applied by other ASes.

It is important that the transmission, storage, and processing requirements imposed by S-BGP not be so great as to overwhelm routers. Each of these requirements must be analyzed separately.

The transmission of RAs in UPDATEs does significantly increase the size of these messages, by about 800 percent. However, because the volume of this traffic is minuscule relative to subscriber traffic, the increase is negligent. The set of files containing certificates, AAs, and CRLs would be about 75–85 MB. Daily transmission of these files between ISPs and repositories would not represent a significant increase in traffic volume for the Internet.

Although the transmission overhead is not a concern, storage of the RAs in each Adj-RIB and the Loc-RIB is a problem. The additional space required to hold these RAs is estimated at about 30–35 MB per peer, if S-BGP were fully deployed today. This is a modest amount of memory for a typical router with a few peers, but a significant amount of storage for routers at Internet exchanges, where a router may have tens or even hundreds of peers.

Thus the management CPU in a router might need a gigabyte or more of RAM under these conditions. (When a large ISP peers with many other ISPs at an exchange, the peering is not symmetric; that is, the large ISP accepts only a few routes from each of the smaller ISPs, filtering out the rest. Thus the amount of additional memory required for RAs in Adj-RIBs for each of these small ISP peers may be considerably less than for symmetric peer relationships.) This requisite memory seems modest by current workstation standards, but most deployed routers cannot be configured with this much memory.

The computational burden of router processing of RAs in UPDATEs is a function of the path length in each UPDATE and the rate at which UPDATEs arrive. The arrival rate is a function of the number of S-BGP peers the router sees, and the rate at which each peer sends UPDATEs. Our analysis suggests that the long-term (24-hour) UPDATE rate for a router with 30 peers is about 0.5 UPDATEs per second. On average, each UPDATE would contain about 3.7 RAs. We originally estimated the busy minute rate as about 10 times the average rate. At this rate, a router could probably perform the requisite signature verification in software (about 18 signature verifications per second). Recent evidence suggests a factor of 100–200 might be a better estimate, in light of experience with major worm attacks, and at that rate it would be hard for software to keep pace.

Heuristics are available to reduce this burden. Analysis shows that about 50 percent of all UPDATEs are sent as a result of route "flaps"; that is, transient communication failures that, when remedied, result in a return to the former route. Thus if a router maintained a depth-two cache for each Adj-RIB-In, it could avoid signature validation about 50 percent of the time. However, this would double the storage requirements for these RIBs, and that would exacerbate the storage problem cited previously.

Our previous analysis also assumed that receipt of each UPDATE would result in transmission of an UPDATE with one new signature. This was an oversimplification; a router generates and transmits an UPDATE only if the newly received route is "better" than the current best route (for the prefix), or if the best route for the prefix is withdrawn by the UPDATE. When a router has many peers, most of the UPDATEs it receives may not yield a better route, and thus will not trigger transmission of a new UPDATE.

On the other hand, when a router does select a new route, an UPDATE may be constructed and sent to each neighbor, requiring one signature per neighbor. This is because an RA specifies the AS number of the neighbor to which it is directed. It is possible to construct an RA that identifies the next hop as a set of AS numbers, corresponding to all the neighbors to which an UPDATE is authorized to be sent. The downside of this strategy is that it makes the RAs larger, contributing to the storage problem noted previously.

The observation made previously suggests a heuristic for UPDATE processing to mitigate signature validation costs. A router can defer validation of the RAs in any UPDATE that it receives, if the UPDATE would not represent a new best route. This optimization could be especially helpful for routers that receive the greatest number of UPDATEs; that is, routers with many neighbors. One might worry that this strategy allows an attacker to force processing, by sending what would be considered "very good" routes, but an S-BGP router could detect such fraudulent UPDATEs and could choose to drop its connection to a peer that behaved this way, in order to counter such an attack.

Initialization/reboot of a BGP router also results in a surge in UPDATE processing, and the deferred processing heuristic is applicable here too, even though reboots are relatively infrequent. Saving RIBs in nonvolatile storage addresses this problem. Most deployed routers do not have sufficient nonvolatile storage to adopt this strategy, but some do have hard drives that would easily accommodate the RIBs.

It is reasonable to assume that next-generation routers could be configured with enough RAM for the RIBs, but this analysis shows that full deployment is not feasible with the currently deployed router base. To add RAM, and possibly to add nonvolatile storage, router vendors will have to upgrade the processor boards where net management processing takes place. That suggests that addition of a crypto accelerator chip would be prudent as part of the board redesign process, for example, to deal with surge conditions noted previously.

Deployment and Transition Issues

Adoption of S-BGP requires cooperation among several groups. ISPs and subscribers running BGP must cooperate to generate and distribute AAs. Major ISPs must implement the S-BGP security mechanisms in order to offer significant benefit to the Internet community. The IANA and RIRs must enhance operational procedures to support generation of prefix and AS number allocation certificates. Router vendors need to offer additional storage in next-generation products, or offer ancillary devices for use with existing router products, and revise BGP software to support S-BGP.

There is some good news; S-BGP can be deployed incrementally. Only neighboring ASes receive full benefit from such deployment. Although we chose a transitive path attribute syntax to carry RAs, and thus it might be possible for non-neighbor ASes to exchange RAs, it seems likely that intervening ASes would not have sufficient storage for the RAs in their RIBs.

Also, the controls needed in routers to take advantage of noncontiguous deployment of S-BGP are quite complex, hence our suggestion that only contiguous deployment of S-BGP be attempted.

External routes received from S-BGP peers need to be redistributed within the AS, both to interior routers and to other border routers, in order to maintain a consistent and stable view of the exterior routes across the AS. Thus an AS must switch to using S-BGP for all its border routers at once, to avoid route loops within the AS.

Status

As of early 2003, an implementation of S-BGP has been developed and demonstrated on small numbers of workstations representing small numbers of ASes. We also developed software for a simple repository, and for NOC tools that support secure upload and download of certificates, CRLs, and AAs to and from repositories, and for certificate management for NOC personnel and routers. This suite of software, plus CA software from another *Defense Advanced Research Projects Agency* (DARPA) program, provide all of the elements needed to represent a full S-BGP system. All of this software is available in open source form.

Summary

S-BGP represents a comprehensive approach to addressing a wide range of security concerns associated with BGP. It detects and rejects unauthorized UPDATE messages, irrespective of the means by which they arise; for example, misconfiguration, active wiretapping, compromise of routers or management systems, etc. S-BGP is not perfect; it has a few residual vulnerabilities, but these pale in comparison to the security features S-BGP provides, and removal of these vulnerabilities would require more fundamental changes to BGP semantics.

The S-BGP design is based on a top-down security analysis, starting with the semantics of BGP and factoring in the wide range of attacks that have or could be launched against the existing infrastructure.

Acknowledgements

Many individuals contributed to the design and development of S-BGP, including Christine Jones, Charlie Lynn, Joanne Mikkelson, and Karen Seo.

Securing BGP Through Secure Origin BGP

by Russ White, Cisco Systems

Networks have come under increasing scrutiny in the area of security. Routing, the part of the network that provides information on how to reach destinations within the network, has been gaining attention from a security perspective as well. *The Internet Engineering Task Force* (IETF) has, in fact, formed a new working group, the *Routing Protocols Security Requirements Working Group* (**http://www.rpsec.org**), to analyze security in routing systems.

Of course, the biggest network in existence is the Internet, and the routing protocol that provides reachability and path information for the Internet is the *Border Gateway Protocol* (BGP), specified in RFC 1771. Several methods of securing the information carried within BGP have been proposed:

- *Internet Route Verification* (IRV), described in "Working Around BGP: An Incremental Approach to Improving Security and Accuracy of Interdomain Routing," Symposium on Network and Distributed Systems Security, February 2003, by Geoffrey Goodell, William Aiello, Timothy Griffin, John Ioannidis, Patrick McDaniel, and Aviel Rubin. IRV relies on out-of-band communication with a route originator to verify the correctness of a route.
- S-BGP, described in the companion article and at:
  www.net-tech.bbn.com/projects/s-bgp
- *Domain Name System* (DNS)-based *Network Layer Reachability Information* (NLRI) origin *Autonomous System* (AS) verification in BGP, which is the oldest attempt at validating the information carried within BGP, is described in **draft-bates-bgp4-nlri-orig-verif-00.html**,

This article discusses *Secure Origin BGP* (soBGP), a solution recently proposed by a group (including me) mostly within Cisco Systems. We believe soBGP to be a deployable mechanism for validating the correctness and authorization of the data carried within BGP, and also for preventing the sorts of attacks resulting from misconfiguration or intentional insertion of bad data into the Internet routing system.

We address four goals when we consider security in terms of BGP:

- Is the AS originating the destination (prefix) authorized to advertise it? In other words, if a router receives an advertisement for the 10.1.1.0/24 network originating in AS65500, is there any way to verify that AS65500 is supposed to be advertising 10.1.1.0/24?
- Does the AS advertising the destination actually have a path to the destination? In other words, if a router is receiving an advertisement from a BGP peer in AS65501 that it can reach 10.1.1.0/24, is there any way to verify that AS65501 actually has a path to the AS origination 10.1.1.0/24?

- Is the peer advertising the route authorized by the originator, or owner, of the destination, to advertise a path to the destination?
- Does the path advertised by a peer AS fall within the policies the local network administrators have set forward? The most obvious issue is whether or not the AS Path advertised by the peer is an acceptable path to send the traffic along.

We argue elsewhere that the second two goals cannot be fully met within an operational internetwork, for many reasons; see **`draft-white-pathconsiderations-00.txt`** for further discussion on this point. In this article, then, we discuss how soBGP can meet the first two goals in operational networks.

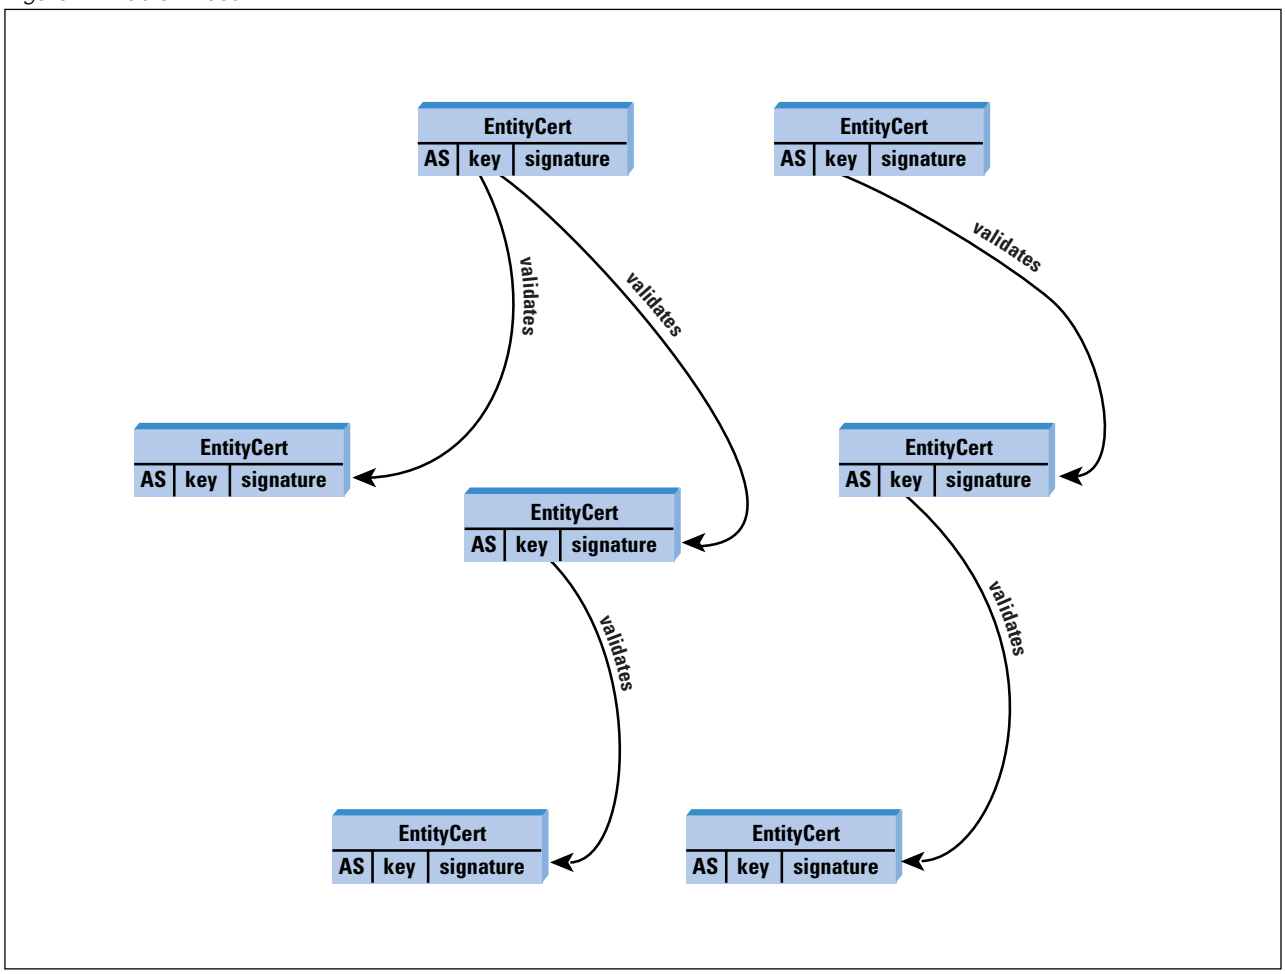
Begin at the Beginning: Who Are You?

The first step in securing anything is authentication; each participant must have some way of knowing who the other participants are, and what information they will be using to sign or encrypt their data. This is a classic problem in cryptography, called *key distribution*. There must be some way to receive keys used to sign or encrypt data, and then to validate that the keys received actually belong to the participant we believe they belong to.

This problem is addressed in soBGP using an *EntityCert,* which ties an AS number to a public key (or a set of public keys) corresponding to a private key the AS will be using to sign various other certificates. An EntityCert is defined in soBGP to be an X.509v3 certificate, similar to those used by *Transport Layer Security* (TLS) and *IP Security* (IPSec). The main problem we face when accepting an EntityCert is knowing whether or not the key carried within the certificate is actually the key of the advertising AS.

soBGP resolves this by requiring the EntityCert to be signed by a third party, validating that this AS actually belongs with this key. A small number of "root keys" distributed out of band could then be used to validate a set of advertised EntityCerts. These are used in turn to build up the database of known good ASm/key pairs in the system, allowing even more EntityCerts to be validated. Thus, EntityCerts can form a web of trust, built on the public keys of a small number of well-known entities, such as top-level backbone service providers, key authentication service providers (such as Verisign), and others.

Figure 1: Web of Trust

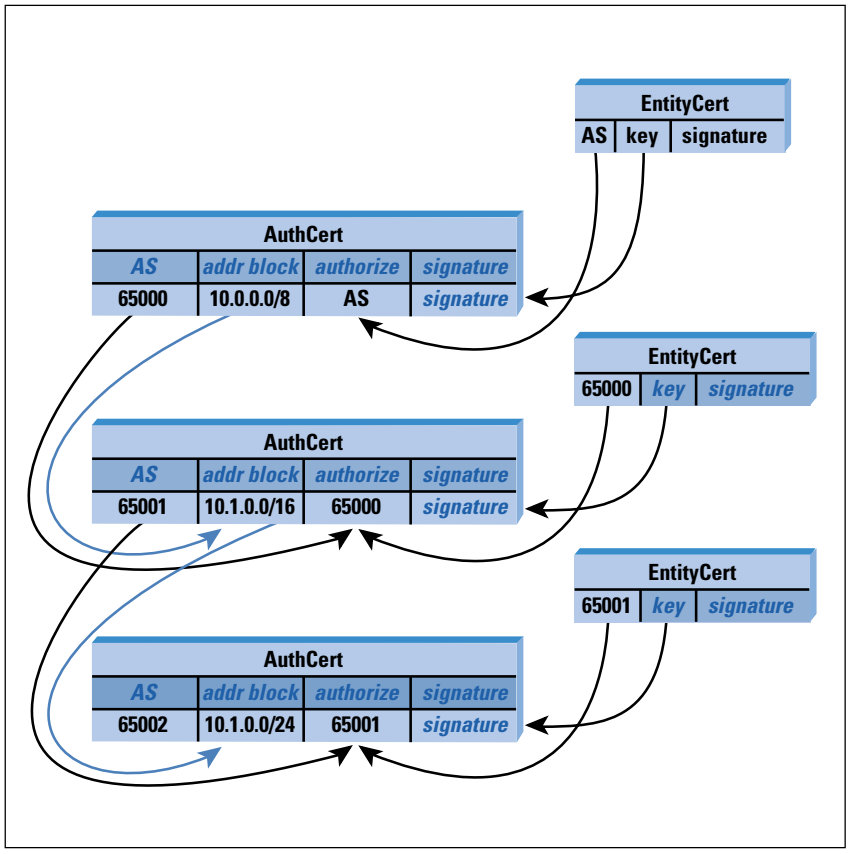


The key each AS distributes in its EntityCert is actually the public half of a private/public key pair. An AS would keep its private key entirely private, holding it on one highly secure device in its network (which is not even required to be online), and generating signatures for other certificates as needed. Only an AS public key is ever exposed in this way, so no special protection mechanisms (for example, tamper-resistant hardware) are required at any border to prevent private keys from being compromised.

The First Goal: Are You Authorized?

Now that we have distributed a public key per AS, we can build a certificate that will provide authorization for an AS to advertise a specific block of addresses. This authorization is provided through an *Authorization Certificate*, or *AuthCert*. An AuthCert ties an AS to a block of addresses that the AS may advertise, as Figure 2 illustrates.

Figure 2: Authorization Example



Starting at the top of the illustration, we find that some AS has authorized AS65000 to advertise prefixes within the block 10.0.0.0/8. The AuthCert is signed using the authorizing AS key. To delegate some part of this block of address space to another AS, AS65001, AS65000 builds an AuthCert tying 10.1.0.0/16 to AS65001. AS65001, in turn, suballocates a smaller part of this address space to AS65002, by building an AuthCert tying AS65002 to 10.1.1.0/24.

Any device receiving these three AuthCerts can check them by:

- Looking up the public key of the authorizer, and verifying the signature on the AuthCert
- Making certain the authorizer is permitted to advertise the address space it has suballocated this block of address space from

The device then builds a local table of address blocks and corresponding ASs authorized to advertise prefixes within those address blocks. Received updates can be checked against this database to verify authorization of the originating AS to advertise a prefix.

Blocks of address space are used here, rather than individual prefixes; an AuthCert can authorize an AS to advertise any number of prefixes within a block of addresses. This reduces the number of certificates within the system, thereby reducing overall cryptographic processing requirements. If a specific AS desires per-prefix authorization, it can build individual AuthCerts for each allocated prefix, rather than for blocks of address space.

Per-Prefix Policy

AuthCerts are not advertised as independent certificates within soBGP; instead, they are wrapped in a *PrefixPolicyCert*. PrefixPolicyCerts contain an AuthCert, a set of policies the originator would like to apply to prefixes advertised within this block of addresses, and a signature generated using the private key of the authorized AS. Policies that may be included in the PrefixPolicyCert include the longest prefix length allowed within the address block, and possibly other policies, such as a list of ASs that may not be or must be in the AS Path of routes to destinations within the address block.

In reality, the per-prefix policies available to the originator are limitless; the main problem is enforcing those policies when they are received by other ASs.

The Second Goal: Do You Really Have a Path?

Our second goal is to be able to verify that the advertiser of a given route actually has a path to the destination. This goal is met in soBGP by building a topology map of the paths of the entire internetwork. Each AS attached to the internetwork builds an *ASPolicyCert*, which contains, primarily, a list of its peers, and signed using the originator's private key. Using this list of transit peers, a map of the internetwork topology may be built, as Figure 3 illustrates.

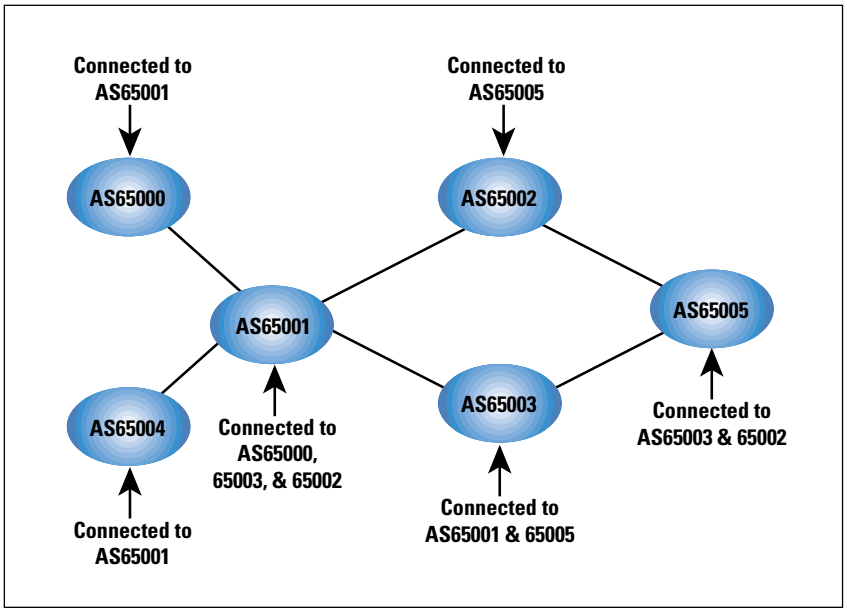


Figure 3: Connectivity Graph Example

If AS65005 receives an update from AS65002, claiming it can reach a destination in AS65000 through the path {65002, 65001, 65000}, it can:

- Check to make certain AS65002 claims to be connected to AS65001 in its ASPolicyCert, and that AS65001 claims to be connected to AS65002 in its ASPolicyCert
- Check to make certain AS65001 claims to be connected to AS65000 in its ASPolicyCert, and that AS65000 claims to be connected to AS65001 in its ASPolicyCert

If, for instance, AS65002 claims a path to a destination inside AS65000 through the path (65002, 65000), AS65002 would be able to discover that the path is invalid, because AS65000 does not claim to be connected to AS65002. This simple two-way connectivity check along a graph can be mixed with various policy statements—stating a specific peer is not a transit, not advertising certain peers, etc.—to provide a much wider range of policies than AS Path-based methods.

Transporting Certificates

One of the primary problems any security system such as soBGP is going to face is transporting security information through the internetwork. We would like to make certain we do not rely on the routing system to provide information about the security of the routing system. In other words, we would not like to rely on unsecured routing information in order to reach a server providing the information required to secure the path to the server itself.

soBGP resolves this by proposing to advertise certificates in much the same way as routing information is propagated today—through an interdomain protocol. Currently the soBGP drafts specify a new type of BGP message, the SECURITY message, which can be used to transport the required certificates, the EntityCert, the PrefixPolicyCert, and the ASPolicyCert, throughout an internetwork. Other methods of transporting data such as these certificates throughout an internetwork are currently being pursued by the IETF; if other methods are offered, soBGP could transport certificates across any such distribution mechanism.

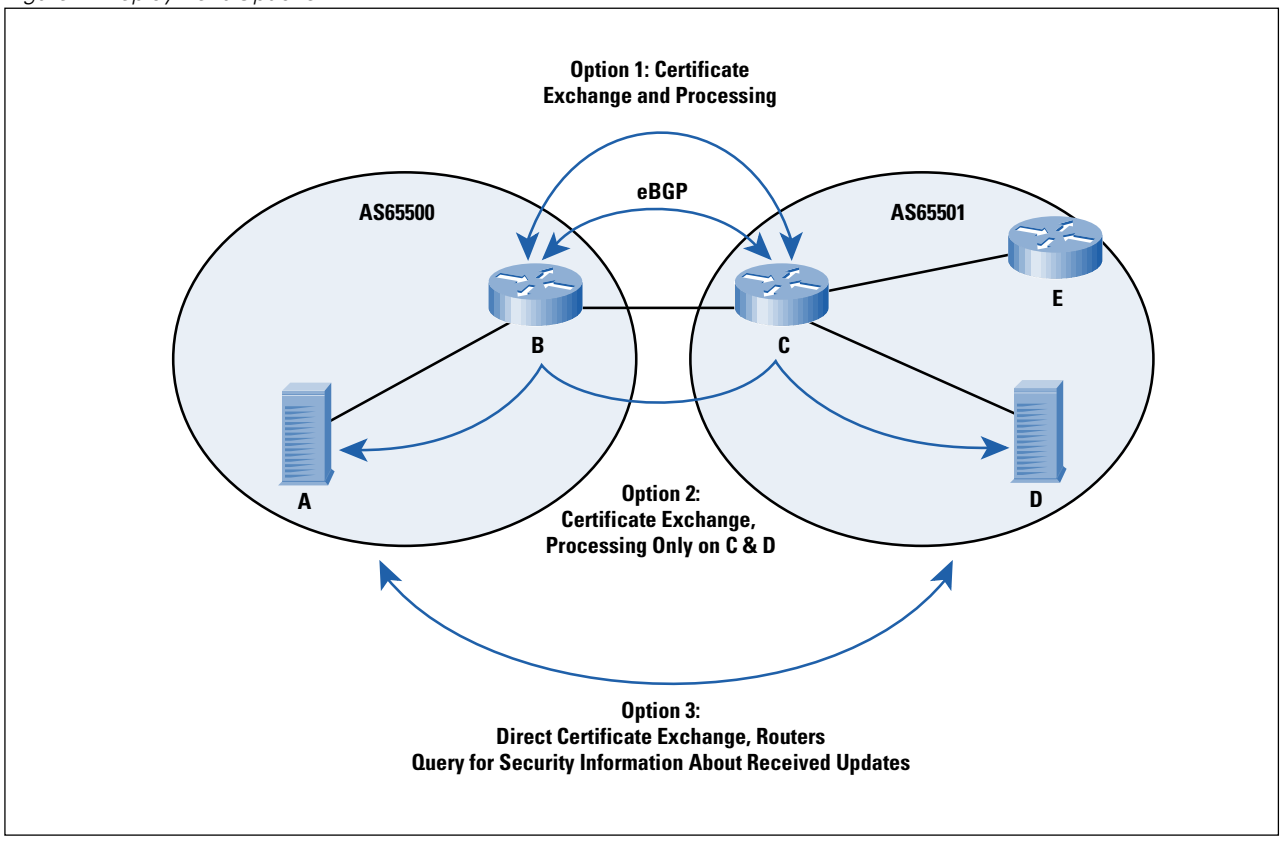
Deployment

Finally, we come to the hardest problem any routing security system is going to face: actually getting it operating in the field, with useful results, with a minimum of equipment changes, and a minimum number of participants. Here, soBGP provides a wide variety of options, primarily because it is not transport-dependent, nor dependent on a yet-to-be constructed centralized set of servers.

Although deployment options abound, here we discuss three, just to show the range of options available. Figure 4 illustrates these options.

The first option shown in this network is direct certificate exchange and processing between border routers. With this option, routers that are capable of the cryptographic processing required to validate received certificates exchange certificates with their peers in other ASs (just as they exchange routing information today), process those certificates, and build local databases from which they perform security checks on received updates.

Figure 4: Deployment Options



Although it may appear that processing, in this situation, would be extensive, it is actually possible to spread the processing required out among the border routers in a large AS. For instance, each certificate that router C receives and processes can be subsequently sent over an encrypted link to Router E. Router E could treat these certificates as though they had been validated locally, because they are received across an encrypted link from a trusted peer within the same administrative domain. Thus, only the edge router that has learned a certificate would actually process the certificate. This spreads the processing along all the edges in the AS.

A second option is for the edge routers, B and C, to exchange the certificates, but not process them. Instead, each edge router would relay the not-yet-validated certificates to internal servers A and D, respectively, thereby validating the certificates by performing the necessary cryptographic operations. As the border routers receive updates, they can query the server about the validity of each update, and take action based on the reply received.

Finally, it is possible for the servers to exchange certificates directly, over a multihop session. Servers A and D would then process the certificates, and the border routers, B and C, would query these servers to determine if received updates are valid or invalid.

Summary

Through this short survey of soBGP, we have shown it to be a flexible, moderately lightweight, yet strong system for validating the information carried through BGP in a large internetwork. It has low overhead processing requirements and very flexible deployment options, but no reliance on centralized servers. We are currently working to develop prototypes of soBGP on several platforms, to show how the technology will work on a wide range of devices.

For more information on soBGP, refer to:
`ftp://ftp-eng.cisco.com/sobgp/index.html`

You will find the most recent versions of the drafts, several slide shows, and other information about soBGP at this site.

Trends in Viruses and Worms

by Thomas M. Chen, Southern Methodist University

The modern computer *virus* was conceived and demonstrated by Fred Cohen in 1983. Like biological viruses, computer viruses reproduce by attaching to a normal program or document and taking over control of the execution of that program to infect other programs. Early viruses could spread slowly mostly by floppies (such as the 1986 *Brain* virus), but the Internet has made it much easier for viruses to move among computers and spread rapidly. Networks have created a fertile environment for worms, which are related to viruses in their ability to self-replicate but are not attached to other programs. Worms are particularly worrisome as standalone automated programs designed to exploit the network to seek out vulnerable computers. The term *worm* was originated by John Shoch and Jon Hupp during their experiments on mobile software at Xerox PARC in 1979, inspired by the network-based *tapeworm* monster in John Brunner's novel, *The Shockwave Rider*[1]. Shoch and Hupp thought of worms as multi-segmented programs distributed across networked computers.

The Internet increases the vulnerability of all interconnected machines by making it easier for malicious programs to travel between computers by themselves. Recent virus and worm outbreaks, such as the *Blaster* worm in August 2003 and the SQL *Sapphire/Slammer* worm in January 2003, have demonstrated that networked computers continue to be vulnerable to new attacks despite the widespread deployment of antivirus software and firewalls. Indeed, a review of the history of viruses and worms shows that they have continually grown in sophistication over the years. This article highlights a series of significant past innovations in virus and worm technology. The purpose is to show that viruses and worms continue to pose a major risk today and most likely into the future as their creators persist in seeking ways to exploit security weaknesses in networked systems.

Stealth

The earliest viruses attempted to hide evidence of their presence, a trend that continues to today. The 1986 DOS-based *Brain* virus hid itself in memory by simulating all of the DOS system calls that normally detect viruses, causing them to return information that gave the appearance that the virus was not there.

The 2001 *Lion* worm installed a rootkit called *t0rn,* which is designed to make the actions of the worm harder to detect through numerous system modifications to deceive *syslogd* from properly capturing system events (*syslogd* is often used to detect worm activity)[2]. More recently, viruses and worms have attempted to hide by actively attacking antivirus software on the infected computer (refer to the section "Armoring").

Social Engineering

The 1987 *Christma Exec* virus was an early example of social engineering, spreading by e-mail among IBM mainframes. An arriving message tricks the user into executing the virus by promising to draw a Christmas tree graphic. The virus does produce a Christmas card graphic on the computer display (drawn using a scripting language called *Rexx*) but sends a copy of itself in the user's name to that user's list of outgoing mail recipients. The recipients believe the e-mail is from the user, so they are more likely to open the e-mail.

Social engineering continues to be common practice in today's viruses and worms, particularly those spread by e-mail. In January 1999, the *Happy99/Ska* worm/Trojan horse hybrid spread by e-mail with an attachment called **`Happy99.exe`**[3]. When the attachment was executed, it displayed fireworks on the screen to commemorate New Year's Day, but secretly modified the **`WSOCK32.DLL`** file (the main Windows file for Internet communications) with a Trojan horse program that allowed the worm to insert itself into the Internet communications process. Every e-mail sent by the user generated a second copy without any text but carried the worm to the same recipients.

The 1999 *PrettyPark* worm propagated as an e-mail attachment called **`Pretty Park.exe`**. The attachment is not explained, but it bears the icon of a character from the television show, *South Park*. If executed, it installs itself into the Windows System folder and modifies the Registry to ensure that it runs whenever any **`.EXE`** program is executed. In addition, the worm e-mails itself to addresses found in the Windows Address Book. It also mails some private system data and passwords to certain *Internet Relay Chat* (IRC) servers. Reportedly, the worm also installs a backdoor to allow a remote machine to create and remove directories, and send, receive, and execute files.

In February 2001, the *Anna Kournikova* virus demonstrated social engineering again, pretending to carry a JPG picture of the tennis player. If executed, the virus e-mails a copy of itself to all addresses in the Outlook address book.

In March 2002, the *Gibe* worm spread as an attachment in an e-mail disguised as a Microsoft security bulletin and patch. The text claimed that the attachment was a Microsoft security patch for Outlook and Internet Explorer. If the attachment is executed, it displays dialog boxes that appear to be patching the system, but a backdoor is secretly installed on the system.

Macro Viruses

The *Concept* virus was the first macro virus, written for Word for Windows 95. The vast majority of macro viruses are targeted to Microsoft Office documents that save macro code within the body of documents. Macro viruses have the advantages of being easy to write and independent of computing platform. However, macro viruses are no longer widespread after people have become more cautious about using the Office macro feature.

Mass E-Mailers

In March 1999, the *Melissa* macro virus spread quickly to 100,000 hosts around the world in three days, setting a new record and shutting down e-mail for many organizations using Microsoft Exchange Server[4]. It began as a newsgroup posting promising account names and passwords for erotic Web sites. However, the downloaded Word document actually contained a macro that used the functions of Microsoft Word and the Microsoft Outlook e-mail program to propagate. Up to that time, it was widely believed that a computer could not become infected with a virus just by opening e-mail. When the macro is executed in Word, it first checks whether the installed version of Word is infectable. If it is, it reduces the security setting on Word to prevent it from displaying any warnings about macro content. Next, the virus looks for a certain Registry key containing the word "Kwyjibo" (apparently from an episode of the television show, *The Simpsons*). In the absence of this key, the virus launches Outlook and sends itself to 50 recipients found in the address book. Additionally, it infects the Word **`NORMAL.DOT`** template using the Microsoft *Visual Basic for Applications* (VBA) macro auto-execute feature. Any Word document saved from the template would carry the virus.

In June 1999, the *ExploreZip* worm appeared to be a WinZip file attached to e-mail but was not really a zipped file[5]. If executed, it appears to display an error message, but the worm secretly copies itself into the Windows Systems directory or loads itself into the Registry. It sends itself via e-mail using Outlook or Exchange to recipients found in unread messages in the inbox. It monitors all incoming messages and replies to the sender with a copy of itself.

In May 2000, the fast-spreading *Love Letter* worm demonstrated a social engineering attack[6]. It propagated as an e-mail message with the subject "I love you" and text that encourages the recipient to read the attachment. The attachment is a Visual Basic script that could be executed with Windows Script Host (present if the computer has Windows 98, Windows 2000, Internet Explorer 5, or Outlook 5). Upon execution, the worm installs copies of itself into the Windows System directory and modifies the Registry to ensure that the files are run when the computer starts up. The worm also infects various types of files (for example, **`.VBS`**, **`.JPG`**, **`.MP3`**, etc.) on local drives and networked shared directories. If Outlook is installed, the worm e-mails copies of itself to addresses found in the address book. In addition, the worm makes a connection to IRC and sends a copy of itself to anyone who joins the IRC channel. The worm has a password-stealing feature that changes the startup URL in Internet Explorer to a Website in Asia. The Website downloads a Trojan horse designed to collect various passwords from the computer.

In 2002, 90 percent of the known viruses were mass e-mailers. Two of the most prevalent ones, *Bugbear* and *Klez,* began a trend of carrying their own *Simple Mail Transfer Protocol* (SMTP) engines. Although e-mail continues to be the most common infection vector, recent worms have been exploring new vectors (see the section "New Infection Vectors").

In addition, mail servers are becoming more powerful in their capabilities to detect and filter malicious code. For these reasons, mass e-mailing may decline as an infection vector for future viruses.

Polymorphism

Polymorphism is based on the simpler idea of encryption, which makes a virus harder to detect by antivirus software scanning for a unique virus signature (byte pattern). Encryption attempts to hide a recognizable signature by scrambling the virus body. To be executable, the encrypted virus is prepended with a decryption routine and encryption key. However, encryption is not effective because the decryption routine remains the same from generation to generation, although the key can change, scrambling the virus body differently. Antivirus scanners can detect a sequence of bytes identifying a specific decryption scheme.

Polymorphic viruses permute continuously to avoid detection by antivirus scanning[7]. The earliest polymorphic virus might have been a virus found in Europe in 1989. This virus replicated by inserting a pseudorandom number of extra bytes into the decryption algorithm, preventing any common sequence of more than a few bytes between two successive infections. Polymorphism became practical when a well-known hacker, *Dark Avenger,* developed a user-friendly *Mutation Engine* program to provide any virus with variable encryption. With a static signature so small, the risk of false positives by antivirus scanners became very high. Other hackers soon followed with their own versions of so-called mutation engines. The 1995 *Pathogen* and *Queeg* viruses were polymorphic DOS file-infecting viruses produced by Black Baron's *Simulated Metamorphic Encryption enGine* (SMEG)[7].

Blended Attacks

The famous 1988 *Morris* worm was the first to use a combination of attacks (or blended attacks) to spread quickly to 6000 UNIX computers in a few hours (10 percent of the Internet at that time)[8].

- It captured the password file and ran a password-guessing program on it using a dictionary of common words.
- It exploited the debug option in the UNIX *sendmail* program, allowing it to transfer a copy of itself.
- It carried out a buffer overflow attack through a vulnerability in the UNIX *fingerd* program.

In May 2001, the *Sadmind/IIS* worm spread by targeting two separate vulnerabilities on two different operating systems. It first exploited a buffer overflow vulnerability in Sun Solaris systems and installed software to carry out an attack to compromise Microsoft *Internet Information Services* (IIS) Web servers.

The July 2001 *Sircam* worm uses two ways to propagate. First, it e-mails itself as an attachment using its own SMTP engine, and if the attachment is executed, e-mails a copy of itself to addresses found in the Windows address book. Second, it spreads by infection of unprotected network shares.

In September 2001, *Nimda* raised new alarms by using five different ways to spread to 450,000 hosts within the first 12 hours[9]. *Nimda* seemed to signal a new level of worm sophistication.

- It found e-mail addresses from the computer Web cache and default *Messaging Application Programming Interface* (MAPI) mailbox. It sent itself by e-mail with random subjects and an attachment named **`readme.exe`**. If the target system supported the automatic execution of embedded MIME types, the attached worm would be automatically executed and infect the target.
- It infected Microsoft IIS Web servers, selected at random, through a buffer overflow attack called a *unicode* Web traversal exploit.
- It copied itself across open network shares. On an infected server, the worm wrote *Multipurpose Internet Mail Extensions* (MIME)-encoded copies of itself to every directory, including network shares.
- It added JavaScript to Web pages to infect any Web browsers going to that Website.
- It looked for backdoors left by previous *Code Red II* and *Sadmind* worms.

Armoring

In November 2002, the *Winevar* worm was an example of an "armored" worm that contained special code designed to disable antivirus software using a list of keywords to scan memory to recognize and stop antivirus processes and scan hard drives to delete associated files[10].

Klez and *Bugbear* are recent examples of worms that attack antivirus software by stopping active processes and deleting registry keys and database files used by popular antivirus programs. The 2003 *Fizzer* and *Lirva* worms also attempt to disable antivirus software.

Dynamic Software Updates

In October 2000, the *Hybris* worm propagated as an e-mail attachment[11]. It connected to the **`alt.comp.virus`** newsgroup to receive encrypted plug-ins (code updates). The method is sophisticated and potentially very dangerous, because the worm payload (destructive capability) can be modified dynamically.

The 2003 *Lirva* worm attempted to connect to a Website on **`web.host.kz`** to download BackOrifice, a notorious remote-access software package that gives complete control to a remote attacker. It also attempted to download another unknown file that was not found on the Website.

This technique was given an interesting twist by the *Welchia* or *Nachi* worm, which began spreading on August 18, 2003, soon after the *Blaster* worm. Apparently, its creator intended *Welchia* as a "good" worm to remove *Blaster*. It attempted to download and install a fix for *Blaster* from a Microsoft Website.

New Infection Vectors

The Linux *Slapper* worm, appearing in September 2002, was among the first to exploit *peer-to-peer* (P2P) technology[12]. It spread to Linux computers by exploiting the long *Secure Sockets Layer 2* (SSL2) key argument buffer overflow in the *libssl* library, used by the *mod_ssl* module of the Apache 1.3 Web server. When the worm infects a new machine, it binds to *User Datagram Protocol* (UDP) port 2002 and becomes part of a P2P network. The parent of the worm on the attacking machine sends to its offspring the list of all hosts on the P2P network and broadcasts the address of the new worm on the network. Then periodic updates to the host list are exchanged between machines on the network. The new worm also scans the network for other vulnerable machines, sweeping randomly chosen class B networks.

In March 2003, the *AimVen* worm spread by the *America OnLine Instant Messager* (AIM) by modifying the AIM program. Whenever an **`.EXE`** file is sent through AIM, the worm overwrites the file with a copy of itself.

The *Fizzer* worm discovered in May 2003 is a mass e-mailer that includes its own SMTP engine like *Klez* and *Bugbear*. It also tries to spread via *KaZaa*, a popular P2P file-sharing application, and shared directories.

The 2003 *Lirva* worm, named after the singer, Avril Lavigne, is a mass e-mailer taking advantage of the same MIME header exploit as *Badtrans* and *Klez*, but also tries to spread by IRC, "I seek You" (ICQ), *KaZaa,* and open network shares[13].

Data-Stealing Payloads

Most fast-spreading worms in the past have not carried destructive payloads. Instead, they have tended to appear to be proof-of-concepts to demonstrate a particular security weakness. Some worms, though, such as *Code Red,* have installed *Denial-of-Service* (DoS) agents or backdoors on infected machines. Recently worms have begun to carry keyloggers and password-stealing Trojans in their payloads.

The 2003 *Fizzer* worm includes a keystroke logging Trojan horse that stores the data in an encrypted file. It establishes its own accounts on IRC and AIM to wait for instructions from the virus writer, who could conceivably fetch the keystrokes data.

The 2003 *Lirva* worm e-mails cached Windows dialup networking passwords to the virus writer, and e-mail random **`.TXT`** and **`.DOC`** files to various addresses.

Bugbear installs a keystroke logging tool into the Windows System folder that e-mails the keystrokes data to preprogrammed addresses[14]. It listens on port 36794 for commands from a remote hacker.

Fast and Furious Worms

A particularly worrisome new trend is extremely fast worms targeted to specific (usually Windows-related) vulnerabilities that might saturate their target population within a few hours or even less than an hour. These worms tend to be simpler and targeted to single rather than multiple vulnerabilities, in order to be highly efficient in their probing for other vulnerable machines.

The first example might be the *Code Red* worm, which actually appeared in three different versions[15]. The first version of *Code Red I* appeared on July 12, 2001, targeted to a buffer overflow vulnerability in Microsoft IIS Web servers. However, a programming error in its pseudorandom address generator caused each worm copy to probe the same set of IP addresses and prevented the worm from spreading quickly. A week later on July 19, a second version of *Code Red I* with the programming error apparently fixed was able to infect more than 359,000 servers within 14 hours. At its peak, the worm was infecting 2000 hosts every minute. A more complex and dangerous *Code Red II* targeted to the same IIS vulnerability appeared on August 4.

More recently, the *Structured Query Language* (SQL) *Sapphire/ Slammer* worm appeared on January 25, 2003, targeted to Microsoft SQL Server machines not running *Service Pack 3* (SP3), such as SQL Server 2000 and *Microsoft Desktop Engine* (MSDE) 2000[16]. It reportedly infected 90 percent of vulnerable hosts within 10 minutes (about 120,000 servers)[17]. The spreading rate was surprisingly fast and resulted in DoS effects (network outages and high packet loss) due to traffic overloading servers and routers. In the first minute, the infection doubled every 8.5 seconds, and hit a peak scanning rate of 55,000,000 scans per second after only 3 minutes. In comparison, *Code Red* infection doubled in 37 minutes (slower but infected more machines). *Slammer* was able to spread so quickly because it appeared to be designed simply for efficient replication. The worm carried no payload and consisted of a single 404-byte UDP packet (including 376 bytes for the worm) that could be sent without having to wait for responses from targeted machines. In contrast, *Code Red* was about 4000 bytes and *Nimda* was 60,000 bytes, and their scanning depended on the time to establish TCP connections to targeted machines. The *Slammer* worm was much more efficient, simply generating copies of itself at the full rate of the infected machine.

Latest Developments

The week of August 12–19, 2003, has been called the worst week for worms in history, seeing *MS Blaster, Welchia* (or *Nachi*), and *Sobig.F* in quick succession. *MS Blaster* or *LovSan* was another fast worm, which appeared on August 12, 2003, targeted to a *Windows Distributed Component Object Model* (DCOM) *Remote Procedure Call* (RPC) vulnerability announced on July 16, 2003[18]. The worm probes for a DCOM interface with RPC listening on TCP port 135 on Windows XP and Windows 2000 PCs. Through a buffer overflow attack, the worm causes the target machine to start a remote shell on port 4444 and send a notification to the attacking machine on UDP port 69.

A *Trivial File Transfer Protocol* (TFTP) "get" command is then sent to port 4444, causing the target machine to fetch a copy of the worm as the file **`MSBLAST.EXE`**. In addition to a message against Microsoft, the worm payload carries a DoS agent (using TCP SYN flood) targeted to the Microsoft Website **`windowsupdate.com`** on August 16, 2003. Although *Blaster* has reportedly infected about 400,000 systems, experts reported that the worm did not achieve near its potential spreading rate because of novice programming.

Six days later on August 18, 2003, the apparently well-intended *Welchia* or *Nachi* worm spread by exploiting the same RPC DCOM vulnerability as *Blaster*. It attempted to remove *Blaster* from infected computers and download a security patch from a Microsoft Website to repair the RPC DCOM vulnerability. Unfortunately, its scanning resulted in a DoS effect on some networks, such as Air Canada's check-in system and the U.S. Navy and Marine Corps computers.

The very fast *Sobig.F* worm appeared on the next day, August 19, 2003, only seven days after *Blaster*[19]. The original *Sobig.A* version was discovered in January 2003, and apparently underwent a series of revisions until the most successful *Sobig.F* variant. Similar to earlier variants, *Sobig.F* spreads among Windows machines by e-mail with various subject lines and attachment names, using its own SMTP engine. The worm size is about 73 kilobytes with a few bytes of garbage attached to the end to evade antivirus scanners. It works well because it grabs e-mail addresses from a variety of different types of files on the infected computer and secretly e-mails itself to all of them, pretending to be sent from one of the addresses. At its peak, *Sobig.F* accounted for 1 in every 17 messages, and reportedly produced over 1 million copies of itself within the first 24 hours. Interestingly, the worm was programmed to stop spreading on September 10, 2003, suggesting that the worm was intended as a proof-of-concept. This is supported by the absence of a destructive payload, although the worm is programmed with the capability to download and execute arbitrary files to infected computers. The downloading is triggered on specific times and weekdays, which are obtained via one of several *Network Time Protocol* (NTP) servers. The worm sends a UDP probe to port 8998 on one of several preprogrammed servers, which responds with a URL for the worm to download. The worm also starts to listen on UDP ports 995–999 for incoming messages, presumably instructions from the creator.

Conclusions

Why does the Internet remain vulnerable to large-scale worm outbreaks? Since at least 1983, the Internet community has understood the risks and mechanics of viruses. The 1988 Morris worm taught the community to be watchful for potentially dangerous worms. Over the years, a variety of antivirus software, firewalls, intrusion detection systems, and other security equipment have been installed. Moreover, the *Computer Emergency Response Team* (CERT) at CMU was established as the first computer security incident response team, which later joined an expansive global coalition of security incident response teams called the *Forum of Incident Response and Security Teams* (FIRST)[20].

Despite our knowledge and infrastructure defenses, many viruses and worms have broken out regularly in the Internet over the years. By some reports, 5 to 15 new viruses and worms are released every day, although a fraction of that number are not released in the wild and most do not spread well. Still, fast-spreading viruses and worms continue to appear with regularity. Outbreaks have become so commonplace that most organizations have come to view them as a routine cost of operation.

The problem is sometimes portrayed as a perpetual struggle between virus writers who keep innovating (as described here) and the antivirus industry, which tries to keep up. However, the problem is actually larger, involving the entire computer industry. Viruses and worms are successful because computers have security vulnerabilities that can be exploited. Clearly, the Internet itself is simply serving its purpose of interconnecting computer systems. The security vulnerabilities exist in the host end systems. Security vulnerabilities continue to exist for many reasons. First, software is often written in an unsecure manner, for example, vulnerable to buffer overflow attacks that are commonly used by worms. Buffer overflow attacks have been widely known since 1995, but this type of vulnerability continues to be found very often (on every operating system.) Second, when vulnerabilities are announced with corresponding software patches, many people are slow to apply patches to their computer for various practical reasons. Weakly protected computers can be compromised, putting the entire community at risk, including secured computers that can still be impacted by the traffic effects of a worm outbreak.

However, there is reason to be hopeful for a solution. Fortunately, worms typically have a weakness of exploiting vulnerabilities that have been known for some time. Worm writers do not invent new exploits for the simple reason that they want to ensure that their worm will spread after it is released. For example, the *Code Red I* worm took advantage of a buffer overflow vulnerability in Microsoft IIS servers that had been known for a month. The *Nimda* worm exploited a unicode Web traversal vulnerability in Microsoft IIS servers that was published a year earlier. The SQL *Slammer/Sapphire* worm exploited a buffer overflow vulnerability in Microsoft SQL servers that had been known for six months. The recent *Blaster* worm exploited a Windows DCOM RPC vulnerability announced two months earlier. Watching for probing activity attempting to exploit known vulnerabilities could help detect and block worm outbreaks at an early stage. Ideas for automatic detection and quarantine of new epidemics is attracting research[21].

Aside from technological considerations, an important issue is accountability. The most obvious parties to hold liable are the virus creators, but it has been observed many times that few virus writers have been prosecuted, and sentences have tended to be light. The author of the 1988 Internet worm, Robert Morris, was sentenced to three years of probation, 400 hours of community service, and a $10,000 fine.

Chen Ing-hau was arrested in Taiwan for the 1998 *Chernobyl* virus, but he was released when no official complaint was filed. Onel de Guzman was arrested for writing the 2000 *LoveLetter* virus, which resulted in $7 billion of damages, but he was released because of the lack of relevant laws in the Philippines. Jan De Wit was sentenced for the 2001 *Anna Kournikova* virus to 150 hours of community service. David L. Smith, creator of the 1999 *Melissa* that caused at least $80 million of damages, was sentenced to 20 months of custodial service and a $7500 fine.

It is notoriously difficult to trace a virus or worm to its creator from analysis of the code, unless inadvertent clues are left in the code. In addition, cases are difficult to prosecute, and malicious intention (as opposed to just recklessness) is difficult to prove. Moreover, long prison sentences have been perceived as overly harsh for arrested virus creators, who have tended to be teenagers and university students. In addition, in the absence of a serious legal deterrent, the general perception persists that virus creators can easily avoid the legal consequences of their actions. Perhaps to address this problem, authorities have been diligently investigating the creators of *Blaster* and *Sobig*. So far, a teenager, Jeffrey Lee Parson, has been arrested for writing the *Blaster.B* variant, a slight modification of the original *Blaster*. Soon afterward, Dan Dumitru Ciobanu was arrested in Romania for writing the *Blaster.F* variant.

Some have argued wishfully that software vendors should be held financially liable for damages resulting from the security vulnerabilities in their products. The assumption is that accountability would increase motivation to write and sell more secure software, a solution that would result in a less inviting environment for viruses and worms. So far, software vendors have managed to acknowledge their role but avoid accountability.

IPv6 Behind the Wall

by Jim Bound

IPv6 has technology advantages over IPv4, and most of them will not be seen by the end user any more than users see features added to other extensions to the Internet Protocol suite, sensors on their automobiles, or from any core technology evolution. This article focuses on three of those IPv6 technology advantages "Behind the Wall."

An essential catalyst for the Next-Generation Internet is the *Internet Protocol Version 6* (IPv6), which will provide an evolution to a more pervasive use of the Internet and networking in general. The current Internet, using IPv4, is insufficient to support the business and operational preconditions for peer-to-peer applications and security, billions of mobile devices, sensor networks, and the requisite distributed computing infrastructure to support a mobile society. The "band aids" applied to permit the current Internet to keep it operating has created additional operational costs and reduced operational capabilities for users and networks.

This article is an IPv6 Forum (**`www.ipv6forum.com`**) statement of the technology advantages of IPv6.

IPv6 Supports End-to-End Applications and Security

There are several schools of thought and opinions on the issue of address space and all project different results, depending on one's mathematical view and philosophy regarding use models. There is also the effect of disruptive technology, which can make moot any projections of IPv4 address space. In that sense, rationing is justified and intelligent. The IPv6 Forum believes we already are experiencing the initial quake of disruptive technology, and that there is a need for users and markets to evolve further with a basic tenet that end-to-end applications and security are a priori for that evolution to begin. The IPv6 Forum believes that *Network Address Translatio*n (NAT) is about control, but that control comes at a cost of the freedom to use peer-to-peer computing over client to server-only computing.

Two users on the Internet today generally cannot each initiate peer-to-peer communications with each other because their location and identity are not available to each other from two disparate networks. In addition, security between them must trust a third party, and absolute private communications is impossible. The reason is that the Internet has evolved so that users are generally behind NATs that preclude peer-to-peer communications, or the exchange of private security credentials. Some will say this affords users security on the Internet. Although NAT does provide a denial-of-service perimeter, it also provides a denial of service to a direct trust relationship between peers. IPv6 is the only way to have peer-to-peer security for the Next-Generation Internet at a reasonable cost and a true privacy trust model on the Internet.

In the field of network computer science when engineers and architects implement translation functions in a solution, a cost is incurred that would not exist without translation. This is due to the need to keep *state* before, during, and after the translation. In software engineering terminology, these *state machines* add time and space costs to the entire operation. In addition, a NAT box is a single point of failure, because it is the only point on the network where a user can exit or enter when translation exists. Translation also does not permit the use of all functions possible without translation because too many participants need to know the mappings, and each function requires a separate state to be maintained, and the time + space costs increase exponentially. The time + space costs of NAT to keep the Internet operational have been passed on to every part of the current Internet business, consumer, and government market sectors, and cannot even support the original functions of the Internet before NAT. The current Internet has no hope of supporting the functions of the Next-Generation Internet required or of offering a solution to the great digital divide that exists currently and is increasing daily.

The good news is that IPv6 is evolving, early adopter deployment has begun, and vendors have delivered initial IPv6 products to the market. IPv6 will not require NAT, and the infrastructure supports a stateless architecture for the Internet, using statefull properties only where they can be used without a translation attribute or policy. IPv6 inherently supports mobile communications, billions of devices, and sensor networks that will be pervasive at a reasonable cost and provide the option to eliminate the digital divide within the current Internet.

IPv6 Supports a Stateless Node Discovery Architecture

A Next-Generation Internet base technology advantage for mobile user devices, ad hoc networks, mobile network providers, and generally for all users is the *Stateless Node Discovery Architecture* inherent within IPv6.

IPv6 nodes can discover each other and form IPv6 addresses to communicate on a network using what is called *Neighbor Discovery* and *Stateless Autoconfiguration*. IPv6 supports an extensible stateless node discovery paradigm, which provides the following features:

- Discover presence of nodes on the network
- Discover Datalink Layer nodes on the network
- Discover routers on the network
- Discover link configuration parameters on the network

These features permit an IPv6 node to obtain and maintain information about the accessibility of another node on the network for communications. Node Discovery is the predecessor to the node obtaining an address from IPv6 autoconfiguration. This core IPv6 technology framework also permits nodes to communicate on networks where there are no routers within an ad hoc network.

A host, when booted on an IPv6 link, first creates a *link-local* address by taking the architecturally defined prefix in Neighbor Discovery **`FE80`**, and appending an *End User Identifier* (EUI), determined by the host, to that prefix. This link-local address is then verified on the link that it is not duplicated with other link-local addresses on that host's link. This host communication is performed using link IPv6 multicast packets, to avoid duplicate link-local addresses, which are not permitted on an IPv6 Link.

The host then uses the link-local address to send on the IPv6 link *Neighbor Solicitations,* and all other hosts on that link see those multicast solicitations, and then return *Neighbor Advertisements* to the host. After this communications process, all nodes on the IPv6 link can now communicate, and communication was accomplished without the use of servers or routers in a stateless manner.

The host also listens for *Router Advertisements* on the IPv6 link (or sends *Router Solicitations*), which provide address prefixes, link configuration parameters, and information as to whether or not to use a stateless or stateful method for address assignment, and additional network configuration parameters using the *Dynamic Host Configuration Protocol for IPv6* (DHCPv6)[1].

If the host is instructed to use the stateless method for address configuration, then it can use the router prefixes announced to form IPv6 addresses from those prefixes by appending the EUI determined from the link-local address to that prefix to create an IPv6 Address. IPv6 supports multiple address types within the address architecture[2,3]. If the host is instructed to use the stateful method for address configuration, then DHCPv6 can be used to configure additional hosts' addresses.

Users will not see these IPv6 stateless advantages for network communications, but they will exist behind the wall of the user to provide a new and improved set of mechanisms for Node Discovery and Address Autoconfiguration far more robust and efficient than using the current IP Version 4 (IPv4) protocol. The IPv6 Stateless Architecture for Node Discovery permits a new model for node communications on links.

The Mobile IPv6 Technology Value Proposition

Mobile IPv6 offers many improvements over Mobile IPv4. Mobile IP as a technology permits users to remain connected across wireline (for example, Ethernet, xDSL) and wireless (for example, 802.11, cellular, satellite) networks, while roaming between networks. This permits users to stay connected while on the way to the airport from home, rather than shutting down their personal digital assistant (PDA)/laptop at home, and reconnecting at the WiFi location at the airport.

Figure 1: Route Optimization with Built-In Security

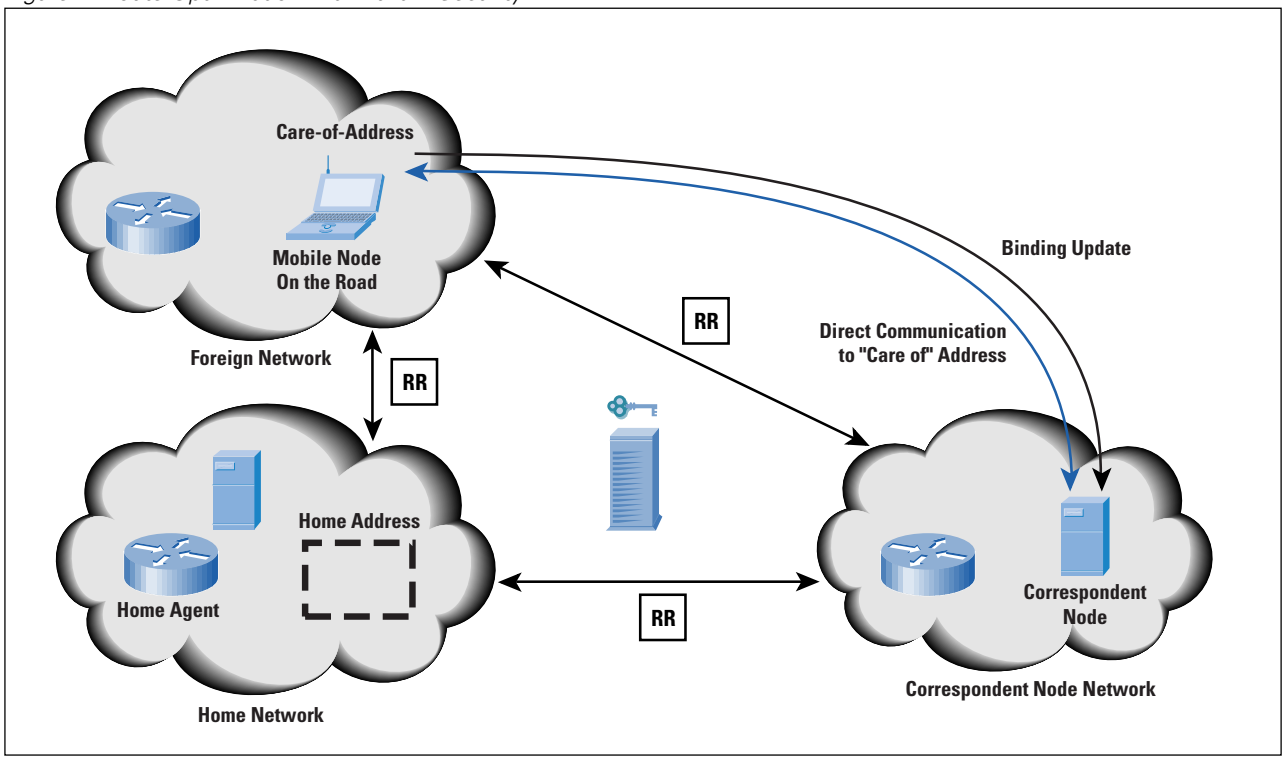

Figure 1 depicts the multiple phases of a mobile IPv6 connection. On the home network, a mobile node receives its home address as any IPv6 node. The mobile node registers that address with the *Home Agent*, which is a router that keeps the location information for the mobile node when it moves to a foreign network, stores the mobile-node *care-of address* when the mobile node is away from home, and performs other functions on behalf of the mobile node when it is away from home. A peer node that the mobile node communicates with is defined as the *Correspondent Node* (which may be stationary or mobile).

Security between the mobile node and home agent can be accomplished using the *IP Security Protocol* (IPSec) architecture. This permits secure communications between the mobile node and the home agent. When a correspondent node receives a packet from a mobile node, it first checks its binding caches to see if it has a cache of the mobile-node care-of address, and if it does not, the correspondent node sends the packet to the mobile-node home address. The home agent receives all packets sent to the mobile node when it is away from home and then tunnels the packets to the mobile-node care-of address.

To permit a mobile node and correspondent node to communicate directly, without going through a home agent, requires the use of *Mobile IPv6 Route Optimization*. First the connection to the correspondent node needs to be secure from the home agent and directly from the mobile node. In the figure, that is done using a procedure defined as *Return Routability* (RR) within the Mobile IPv6 protocol. The network path between the mobile node and correspondent node is secured through the RR procedure.

Mobile IPv6 uses the extensibility of the IPv6 protocol defining new Neighbor Discovery messages and types, *Routing Header,* and the use of the *Destination Option* in an IPv6 packet, which does not exist in IPv4. Discussion of those extensions is beyond the scope of this article, and is left as an exercise for readers to read the actual Mobile IPv6 specification.

Mobile IPv6 has core technical operational advantages over Mobile IPv4, as follows:

- There is no need to deploy special routers as "foreign agents," as in Mobile IPv4. Mobile IPv6 operates in any location without any special support required from the local router.
- Support for route optimization is a fundamental part of the protocol, rather than a set of nonstandard extensions.
- Mobile IPv6 route optimizations can operate securely even without prearranged security associations. It is expected that the route optimizations can be deployed on a global scale among all mobile-node correspondent nodes.
- Support is also integrated into Mobile IPv6 for allowing route optimizations to coexist with routers that perform ingress filtering.
- The IPv6 *Neighbor Unreachability Detection* assures symmetric reachability between the mobile node and its default router in the current location.
- Most packets sent to a mobile node away from home in Mobile IPv6 are sent using an IPv6 routing header rather than IP encapsulation, reducing the amount of resulting overhead compared to Mobile IPv4.
- Mobile IPv6 is decoupled from any particular link layer because it uses IPv6 Neighbor Discovery instead of IPv4 *Address Resolution Protocol* (ARP). This also improves the robustness of the protocol.
- The use of IPv6 encapsulation (and the routing header) removes the need in Mobile IPv6 to manage tunnel soft state.
- The dynamic home-agent address discovery mechanism in Mobile IPv6 returns a single reply to the mobile node. The directed broadcast used in IPv4 returns separate replies from each home agent.

Summary

This article has presented three of the key technology advantages of IPv6 behind the wall. There are others, but they are technically too complex to define in a short article, but rather the subject of IPv6 implementation white papers. The IPv6 architecture extends the potential for the Next-Generation Internet to support rapid renumbering of networks, Quality of Service, extensions for ad hoc networks, and the hope of extending the Internet beyond the capabilities and functions today with IPv4. Most important is that IPv6 enhancements will be developed without using "band aids," as is currently being done with today's IPv4 architecture. The author of this article would like to thank Tony Hain and Patrick Grossetete from Cisco Systems for their review.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

Fragments

Peter T. Kirstein Receives Postel Award

Peter Kirstein is this year's recipient of the prestigious *Jonathan B. Postel Service Award*. A founding member of the Internet Society, Professor Kirstein is one of the pioneers of the Internet and was directly involved with its development and evolution. He was awarded the Postel Service Award in recognition of his foresight, persistence and innovation in navigating international technical and political complexities, and thus enabling the global propagation of the Internet. The Postel Award was presented on July 16, during the 57th meeting of the *Internet Engineering Task Force* (IETF) in Vienna, Austria.

"The Internet Society is pleased to recognize Peter's significant contribution to the development of the Internet by awarding him this year's Postel Award," said Internet Society President/CEO Lynn St. Amour. "His commitment to the evolution and growth of the Internet, particularly during the 1970s, made possible the global infrastructure we have today. And, his efforts continue, most recently working in the Southern Caucasus and Central Asia regions." Steve Crocker, noted Internet authority and chair of this year's Postel award committee, commented on Kirstein's foresight in laying the groundwork for the Internet's global scope. "Peter Kirstein saw that the future of networking lay in international cooperation and interconnection, and deftly organized the steps to make it happen. He used both technical and personal skills and enabled many others to do magnificent work."

In 1973, Kirstein established one of the first two international nodes of the ARPANET, playing a very active part in the ensuing SATNET activity, which covered five countries. His group continued to provide the principal Internet link between the UK and the US throughout the 1980s, during which time he was responsible for both the **`.UK`** and **`.INT`** domains. He continues to collaborate in US *Defense Advanced Research Agency* (DARPA) programs. He has led six European projects in computers and communications funded by the European Commission, and participated in twelve more. Currently, he is leading the *Silk Project,* which is providing satellite-based Internet access to the Newly Independent States in the Southern Caucasus and Central Asia. In June, he was awarded a *Commander, Order of the British Empire,* for his services to Internetworking research.

He has chaired the International Collaboration Board, which currently involves six NATO countries, since 1983, and served on the Networking Panel of the *NATO Science Committee* (serving as chair in 2001). He has been on Advisory Committees for the *Australian Research Council,* the *Canadian Department of Communications,* the German GMD, and the Indian *Education and Research Network* (ERNET) Project. Kirstein obtained his undergraduate degree in Mathematics and Engineering from Gonville and Caius College, Cambridge University, his PhD in Electrical Engineering from Stanford University, and was awarded a DSc in Engineering from the University of London.

Kirstein expressed his appreciation for the award and respect for Jon Postel's work, explaining, "Postel's efforts to ensure the successful development and deployment of the Internet was an inspiration to us all. His stewardship of the RFC series was essential to the successful development of the Internet. His conscientious and painstaking operation of the Domain Name System and the Internet Assigned Numbers Authority were indispensable to the international growth of the system. I am particularly pleased to be recipient of an award in his name, and feel greatly honored to be considered worthy of having my activities linked with his memorial."

The Jonathan B. Postel Service Award was established by the Internet Society to honor those who have made outstanding contributions in service to the data communications community. The award is focused on sustained and substantial technical contributions, service to the community, and leadership. With respect to leadership, the nominating committee places particular emphasis on candidates who have supported and enabled others in addition to their own specific actions.

The award is named after Dr. Jonathan B. Postel, who embodied all of these qualities during his extraordinary stewardship over the course of a thirty-year career in networking. He served as the editor of the RFC series of notes from its inception in 1969, until 1998. He also served as the ARPANET "numbers Czar" and the Internet Assigned Numbers Authority over the same period of time. He was a founding member of the *Internet Architecture* (nee *Activities*) *Board* (IAB) and the first individual member of the Internet Society, where he also served as a trustee.

Previous recipients of the Postel Award include Jon himself (posthumously and accepted by his mother), Scott Bradner, Daniel Karrenberg and Stephen Wolff. The award consists of an engraved crystal globe and $20,000.

The *Internet Society* (ISOC) (**`www.isoc.org`**) is a not-for-profit membership organization founded in 1991 to provide leadership in Internet related standards, education, and policy. With offices in Washington, DC, and Geneva, Switzerland, it is dedicated to ensuring the open development, evolution and use of the Internet for the benefit of people throughout the world. ISOC is the organizational home of the IETF, the IAB, the *Internet Engineering Steering Group* (IESG) and other Internet-related bodies who together play a critical role in ensuring that the Internet develops in a stable and open manner. For over 12 years ISOC has run international network training programs for developing countries and these have played a vital role in setting up the Internet connections and networks in virtually every country connecting to the Internet during this time.

Deployment of Internationalized Domain Names

The *Internet Corporation for Assigned Names and Numbers* (ICANN) recently announced the commencement of global deployment of *Internationalized Domain Names* (IDNs)[2,3,4], which will allow use on the Internet of domain names in languages used in all parts of the world.

In October 2002, the IESG approved the publication of a standardized way of integrating IDNs into the Internet's *Domain Name System* (DNS). After the proposed technical standard was published in March 2003, the ICANN Board endorsed an approach for implementation of the technical standard that had been developed cooperatively by ICANN and leading IDN registries.

Following up on the Board's endorsement, ICANN and the leading IDN registries finalized an agreed text of the principles to be followed in IDN registration activities. Those "Guidelines for the Implementation of Internationalized Domain Names"[1] were published. IDN registries adhering to the Guidelines will employ language-specific registration and administration rules that are documented and publicly available. These IDN registries will work collaboratively with each other and with interested stakeholders to develop the language-specific policies, with the objective of achieving consistent approaches to IDN implementation to maintain Internet interoperability for the benefit of DNS users worldwide.

The registries for the **.cn** (China), **.jp** (Japan), and **.tw** (Taiwan) country codes, as well as for the **.info** and **.org** generic top-level domains, have committed to adhere to the Guidelines. As authorized by the ICANN Board in March, registries seeking to deploy IDNs under their agreements with ICANN will be authorized to do so on the basis of the Guidelines. In addition, the ICANN Board has recommended the Guidelines to other registries, and encourages broad participation by registries, language experts, and others in consultative, collaborative, community-based processes to study and develop appropriate language-specific IDN registration rules and policies.

As the deployment of IDNs proceeds, ICANN and the participating IDN registries have agreed to work together to review Guidelines at regular intervals based on their deployment experience, and to make any necessary adjustments.

From The Editor

I will remember 2003 as the year when high-speed Internet access became widely available in public locations such as airports, hotels, and coffee shops. As a frequent traveler, I really appreciate not having to find a suitable telephone jack and corresponding country-specific telephone adapter plug in order to get my e-mail. The IEEE 802.11 "WiFi" standard has truly arrived. I even stayed in a new hotel in Norway that provided WiFi access in every room by placing base stations in the hallways. When I first stepped into my hotel room and noticed that it had only a *digital* telephone and no sign of any Ethernet jacks I worried, but a quick check revealed that I could purchase a scratch-off card at reception that provided me with a username and password valid for 24 hours. A clear example of a "technology generation leap."

The year 2003 was also the year in which unsolicited e-mail, or "spam," became a major problem for all Internet users. Various filtering systems have thankfully been devised and deployed, but this problem has no easy solution. It will be interesting to see what impact new antispam legislation will have over the coming months and years.

The first article presents an in-depth look at the IP Version 4 address space and its measured and projected consumption rate. When work first started on the design of IP Version 6, projections indicated that we'd run out of IPv4 addresses within a few years. Geoff Huston takes a fresh look at this in an article entitled "IPv4—How long do we have?"

The job of System Administrator, or "sysadmin," is a challenging one, and if your job includes keeping the network running 24 hours a day, you will probably appreciate some of the tips in our second article, entitled "Low-Tech Network Maintenance."

For the second time recently, Queen Elizabeth II has honored an Internet pioneer. Tim Berners-Lee, the inventor of the World Wide Web and director of the *World Wide Web Consortium* (W3C), was made a *Knight Commander, Order of the British Empire* in the 2004 New Years Honours list. (See "Fragments," page 28).

Which brings us to the IPJ publication schedule. If you are a regular subscriber to the IPJ, you probably have noticed a somewhat irregular publishing schedule in 2003. This December 2003 issue is indeed being published in January 2004. This results from our effort to produce timely quality articles in a world where the experts are not staff writers. Of course, you should still expect to receive four issues per year, and your feedback to **ipj@cisco.com** will help make IPJ even better.

IPv4—How long do we have?

by Geoff Huston, Telstra

One of those stories that keeps on appearing from time to time is the claim that somewhere in the world, or even all over the world, we are "running out of IP addresses," referring to the consumption of unallocated IPv4 addresses[1]. In one sense this is a pretty safe claim, in that the IPv4 address pool is indeed finite, and, as the IPv4 Internet grows it makes continual demands on previously unallocated address space. So the claim that the space will be exhausted at some time in the future is a relatively safe prediction. But the critical question is not "if" but "when," because this is a question upon which many of our current technology choices are based.

Given this revived interest in the anticipated longevity of the IPv4 address space, it is timely to revisit a particular piece of analysis that has been a topic of some interest at various times over the past decade or more. The basic question is: "How long can the IPv4 address pool last in the face of a continually growing network?" This article looks at one approach to attempt to provide some indication of "when." Like all predictive exercises, many assumptions have to be made, and the approach described here uses just one of numerous possible predictive models—and, of course, the future is always uncertain.

The IPv4 Address Space

The initial design of IPv4 was extremely radical for its time in the late 1970s. Other contemporary vendor-based computer networking protocols were designed within the constraints of minimizing the packet header overhead in order to improve the data payload efficiency of each packet. At the time address spans were defined within the overall assumption that the networks were deployed as a means of clustering equipment around a central mainframe. In many protocol designs 16 bits of address space in the packet headers was considered to be extravagant. To use a globally unique address framework of 32 bits to address network hosts was, at the time, a major shift in thinking about computer networks from a collection of disparate private facilities into a truly public utility.

To further add to the radical nature of the exercise, the Internet Network Information Center was prepared to hand out unique blocks of this address space to anyone who submitted an application. Address deployment architectures in other contemporary protocols did not have the address space to support such address distribution functions, nor did they even see a need for global uniqueness of computer network addresses. Network administrators numbered their isolated corporate or campus networks starting at the equivalent of "1," and progressed onward from there. Obviously network splits and mergers caused considerable realignment of these private addressing schemes, with consequent disruption to the network service.

By comparison, it seemed, the address architecture of the Internet was explicitly designed for interconnection. But even with 32 bits to use in an address field, getting the right internal structure for addresses is not as straightforward as it may initially seem.

The Evolution of the IPv4 Address Architecture

IP uses the address to express two aspects of a connected device: the identity of this device (endpoint identity) and the location within the network where this device can be reached (location or forwarding identity). The original IP address architecture used the endpoint identity to allow devices to refer to each other in end-to-end application transactions, whereas within the network the address is used to direct packet-forwarding decisions. The address was further structured into two fields: a *network* identifier and a *host* identifier within that network. The first incarnation of this address architecture used a division at the first octet: the first 8 bits were the network number and the following 24 bits were the host identifier. The underlying assumption was one of deployment across a small number of very large local networks. This view was subsequently refined, and the concept of a class-based address architecture was devised for the Internet. Half of the address space was left as a 8/24-bit structure, called the *Class A* space (allowing for up to 127 networks each with 16,777,216 host identities). A quarter of the remaining space used a 16/16-bit split (allowing for up to 16,128 networks, each with up to 65,536 hosts), defining the *Class B* space. A further eighth of the remaining space was divided using a 24/8-bit structure (allowing for 2,031,616 networks, each with up to 256 hosts), termed the *Class C* space. The remaining eighth of the space was held in reserve.

This address scheme was devised in the early 1980s, and within a decade it was pretty clear that there was a problem with impending exhaustion. The reason was an evident run on Class B addresses. Although very few entities could see their IP network spanning millions of computers, the personal desktop computer was now a well-established part of the landscape, and networks of just 256 hosts were just too small. So if the Class A space was too big, and the Class C too small, then Class B was the only remaining option. In fact, the Class B blocks were also too large, and most networks that used a Class B address consumed only a few hundred of the 65,535 possible host identities within each network. The addressing efficiency of this arrangement was very low, and a large amount of address space was being consumed in order to number a small set of devices. Achieving even a 1 percent host density (expressed as a ratio of number of addressed hosts to the total number of host addresses available) was better than normal at the time, and 10 percent was considered pretty exceptional.

Consequently, Class B networks were being assigned to networks at an exponentially increasing rate. Projections from the early 1990s forecast exhaustion of the Class B space by the mid-1990s. Obviously there was a problem, and the *Internet Engineering Task Force* (IETF) took on the task of finding some solutions. Numerous responses were devised by the IETF.

As a means of mitigation of the immediate problem, the IETF altered the structure of an IP address. Rather than having a fixed-length network identifier of 8, 16, or 24 bits, the network part of the address could be any length at all, and a network identifier was now the couplet of an IP address field containing a network part and the bit length of the network part. The boundary between the network and host part could change across the network, so rather than having "networks" and "subnetworks" as in the class-based address architecture, there was the concept of a variable length network mask. This was termed the "classless" address architecture (or "CIDR"), and the step was considered to be a short-term expediency to buy some additional time before address exhaustion. The longer-term plan was to develop a new IP architecture that could encompass a much larger connectivity domain than was possible with IPv4.

We now have IPv6 as the longer-term outcome. But what has happened to the short-term expediency of the classless address architecture in IPv4? It appears to have worked very well indeed so far, and now the question is: how long can this supposedly short-term solution last?

Predictions of Address Consumption

Predicting the point of IPv4 address exhaustion has happened from time to time since the early 1990s within the IETF[2]. The initial outcomes of these predictive exercises were clearly visible by the mid-1990s: the classless address architecture was very effective in improving the address utilization efficiency, and the pressures of ever-increasing consumption of a visibly finite address resource were alleviated. But a decade after the introduction of CIDR addressing, it is time to understand where we are heading with the consumption of the underlying network address pool.

Dividing up the Address Space

There are three stages in address allocation. The pool of IP addresses is managed by the *Internet Assigned Numbers Authority* (IANA). Blocks of addresses are allocated to *Regional Internet Registries* (RIRs), who in turn allocate smaller blocks to *Local Internet Registries* (LIRs) or *Internet Service Providers* (ISPs).

Currently 3,707,764,736 addresses are managed in this way. It is probably easier to look at this in terms of the number of "/8 blocks," where each block is the same size as the old Class A network, namely 16,777,216 addresses. The total address pool is 221 /8s, with a further 16 /8s reserved for multicast use, 16 /8s held in reserve, and 3 /8s designated as not for use in the public Internet.

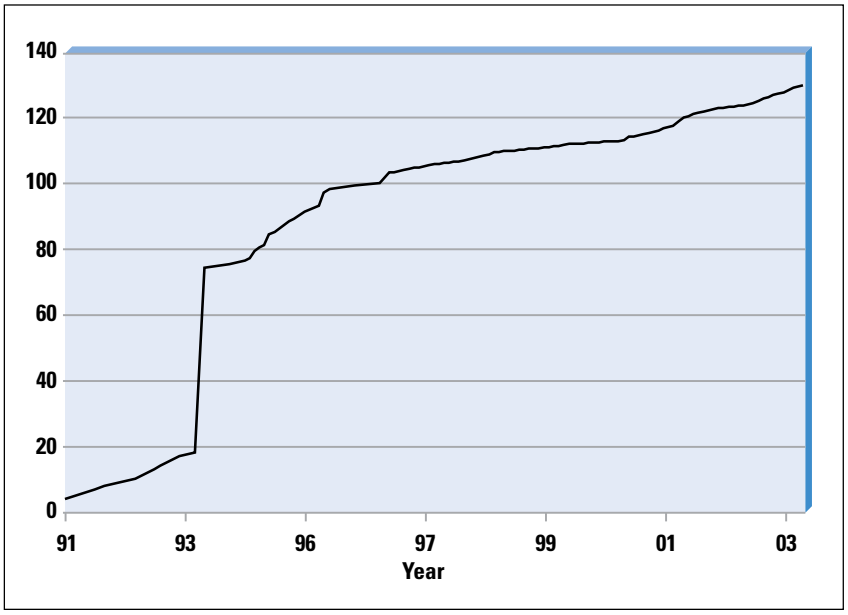
In looking at futures, there are three sources of data concerning address consumption:

- How quickly is the IANA passing address blocks to the RIRs, and when will IANA run out?
- How quickly are the RIRs passing address blocks to LIRs, and when will this run out?
- How much address space is actually used in the global Internet, and how quickly is this growing? When will this run out?

The IANA Registry

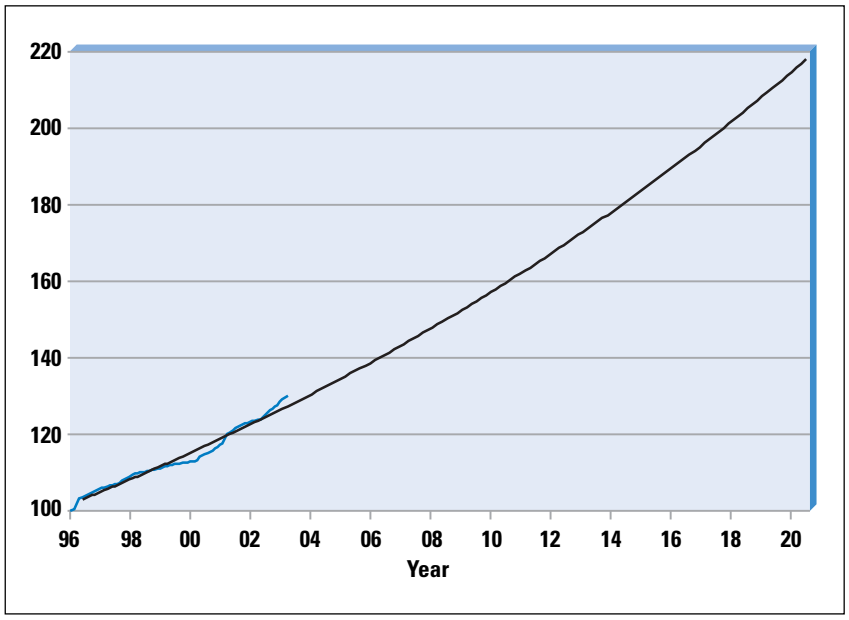
So the first place to look is the IANA registry file[3]. This registry reveals that of these 221 /8 blocks, 89 /8 blocks are still held as unallocated by the IANA, 129.9 /8 blocks have been allocated, and the remaining 2.1 / 8 blocks are reserved for other uses. The IANA registry also includes the date of allocation of the address block, so it is possible to construct a time series of IANA allocations, as shown in Figure 1.

Figure 1: IANA Allocated IPv4 /8 Address Blocks



Interestingly, there is nothing older than 1991 in this registry. This exposes one of the problems with analyzing registry data, in that there is a difference between the current status of a registry and a time-stamped log of the transactions that were made to the registry over time. The data published by the IANA is somewhere between the two, and the log data is incomplete; in addition, the current status of some address blocks is unclear. It appears that the usable allocation data starts in 1995. So if we take the data starting from 1995 and perform a linear regression to find a best fit of an exponential projection, it is possible to make some predictions as to the time it will take to exhaust the remaining unallocated 89 /8s. (Figure 2).

Figure 2: IANA Allocated IPv4 /8 Address Blocks



It is worth a slight digression into the method of projection being used here. The technique is one of using a best fit of an exponential growth curve to the data. The underlying assumption behind such a projection is that the growth rate of the data is proportional to the size of the data, rather than being a constant rate. In network terms, this assumes that the rate of consumption of unallocated addresses is a fixed proportion of the number of allocated addresses, or, in other words, the expansion rate of the network is a proportion of its size, rather than being a constant value. Such exponential growth models may not necessarily be the best fit to a network growth model, although the data since 1995 does indicate an underlying exponential growth pattern. Whether this growth model will continue into the future is an open issue.

The projection of 2019 as the date for consumption of the unallocated address space using this technique is perhaps surprising, because it seems that the network is bigger now than ever, yet the amount of additional address space required to fuel further accelerating growth for a further decade is comparatively small. This is true for many reasons, and the turning point when these aspects gained traction in the Internet appeared to be about 1995. They include:

- The first 1.6 billion addresses (equivalent to some 100 /8 blocks) were allocated using the class-based address architecture. Since this date address allocation has used a classless architecture, and this has enabled achievement of significantly improved efficiencies in using the address space.
- The RIRs came into the picture, and started using conservation-based policies in address allocations. The RIR process requires all address applicants to demonstrate that they can make efficient and effective use of the address space, and this has dampened some of the wilder sets of expectations about the address requirements of an enterprise.

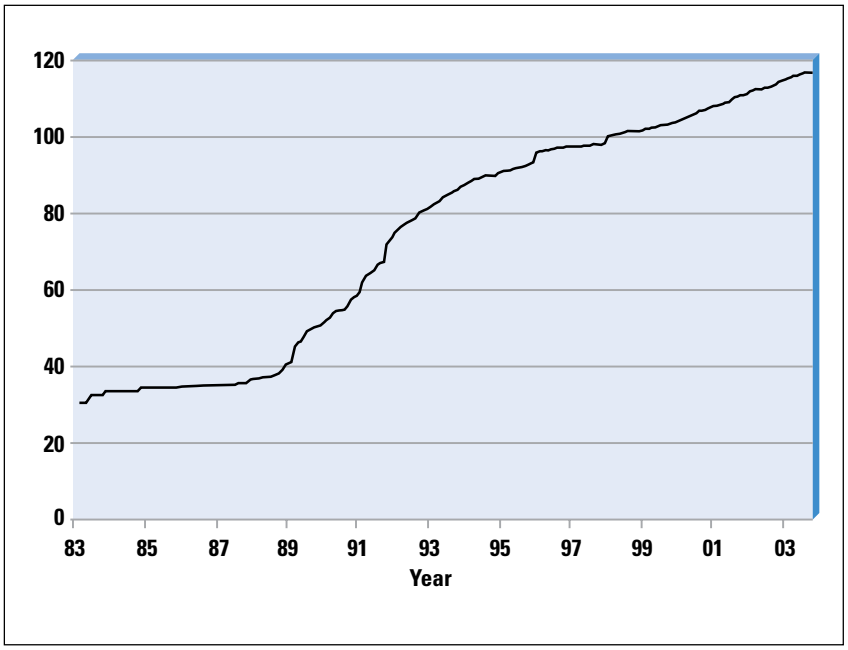
- Address compression technologies became widely deployed. Dynamic *Network Address Translation* (NAT) devices have, for better or worse, become a common part of the network landscape. NAT devices allow large "semi-private" networks to use a very small poll of public addresses as the external view of the network, while using private address space within the network. *Dynamic Host Configuration Protocol* (DHCP) has allowed networks to recycle a smaller pool of addresses across a larger set of intermittently connected devices.

Whether these factors will continue to operate in the same fashion in the future is an open question. Whether future growth in the use of public address space operates from a basis of a steadily accelerated growth is also an open question. The assumption made in this exercise is that the projections depend on continuity of effectiveness of the RIR policies and their application, continuity of technology approaches, and absence of disruptive triggers. Although the RIRs have a very well-regarded track record and there are strong grounds for confidence that this will continue, obviously the latter two assumptions about technology and disruptive events are not all that comfortable. With that in mind, the next step is to look at the RIR assignment data.

The RIR Registries

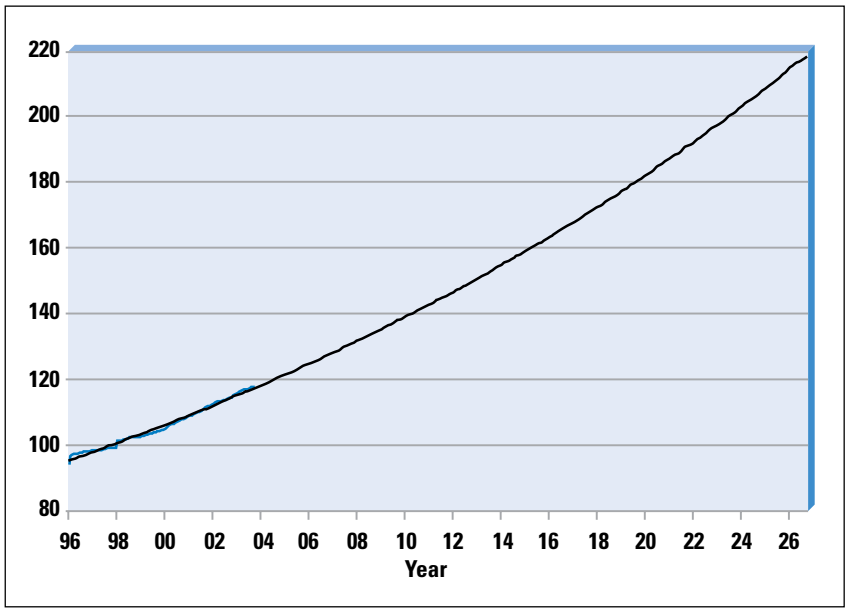
The RIRs also publish a registry of their transactions in "stats" files. For each currently allocated or assigned address block the RIRs have recorded, among other items, the date of the RIR assignment transaction that assigned an address block to a LIR or ISP. Using this data we can break up the 129.9 /8 blocks further, and it is evident that the equivalent of 116.7 /8 blocks have been allocated or assigned by the RIRs, and the remaining space, where there is no RIR allocation or assignment record, is the equivalent of 13.2 /8 blocks. These transactions can again be placed in a time series, as shown in Figure 3.

Figure 3: RIR Assigned IPv4 /8 Address Blocks



The post-1995 data used to extrapolate forward using the same linear regression technique described previously to find a curve of best bit using the same underlying growth model assumptions yields:

Figure 4: RIR Assigned IPv4 /8 Address Blocks—Projection



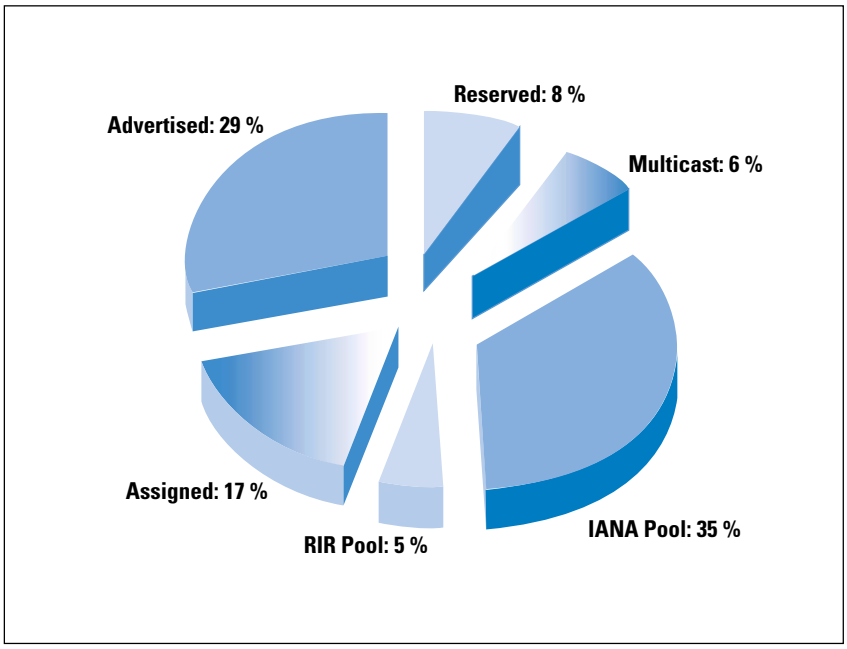
This form of extrapolation gives a date of 2026 for the time at which the RIRs will exhaust the number pool. Again the same caveats about the use of this approach as a reliable predictor apply here, and the view forward is based on the absence of large-scale disruptions, or some externally induced change in the underlying growth models for address demand.

The BGP Routing Table

When addresses are assigned to end networks, the expectation is that these addresses will be announced to the network in the form of routing advertisements. So some proportion of these addresses is announced in the Internet routing table. The next task is to establish the trends of the amount of address space covered by the routing table. The approach used has been to take a single view of the address span of the Internet. This is the view from one point, inside the AS1221 network operated by Telstra.

The data as of October 2003 shows that some 29 percent of the total IPv4 address space is announced in the *Border Gateway Protocol* (BGP) routing table, whereas 17 percent has been allocated to an end user or LIR but is not announced on the public Internet as being connected and reachable. A total of 5 percent of the address space is held by the RIR's pending assignment or allocation (or at least there is no RIR recorded assignment of the space), while 35 percent of the total space remains in the IANA unallocated pool. A further 8 percent of the space is held in reserve (Figure 5).

Figure 5: IPv4 /8 Address Space



This BGP data is based on an hourly inspection of the amount of address space advertised within the Internet routing table. The data collection commenced in late 1999, and the data gathered so far is shown in Figure 6. The problem with this data is that there is some considerable amount of fluctuation in the amount of address space advertised over time. The major step changes are due to a small number of /8 advertisements that periodically are announced and withdrawn in BGP. In order to obtain reasonable data for generating projections, some noise reduction on this data needs to be undertaken. The approach used has been to first filter the data using a constant value of 18 /8 prefix announcements, and then use a sliding average function to create a smoothed time series. This is indicated in Figure 7.

The critical issue when using this data for projection is to determine what form of function can provide a best fit to the data. A good indication of the underlying trends in the data can be found by analyzing the first-order differential of the data. An underlying increasing growth model would have an increasing first-order differential, whereas a decreasing growth model would have a negatively inclined differential. A least-squares best-fit analysis of the data shows that the growth rates have not been consistent over the past three years. A reasonable fit for this data appears to be a constant growth model, or a linear growth projection, with a consumption rate of some 3 /8 blocks per year.

Figure 6: Advertised IPv4 /8 Address Space (/8 Blocks)

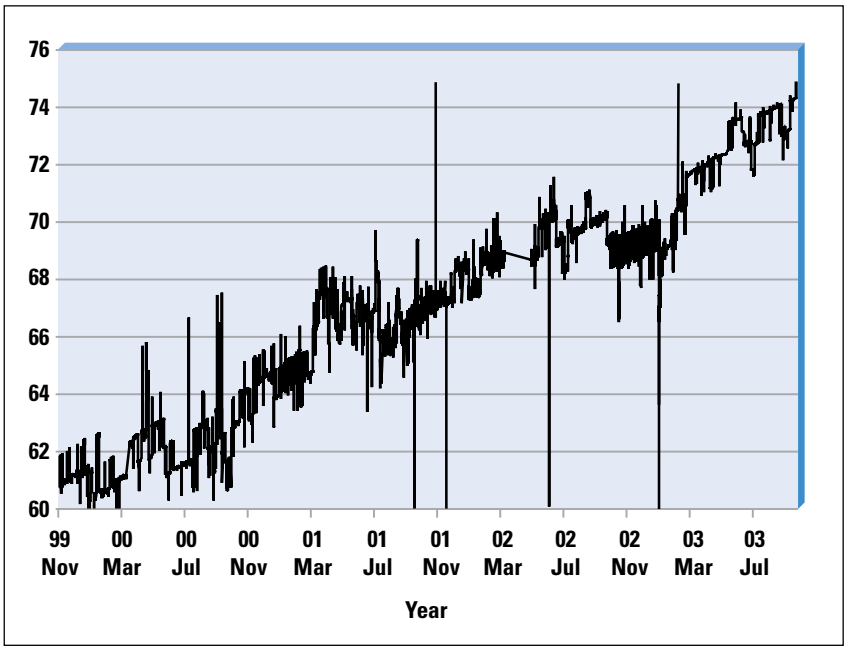


Figure 7: Smoothed IPv4 /8 Advertised Address Blocks

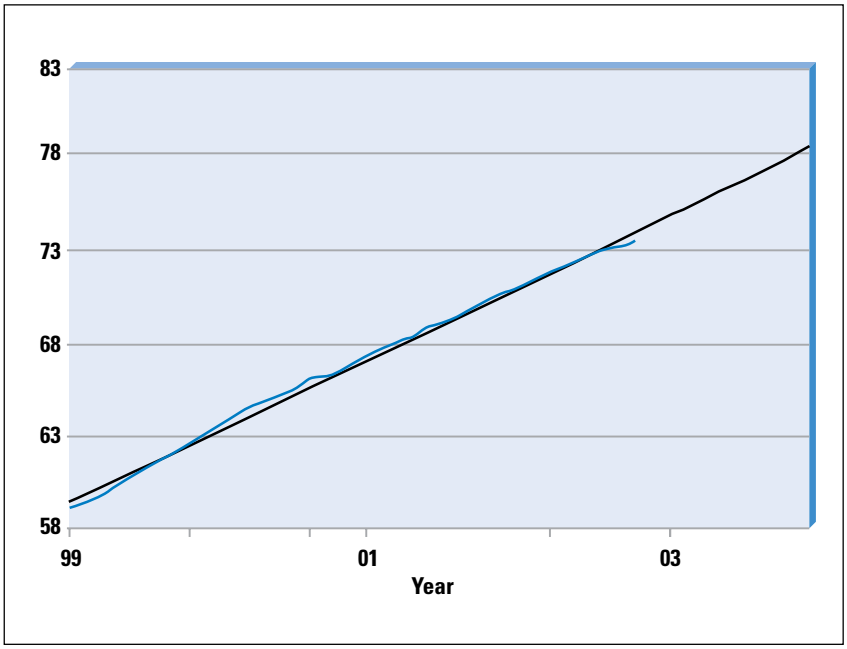


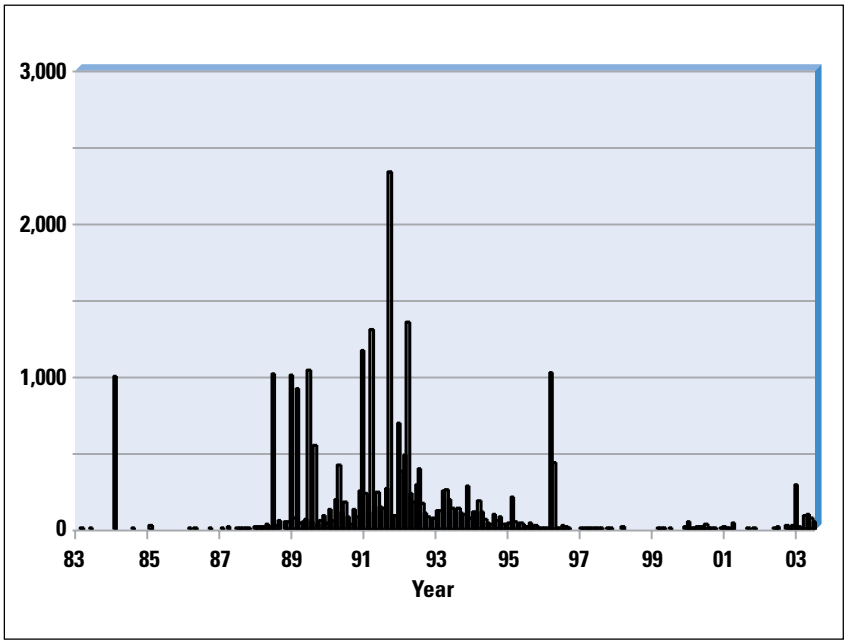
Combining the Three Views

One question remains before we complete the projections for IPv4 address space. There are 43.3 /8 blocks, or some 17 percent of the total IPv4 address space that has been allocated for use, but is not visible in the Internet routing table. This is a very significant amount of address space, and if it is growing at the same rate as the advertised space, then this will have a significant impact on any overall model of consumption of the use of address space.

The question here is whether this "invisible" address pool is a legacy of the address allocations policies in place before the RIR system came into operation in the mid 1990s, or some intrinsic inefficiency in the current system. If it is the latter, then it is likely that this pool of unannounced addresses will grow in direct proportion to the growth in the announced address space, whereas if it is the former, then the size of the pool will remain relatively constant in the future.

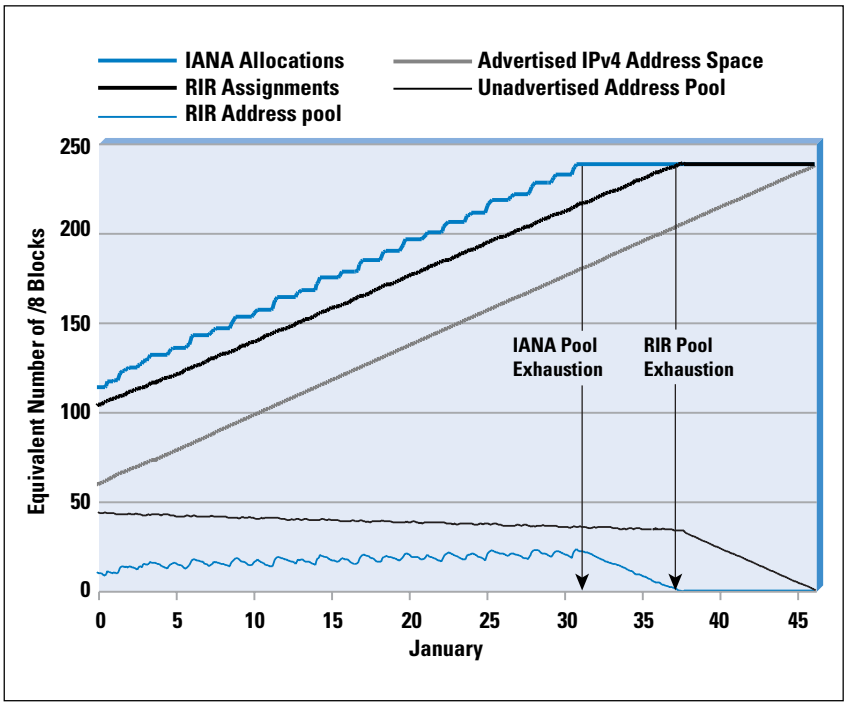
We can look back through the RIR allocation data and look at the allocation dates of unannounced address space (Figure 8). This view indicates that the bulk of the space is a legacy of earlier address allocation practices, and that since 1997, when the RIR operation was fully established, there is an almost complete mapping of RIR allocated address space to BGP routing announcements. The recent 2003 data indicates that there is some lag between recent allocations and BGP announcements, most probably due to the time lag between an LIR receiving an allocation and subsequent assignments to end users and advertisement in the routing table.

Figure 8: Age Distribution of Unadvertised Address Blocks (/8 Address Blocks)



This confirms that in recent years all the address space that has been assigned by the RIRs appears in the Internet routing table, implying that projections of the amount of address space advertised in the routing table is a good correlation to projections of address space consumption. With this in mind it is now possible to construct a model of the address distribution process, working backward from the BGP routing table address size. From the sum of the BGP table size and the LIR holding pool, we can derive the total RIR-managed address pool. To this number is added the RIR holding pool low size and its low threshold where a further IANA allocation is required. This allows a view of the entire system, projected forward over time, where the central driver for the projection is the growth in the network itself, as described by the size of the announced IPv4 address space. This is shown in Figure 9.

Figure 9: IPv4 Projections of Address Consumption



It would appear that the point of effective exhaustion is the point where the RIRs exhaust available address space to assign. In this model, RIR exhaustion of the unallocated address pool would occur in 2037.

Uncertainties

Of course such projections are based on the underlying assumption that tomorrow will be much like today, and the visible changes that have occurred in the past will smoothly translate to continued change the future. This assumption obviously has some weaknesses, and many events could disrupt this prediction.

Some disruptions could be found in technology evolution. An upward shift in address take-up rates could occur because of an inability of NAT devices to support emerging popular applications. Widespread deployment of peer-to-peer applications implies the need for persistent address presentation, which may imply greater levels of requirement for public address space. The use of personal mobile IP devices (such as PDAs in their various formats) using public IPv4 addresses would place a massive load on the address space, simply because of the very large volumes associated with deployment of this technology[4].

Other disruptions have a social origin, such as the boom and bust cycle of Internet expansion in recent years. Another form of disruption in this category could be the adoption of a change in the distribution function. The current RIR and LIR distribution model has been very effective in limiting the amount of accumulation of address space in holding pools, and allocating addresses based on efficiency of utilization and conformance to the routing topology of the network.

Many other forms of global resource distribution use a geopolitical framework, where number blocks are passed to national entities, and further distribution is a matter of local policy[5]. The disruptive nature of such a change would be to immediately increase the number of "holding" points in the distribution system, locking away larger pools of address space from being deployed and advertised and generating a significant upward change in the overall address consumption rates due to an increase in the inefficiency of the altered distribution function.

The other factor to be aware of is the steadily decreasing "buffer" of unallocated addresses that can be used to absorb the impacts of a disruptive change in address consumption rates. Although at present some 60 percent of the address space—or some 2.6 billion addresses—are available in the unallocated address pools or held in reserve, this pool will reduce over time. If a disruptive event is, for example, a requirement to directly address some 500 million devices, then such an event would reduce the expectancy of address space availability by some years, assuming it occurred within the period when sufficient address space remains to meet such a surge of demand.

The other source of uncertainty is that this form of predictive modeling assumes that the ratios of actual connected devices and the amount of address space deployed to service this device pool remain relatively constant.

This model also assumes some form of continuity of current address allocation polices. This is not a likely scenario, because it is likely that address policies will reflect some notion of balance between the level of current demand against future demands. As the unallocated address pool shrinks it is possible that policies will alter to express the increased level of competitive demand for the remaining resource. Consumption rates would be moderated by such a change in allocation policy. The commonly cited intended evolutionary path for the Internet is to a transition to ubiquitous use of IPv6, and at some point in that transition process it is reasonable to assume that further demands for IPv4 space will dwindle. It may be that at such a "crossover" time allocation policies may then be altered to reflect a drop in both current and future demands for IPv4 address space.

In attempting to assess the possible future path of address allocation policies, it is also evident that, from a market rationalist perspective, there is a certain contrivedness about the current address allocation process. The current address management system assumes a steady influx of new addresses to meet emerging demands, and the overall address utilization efficiency is not set by any form of market force, but by the outcomes of the application of RIR address allocation policies to new requests for address space. A market rationalist could well point to the use of market price as a means of determining the most economically efficient form of utilization of a commodity product. Such a position is based on the observation that the way that the consumer chooses between alternative substitutable services is by a market choice that is generally price sensitive.

If price is removed from an IPv4 address market, the choices made by market players are not necessarily the most efficient choices, and some would argue that the current situation underprices IPv4 at the expense of IPv6.

However, in venturing into these areas we are perhaps straying a little too far from exploring the degree of uncertainty in these predictive exercises. A discussion of the interaction between various forms of distribution frameworks and likely technology outcomes is perhaps a topic for another time.

So just how long does IPv4 have?

The assumptions used here include assuming that the trends in the growth in the advertised space are directly proportional to the future consumption rates for IP addresses, and that the constant growth model remains a best fit for this time series of data. It also assumes a continuation of the current utilization efficiency levels in the Internet, a continuing balance between public address utilization and the use of various forms of address compression, and continuity of current address allocation policies, as well as the absence of highly disruptive events. With all this in mind, then it would appear that the IPv4 world, in terms of address availability, could continue for up to another three decades or so without reaching any fixed boundary of exhaustion.

But it must be remembered that each of these assumptions is relatively sweeping, and to combine them as we have done here is pushing the predictive exercise to its limits, or possibly beyond them. Three decades out is way over the event horizon for any form of useful prediction for the Internet, so if we restrict the question to at most the next five to eight years, then we can answer with some level of confidence that, in the absence of any significant disruptions to the current deployment model of the Internet, there is really no visible evidence that IPv4 will exhaust its address pool by 2010, based on the available address consumption data.

Notes

[1] "Tackling the net's number shortage." BBC News, World Edition, 26 October 2003. The item starts with the claim: "BBC ClickOnline's Ian Hardy investigates what is going to happen when the number of net addresses—Internet Protocol numbers—runs out sometime in 2005."
http://news.bbc.co.uk/2/hi/technology/3211035.stm

[2] The work was undertaken in the *Address Lifetime Expectations* (ALE) Working Group of the IETF in 1993–1994. The final outcome from this effort was reported from the December 1994 meeting of this group: "Both models currently suggest that IPv4 addresses would be depleted around 2008, give or take three years."

[3] This registry is online at:
http://www.iana.org/assignments/ipv4-address-space

[4] On the other hand, it is evident that the growth of the Internet in recent years has been fueled by the increasing prevalence of NAT devices. In order for applications to be accepted into common use in today's Internet, they need to be able to function through various NAT-based constraints, and increasing sophistication of applications in operating across NAT devices is certainly evident today.

[5] Such a geopolitical distribution system is used in the E.164 number space for telephony ("ENUM").

GEOFF HUSTON holds a B.Sc. and a M.Sc. from the Australian National University. He has been closely involved with the development of the Internet for the past decade, particularly within Australia, where he was responsible for the initial build of the Internet within the Australian academic and research sector. Huston is currently the Chief Scientist in the Internet area for Telstra. He is also the Executive Director of the Internet Architecture Board, and is a member of the APNIC Executive Committee. He is author of *The ISP Survival Guide*, ISBN 0-471-31499-4, *Internet Performance Survival Guide: QoS Strategies for Multiservice Networks*, ISBN 0471-378089, and coauthor of *Quality of Service: Delivering QoS on the Internet and in Corporate Networks*, ISBN 0-471-24358-2, a collaboration with Paul Ferguson. All three books are published by John Wiley & Sons. E-mail: **gih@telstra.net**

Low-Tech Network Maintenance

by Locum sysadmin

In an ideal world, we all maintain networks composed of shiny, high-end equipment. Server rooms are stacked to the brim with racks of blinking lights. Neat bundles of cable wend their way through cable loops to orderly, labeled patch bays. When the occasional piece of equipment fails, a hot replacement is slotted in by trained technicians, often before users even notice the outage. Sleek, modern servers hum contentedly, offering their services all day, every day. All is well.

And then there are the other environments ...

Imagine, if you will, that you are a programmer, working for a small company. You are perhaps vaguely aware that all is not well with the small network that you use each day, but the system administrator (*sysadmin*, if there is one) is so busy with other duties that addressing your concerns seems to be last on the list. The occasional delay in CVS checkouts or e-mail that just never quite makes it seem like minor issues compared to... well, whatever it is that so occupies the sysadmin.

Or perhaps there is no sysadmin ... the network topology is neither ring, nor star, but more "accreted." It is possible that the nephew of one of the managers was responsible for its setup. Like coral, successive waves of employees have washed over the network, leaving their small additions—a cheap 8-port hub here, some gaffer-taped wiring there.

You become aware that your LAN/WAN environment is a real-world test of how deeply Ethernet hubs may be cascaded. A trip to the server room (or server closet) reveals a mess of cabling that closely resembles blue spaghetti. Access to the outside world can take several forms, but it is not uncommon to find a couple of dialup modems lurking quietly in the mess, unnoticed until a failure in the regular link means a failover to the pleasures of 30 employees sharing a 33.6k modem. The concept of labeling cables never made it to this paleolithic theme park, so if you ever trip on one of the floor-dwelling blue vines, locating its original socket can be a challenging occupation.

The servers themselves seem to be an interactive museum display charting the history of computing up until the late 1990s. Old UNIX boxes spill a mess of cables and hard drives over the bench, generic white-box servers of unknown vintage litter the room, "Powered by Linux" or FreeBSD stickers adorning them. Discolored 15-inch monitors sometimes display a blue screen of death, letting you know that some people still love NT4. Assorted tape drives blink quietly away, backing up regularly, though no one seems quite sure what they are backing up, or how to recover them. An elderly Sun box whiles away its retirement transferring mail and playing host to the occasional crackers who exploit security holes in its ancient *sendmail*, then give up in disgust.

The spare parts for the network might occupy a shelf in the server room, or perhaps they nestle on top of a rack unit. A motley assortment of chewed-looking Category 5 cables, network cards so ancient that their manufacture date is in Roman numerals, and a sculpture of BNC connectors—the thought of turning here for help fills you with dread. A dead network adapter usually means a surreptitious raid of the petty cash and a trip to the local computer-parts store for a no-name Ethernet card.

Then—as it always does—disaster strikes. Somewhere, something goes wrong. One thing that you can be sure of is that it will happen at the worst possible time. It is likely that a crucial presentation will be under way, or perhaps a software release is due by close of business. Maybe you are hosting a server for a client, and the client has noticed its absence, and is on the phone, using words like "unscheduled outage" and "penalty clause." If your clients are so inclined, words like "kneecap" and "sledgehammer" might also be heard. Another fact you can be reasonably sure of is that the sysadmin will not be present, and the next-most technical person will be called upon to work up a minor miracle to fix the ailing network.

Sound far-fetched? Believe it or not, I have been in this situation more than once. What follows are some hints that may help in fixing networks in suboptimal conditions, and as always, with the understanding that it must be done as cheaply as possible.

Many of the hints use features found on Linux boxes, beloved for its technical excellence (and its low cost). Most of the tips here can be adapted for whatever type of operating system you have.

Audible Ping

Ping is the venerable tool that we all know and love, and is the reigning king of the low-tech diagnostic tools. Linux (and other operating systems that use GNU tools) features an extension to *ping* that produces a beep on receipt of a response. The *audible ping* is designated by the **`-a`** command-line option.

Something as simple as **`ping -a missinghost.your.net`**, left running from a console in the server room, can alert you when you have finally reestablished network connectivity. It is like having a cable tester that can traverse routers.

Where Are You?

In a server room full of unlabeled generic boxes, it can sometimes be tricky to know which box is which. The following conversation is typical:

Hapless1: "Okay, I've logged into **`srv7`** by SSH [*Secure Shell Protocol*], and I think its second hard drive has died. Can you turn off its power switch when I shut it down?"

Hapless2: "Sure, which box is it?

Hapless1: "Ummm... its hostname is **`srv7`**..."

Hapless2: "None of them are labeled!"

Hapless1: "Okay... [**`cat /proc/cpuinfo`**] it's a Pentium 2."

Hapless2: "That narrows it down to five boxes..."

This kind of guessing game can continue for quite some time. Following the ground-breaking research of Murphy, if you guess wrong, it is reasonably certain that you will pick a critical server to drop. My least-favourite twist on this is when the boxes have been labeled—but labeled wrong—or labeled with yellow post-it notes (which fall off as the temperature in the server room increases).

If you are using a Linux box, and it has a CD-ROM drive, why not try ejecting it? Using the **`eject /dev/cdrom`** (or other device name as appropriate) command will make the box spit out its CD tray. It is like telling the real **`srv7`** to put its hand up.

[Cautionary note: Be careful of doing this to machines where the CD-ROM tray is behind a closed door, such as with the Digital Prioris or the IBM NetVista. Like a tractor-pull for plastic components, you *will* find out whether the server door is stronger than the internal tray mechanism of the CD-ROM drive.]

[Disappointing note: Calling eject on a nonremovable drive does not cause the hard drive to eject its platters. Bummer! A hard drive that could unleash a couple of platters at 10,000 revolutions per minute would be an interesting sight.]

Change Default Passwords (and record them for your successor)

Sometimes in one of these computer ghettos, you will stumble across an unexpectedly nice piece of equipment, such as a managed switch or a decent router. The chances are strong that it will have been left in its default configuration, so that any devious member of staff can *telnet* to it, change its configuration, leaving the network even more fouled up.

Your natural inclination should be to change these passwords—even if people do not act maliciously, they can sometimes foul up equipment accidentally. However, because you have been pressed into service as the network admin, remember that the same fate will likely befall another hapless victim one day. As a mark of consideration, record the equipment description, location, serial number, and new password, on paper. If the company has a safe, store it there. If the company has a safety deposit box, store it there. Make sure someone (a manager or director) knows about it. The time you save may be your own.

Do-It-Yourself Router

Perhaps you have identified that the network really ought to be split up—maybe moving testing to its own segment so that the incessant load-testing does not choke the network for everyone. However, requests for budget allocation to buy a router might not actually be fulfilled. It is at times like this that an old Pentium, two network cards, and a copy of the *Linux Router Project* (LRP) can be pressed into service as a cheap router.

The throughput of such a lo-fi router may not match that of a dedicated unit, but it may suffice for a small organization.

For bonus points, you might also consider setting up some firewall rules on the router, so that the next virus-ridden e-mail opened by someone in marketing does not flood the entire network with excess traffic.

Nagios

Network monitoring tools can make a world of difference to your quality of life as a temporary network administrator. Rather than waiting for users to alert you to a downed Internet connection, you can detect and repair problems as they occur. The ability to maintain logs of link downtime can also help support arguments to replace unreliable links.

Nagios[1] is a free network monitoring tool. It provides services such as:

- Monitor if a host is up
- Monitor if key services on a host are up
- Monitor if a host is running services it should not

A Web interface allows easy access to status reports. It can be configured to notify you when problems occur, for example, with an e-mail message. Of course, if the mail server is down, this notification method might not be so useful. Such a situation might be better handled by using the Nagios *Short Message Service* (SMS) messaging component.

Given that you might not have a dedicated *Global System for Mobile Communications* (GSM) modem available for sending these SMS notifications, you might like to investigate the Gnokii project[2]. Ostensibly a project to assist the user in communicating with a mobile phone handset (over data-link cable or infrared), with a capable handset users can initiate sending SMS messages from their handset with Gnokii.

Snort

Intrusion detection might seem a luxury on a network that is struggling to stay operational, but when the price is right (free) and you can spare time to set it up, *Snort* offers a range of features that is surprisingly good. *Snort* can even run without an IP address, making its host computer a fairly difficult target for intruders. The documentation at the *Snort* Website[3] is quite comprehensive, and I recommend it.

Squid

Squid[4] is a popular, free HTTP and FTP proxy server. The simple act of caching banner and button graphics for frequently accessed sites can give an apparent increase in Internet bandwidth. The impression for the end user is that things just get faster, because all those pretty graphics load immediately. You may know it is just a nifty trick, but why let on?

Nmap

One characteristic of chaotic networks is that, like weeds after heavy rain, network services spring up everywhere. Programmers are prime offenders in this respect. But be wary—a service with a security flaw, running on an exposed server, can provide an easy beachhead for crackers (a lesson I learned the hard way).

Nmap[6] is a free network scanner that can assist in finding servers that seem to be running more services than they ought to. It operates in several modes, and offers a range of switches to control its operation.

One of the features that seems more oriented toward people who are scanning networks they are not supposed to is the "Timing policy," specified with the **-T** command-line switch. The options offered here are *Paranoid, Sneaky, Polite, Normal, Aggressive, and Insane*. This feature actually comes in handy if the target of your attentions is heavily laden, or lives at the end of a slow link. If you are in the process of tuning a firewall to detect port scans, *Nmap* offers an excellent test facility too.

Another feature that will likely be helpful is the *Nmap* OS fingerprinting facility. Using a combination of techniques[5], it produces remarkably accurate results for most scans. Combine this result with a port scan and you can build a great picture of which machine has grabbed the wrong IP address (a favorite trick of laptop users: "I didn't know what my IP address was supposed to be, so I picked one.") You also can form a rough network map by OS-fingerprinting every active host on your network.

Immunization

It is a good idea to stay up-to-date on your tetanus shots because occasionally you will nick your hands on the sharp bits of metal found in computer equipment.

Traceroute

When licenses for your VisualRouteAnalyser2000 and TrafficGraphic tools have expired, remember that *traceroute* can be one of the most valuable tools to ascertain exactly where things are going wrong. The only (obvious) word of caution is to be aware that overzealous firewall rules can produce spurious results from *traceroute*.

Tag Cables

The desirability of labeling cables is so obvious that it seems silly to even mention it, but it might not have been standard practice for the sysadmin before you. All the more reason you should do the right thing. Sure, *you* know that the purple cable is the link from **gw-eng** to **gw-test**, but will the next person who has to diagnose network issues?

The other impediment to labeling cables is that the sheer volume of unmarked cables makes the task seem futile. Why bother labeling the new one you have just put in, when there are another 40 unknowns? Take heart—by gradually labeling a few here and there, the cables will gradually get less scary each time. Sometimes it can seem like the labor of Sisyphus, but every little bit helps.

Label Equipment

Post-it notes do not constitute an adequate label for network equipment or servers. You are strongly urged to preserve the sanity of other sysadmins by clearly labeling all equipment, using adhesive labels (in a pinch, the labels for a floppy disk will do).

At a minimum I would suggest that host name and operating system (where appropriate), IP address, and a dire warning against tampering with the unit be included. Bonus points are awarded to people who also maintain an equipment audit and record the details of the unit, plus a list of known services that it is running. Of course these will quickly become outdated, but with a known starting point confusion may be reduced.

Destroy Faulty Cables

After several hours of cable tracing, network-card replacement, checking switch link lights, and so on, it may be that you identify a network problem as being caused by a faulty network cable. It can happen anywhere, and is not necessarily a reflection on the skills of the [acting] sysadmin. (Although if the network cable has clearly been mangled and you should have spotted it with a quick visual inspection, you will probably feel a little silly if the time to locate the fault exceeded two hours).

So you whip a replacement cable out of your secret stash (you should have a secret stash of known-good cables) and voila! Network outage fixed. Now comes the most important duty of all—do not discard the damaged cable anywhere that subsequent admins might find it. On several occasions, damaged cables have been put back in operation, only to cause a repeat of the problem that caused them to be removed from service in the first place. It is not uncommon in server rooms to have an empty box that serves as a rubbish bin, but those unfortunates who come after you may not recognize its role as a waste repository in a time of crisis.

If waste is so abhorred that discarding cables is frowned upon, perhaps you can redo the ends of the cable and vigourously retest. Some even maintain that a long cable run can be split into several shorter runs and reused, because the cable fault is likely to be caused by a single break. I disagree—any cable that has broken in one place is likely to suffer further breaks. Demonstrating this principle to overly frugal managers is sometimes best achieved by ensuring the outcome of the demonstration. I suggest laying the cable through a close-fitting door frame and slamming the door on it a few times prior to testing.

Help Dying Equipment on Its Way

Sometimes it can be difficult to discard equipment. Combine this with the almost pathological frugality common in the small business owner, and you find the most decrepit network gear being nursed along. “I just know this old hub has another few years in it. Sure, a few of the Ethernet ports are stuffed, it overheats on warm days, and looks like it might have a mouse nest in the power supply, but that is no reason to discard it.” Nothing is going to convince the owner of this piece of gear that it is time to “redeploy” it in the rubbish bin.

Sometimes you have to be cruel to be kind. Without wanting to seem too much like the *Bastard Operator from Hell* (BOFH)[7], you may have to help some of this equipment meet its end. It is difficult to identify any one method that fulfills this requirement. My best suggestion is to avoid solutions that leave any externally visible marks (unless they are carbonization marks caused by electrical fault).

You may find that some equipment shows a perverse ability to survive conditions well outside their "recommended operating environment," and nothing short of a sledgehammer will cause those last two operational ports to die. My recommendation here is to do some network reorganization so that the people responsible for the retention of the equipment are directly affected by it. Nothing says "replace me" quite like frequent trips to the server room to toggle the power switch on an ailing hub. It is surprising how fast requisition orders get signed when managers can no longer browse their favorite Websites.

Conclusion

The crisis has passed. Your time as a sysadmin has passed, and you are free to return to your real job. You have acquitted yourself admirably as sysadmin, and you have learned something in the process.

Like the end of a horror movie, you know that it does not really end here. Somewhere, something is waiting to go wrong. Will you be ready the next time?

Letters to the Editor

Ole,

I just finished reading the article about Secure BGP [*Border Gateway Protocol*] by Stephen T Kent. It was very informative and educational with regard to the application and overhead of using the additional BGP attributes and IPSec [*IP Security*]. However, it should be noted that the reliance of a PKI [*Public Key Infrastructure*]-based system, although strong, may also present another possible exploit. If the PKI KDS (*Key Distribution System*) is attacked and subsequently knocked out, including redundant *Key Distribution Engine* (KDE) servers, this may cause serious ramifications to the operation of *Secure BGP* [S-BGP].

Here is a very informative link regarding S-BGP resources for your readers: **http://www.ir.bbn.com/projects/s-bgp**

Also, did you know that the *North American Operators' Group* (NANOG) in conjunction with Cisco engineers recently conducted a BGP vulnerability test? This test confirms that BGP implemented properly is pretty secure in and of itself, without the need for something like S-BGP. The article, titled "BGP Vulnerability Testing: Separating Fact from FUD," was written by Sean Convery and Matthew Franz, Cisco Systems. The article can provide a contrast to the one submitted by Kent and give the technical community both sides of the BGP security issues. Following is the link:
http://www.nanog.org/mtg-0306/pdf/franz.pdf

I thoroughly enjoy IPJ and look forward to each issue. Keep up the great work.

—*Jeffrey J. Sicuranza, Applied Methodologies Inc.*
jsicuran@optonline.net

The author responds:

Ole,

Jeffrey makes a few observations about S-BGP in his letter, and they merit responses.

First, I would hope that the discussion of the security features of S-BGP and their direct derivation from the semantics of BGP was as informative as the discussion of performance aspects of the system. After all, a system with good performance but questionable security is probably a poor candidate to S-BGP routing.

Jeffrey raises the question of whether the reliance of S-BGP on certificates, CRLs [*Certificate Revocation Lists*], and address attestations creates significant vulnerabilities that need to be addressed. This is a fair question, but one which I think we have addressed.

The data that S-BGP stores in repositories is data that changes slowly, and thus the system tolerates unavailability of these repositories fairly well. Note that no router ever accesses these repositories in order to verify a route attestation received in an UPDATE. Instead, each ISP [*Internet Service Provider*] or multihomed subscriber NOC [*Network Operations Center*] accesses the repositories to retrieve this data, process it, and distribute the extracted public keys and authorization data to the routers in its network. We anticipate that this process might occur roughly every 24 hours. Because the information represented by the signed objects in the repositories changes very slowly, this retrieval rate seems appropriate. One would expect that these repositories can be engineered to meet these availability requirements. In the worst case, network operators can choose to keep working with the last set of data that they have successfully retrieved. This works because operators process the data before distributing it to their network, and thus can override expired CRLs, etc. So, I think the answer to Jeffrey's cited concern is that S-BGP is not very vulnerable to attacks against these repositories.

I strongly disagree with the conclusions Jeffrey draws from the BGP vulnerability tests he cites. Numerous incidents of BGP security breaches have been reported over the last few years, so there is no question that BGP, as implemented, deployed, and operated, is insecure. Correct implementation of BGP and improved network operator management practices certainly can reduce BGP vulnerabilities. However, the article in question is hardly a refutation of the wide range of vulnerabilities that exist both in practice and in principle. Much of it focuses on a narrow range of attacks, not broader security concerns.

In addressing broader security concerns, for example, the article argues that proper filtering of routes will mitigate the impact of a compromised router. But we know that such filtering is not feasible for many transit network connections, and route filterers are prone to configuration errors. Reliance on transitive trust (for example, assuming that peers filter routes appropriately) makes BGP intrinsically insecure. Relying on *all* ISP operators to *never* make exploitable errors in configuring their route filters, where such filters can be used, is a fundamentally flawed security approach. S-BGP accounts for the reality that not every ISP will operate its network perfectly, and employs mechanisms to allow other ISPs to detect and reject a wide class of errors (or attacks) that may result from such imperfect operation. Thus I reassert that the security vulnerability characterizations that appear in the S-BGP publications are accurate, not overblown.

As a side note, I find it odd that some critics of S-BGP argue that it fails to account for operational reality, yet they offer alternatives that are based on unrealistic assumptions about network operators acting perfectly!

Book Review

IP for 3G

IP for 3G, Networking Technologies for Mobile Communications, by David Wisely, Philip Eardley, and Louise Burness, ISBN 0-471-48697-3, John Wiley & Sons, 2002.

I was looking for a book covering mobile communication issues from an IP perspective and IP issues from a mobile communications perspective in order to better clarify details of IP and *third-generation* (3G) convergence. The issue is becoming more and more concrete with the early implementations of 3G networks, so this is a timely book for networking professionals.

Organization

This well-organized textbook helps readers easily understand the "IP-for-3G" issues. It gives a clear vision of that convergence as well as the current snapshot of the recent developments about the subject within the research community. The book is more than an introductory textbook; but readers interested in more technical elaboration can refer to a detailed list of references and further readings given at the end of each chapter.

The book begins with a short chapter that explains the case for IP for 3G. The authors discuss in detail what the term means. They give possible interpretations of IP (Internet, IP Protocol, applications) and their consequent implications on the meaning of IP for 3G. Then they elaborate the IP case within first the "Engineering Reasons for IP for 3G" and then "Economic reasons for IP for 3G" sections.

The second chapter is an introduction to 3G networks. The chapter mostly concerns the core and the access part of 3G networks, skipping the air interface part, because core and access are where IP would make a real difference to the performance and architecture of a 3G network. The chapter reviews briefly the history of 3G developments, from conception to implementation. Then the architecture of *Universal Mobile Telecommunications Service* (UMTS) is introduced, followed by the section where elements of the core network and the architecture of the radio access part are examined. For each part, main functional components such as *Quality of Service* (QoS), mobility management, security, transport, and network management are discussed in detail.

The third chapter discusses the basics of IP and IP networks. Authors give excellent remarks about IP design principles, which are then compared to those of classical telecommunications. Subsequent short sections inform readers about IP addressing schemes, routing, layer behavior, etc. The final section covers the issue of application layer security, which is irrelevant to me for the content of this book. A note: Some of the following chapters require better IP know-how, especially about domain segmentation and intra- and interdomain routing issues. Readers with no prior information are encouraged to refer to other materials before examining the details of, for example, mobility management and QoS.

The fourth chapter is about the multimedia support and session management. First, the concept of session management is introduced. The chapter focuses mainly on the control plane functions of the session management, and the data plane functions are covered in detail in the sixth chapter. The concept of the *Virtual Home Environment* (VHE) is introduced, which forms one of the major requirements of the next-generation mobile system. The authors then review control plane session management protocols, namely H.323 and the *Session Initiation Protocol* (SIP). More discussion is given to SIP, because it is included in the next generation of UMTS standards as the major session management protocol.

The fifth chapter reviews a major problem of the IP-for-3G concept: mobility management. Other key issues of IP such as QoS, IPv6, and session management have always been subject to preceding studies, because those protocols have already been proposed for use in stationary networks. However, the issue of mobility management is a major subject to be investigated for any proper convergence scenario. Personally, I find that this is the biggest challenge of the "long-time-discussed" convergence of IP and mobile communications, and hard work is still ongoing in order to properly resolve the mobility problem. The chapter reviews the basics of mobility such as personal or terminal mobility. From there, macromobility (interdomain or global mobility) and micromobility (intradomain or local mobility) concepts are discussed, followed by proposed protocols for each type of mobility. Mobile IP is examined as the (unique) macromobility protocol. More attention is given to micromobility because it is the most sensitive part of the mobility, under the assumption that 3G BTSs (B nodes) will be simple routers with some extra capabilities. Two variants are discussed, mobile IP schemes, which are based on dynamic tunneling mechanisms, and "per-host forwarding" schemes based on dynamic routing functions. A comparison of major proposals for micromobility management protocols follows.

The sixth chapter considers current IP QoS mechanisms, their operation and capabilities. Those mechanisms created mostly for stationary IP networks may provide a bounded QoS for some "non-real-time" applications, but they are not enough to support any QoS request within the wireless or mobile environment. After giving details of current QoS mechanisms and discussing wireless implications for TCP QoS as well as mobility and wireless issues for *Real Time Protocol* (RTP) QoS, the chapter examines the key elements of QoS and generic features that any prospective QoS mechanism must have. Finally, the authors analyze recent Internet QoS mechanisms such as *Integrated Services* (IntServ), *Differentiated Services* (DiffServ), *Multiprotocol Label Switching* (MPLS), and *Resource Reservation Protocol* (RSVP). The closing section proposes a possible outline solution for how to provide IP QoS for 3G, based on previous work done during the EU BRAIN project.

In the final chapter, the authors summarize all previously given subjects to sketch out the vision of an "All-IP" mobile network. Principles, architecture, routing and mobility issues, QoS, security issues, and interfaces are all discussed to elaborate the generic vision of All-IP networks. Finally, 3G network evolution covering UMTS R4 and R5, and what is beyond 3G, are all discussed.

The book is perfect in the sense that it touches a very hot topic, most of the technical details of which are still in the process of evolving. The authors manage very well the level of details about each subject; they first discuss the overall material before examining details, so readers can obtain a generic but complete view before studying technical details. Each chapter is followed by a comprehensive list of references and further readings, each of them classified by topic. The only fault I find in the book is that SIP should be discussed in more detail.

Recommended

Overall, I would highly recommend this book to any network professional, especially one who is part of any IP-3G convergence process for mobile operators. Still, data network professionals can glean much from the book, because the aim is to carry—a little differently—the same old data, whether or not it contains multimedia, voice, or standard data information.

Tim Berners-Lee Knighted by Queen Elizabeth

31 December 2003 — Tim Berners-Lee, the inventor of the World Wide Web and director of the *World Wide Web Consortium* (W3C), will be made a *Knight Commander, Order of the British Empire* (KBE) by Queen Elizabeth. This was announced earlier today by Buckingham Palace as part of the 2004 New Year's Honours list.

The rank of Knight Commander is the second most senior rank of the Order of the British Empire, one of the Orders of Chivalry awarded. Berners-Lee, 48, a British citizen who lives in the United States, is being knighted in recognition of his "services to the global development of the Internet" through the invention of the World Wide Web.

"This is an honor which applies to the whole Web development community, and to the inventors and developers of the Internet, whose work made the Web possible," stated Berners-Lee. "I accept this as an endorsement of the spirit of the Web; of building it in a decentralized way; of making best efforts to keep it open and fair; and of ensuring its fundamental technologies are available to all for broad use and innovation, and without having to pay licensing fees."

"By recognizing the Web in such a significant way, it also makes clear the responsibility its creators and users share," he continued. "Information technology changes the world, and as a result, its practitioners cannot be disconnected from its technical and societal impacts. Rather, we share a responsibility to make this work for the common good, and to take into account the diverse populations it serves." For more information see:

http://www.w3c.org/2003/12/timbl_knighted

SECSAC Publishes DNS Report

The *Security and Stability Advisory Committee* (SECSAC) has published a report entitled "DNS Infrastructure Recommendation." For details see:

http://www.icann.org/committees/security/dns-recommendation-01nov03.htm

Coordination, not Governance says ISOC re WSIS

The *Internet Society* (ISOC) published the following text at the *World Summit on the Information Society* (WSIS 2003) which was held in Geneva in early December, 2003:

ISOC is a global not-for-profit membership organisation founded in 1991 to provide leadership in Internet-related standards, education, and policy issues. We are dedicated to ensuring the open development, evolution and use of the Internet for the benefit of people throughout the world. Our education initiatives, for example, have helped bring Internet connectivity to virtually all developing countries over the last 12 years.

ISOC is the organisational home of the *Internet Engineering Task Force* (IETF)—an open consensus-based group responsible for defining Internet protocols and standards. Through our participation in WSIS 2003 we aim to increase understanding and awareness of what is important in order to develop and maintain the Internet's stability, open nature and global reach.

The Internet has come of Age

In many countries, the Internet has become a mass medium. This has brought with it reflexive pressure on policy makers to regulate it as if it were radio, television, or other mass media. While Governments naturally seek to address their citizens' interests regarding online privacy, spam, Internet security, intellectual property protection, the price of Internet access, and the digital divide, our position is that better use of technology, and broad participation in today's Internet coordination processes, not Government regulation, are the most effective and appropriate ways to satisfy these concerns.

The biggest barrier to the Internet fulfilling its immense potential could turn out to be misinformed and inappropriate intervention in the way in which the Internet's technologies, resources and policies are developed, deployed and coordinated. The Internet Society can help provide guidance here.

What is the nature of the Internet?

The Internet is a modern distributed communications medium. No one is in charge of the Internet and yet everyone is in charge. Unlike the antiquated system of national telephone network monopolies, the global Internet consists of tens of thousands of interconnected networks run by Internet Service Providers, individual companies, universities, Governments, and other institutions. Some of these are global in scope, others regional or local. Hundreds of different organisations and thousands of different companies make decisions every year that contribute to how the Internet develops.

These varied entities, together with the users of the Internet and the developers of Internet technologies and applications, have specific needs for coordination. Collaborative processes that are critical for the future stability and evolution of the Internet, and which should not be modified arbitrarily or abruptly, satisfy these needs.

Coordination, not Governance

It is misleading to use the term "Internet Governance" when the Internet is clearly not a single entity to govern. It is more useful to refer to "Internet Coordination." The multiple facets of the Internet require different types of coordination, each calling for specific competencies and sensitivities to balance the needs of the Internet user community globally and locally. Specific Internet Coordination activities are taking place globally at three levels:

- Coordination of the definition of Internet standards
- Coordination of the availability and assignment of Internet resources
- Coordination of the policies preventing misuse of the Internet

This coordination is best performed by the existing set of organisations using proven processes. Because of the diverse nature of these activities, it is unrealistic to expect a single body— Government or otherwise—to take on all these roles effectively.

Coordinating Internet standards

The IETF under the umbrella of the Internet Society, is one of the oldest and most successful Internet coordination processes. Other organisations are also involved in Internet-related standards, including the IEEE, the W3C and the ITU.

Many of the protocols at the heart of today's Internet (for example, TCP, IP, HTTP, FTP, SMTP, Telnet, PPP, POP3, the DNS protocol etc.) were developed through IETF standards activities. The results of the IETF are well engineered and practical open protocol standards that are trusted and open to global implementation with little or no licensing restrictions—they are freely available on the Internet, without cost, to everyone.

The strength of the IETF process lies in its unique culture and talented global community of network designers, network operators, service providers, equipment vendors, and researchers. They all openly contribute their individual technical experience and engineering wisdom in an environment that fosters innovation and the open exchange of ideas. This process, which is open to anyone, helps quickly identify and articulate problems of common interest. It also helps build the trust required to make the further investments necessary for a protocol to be usefully implemented and deployed. Ultimately, however, it is the Internet users themselves that determine whether or not a protocol is valuable and useful enough for widespread use. Here the IETF track record of producing useful, widely deployed protocols is unrivaled.

Coordinating Internet resources: The Internet Registry System

There has always been a need to manage the allocation of Internet resources such as the unique addresses that identify devices connected to the Internet (IP addresses), generic top-level domain names (for example, **`.org`**), country code top-level domain names (for example, **`.ch`**), domain names (such as **`www.isoc.org`**), and the systems that translate domain names into IP addresses (for example, the *Domain Name System* or DNS).

This coordination activity has been handled by long-standing, not-for-profit membership organisations such as the *Regional Internet Registries* (RIRs) and *top-level domain* (TLD) registries.

More recently, coordination at a global level has been supported by the *Internet Corporation for Assigned Names and Numbers* (ICANN). Established in 1998, ICANN is also a not-for-profit organisation. Business, technical, non-commercial, academic, governmental and end-user communities participate in ICANN.

These organisations are a meeting point for bottom-up, consensual, industrial self-regulation by the groups and individuals that use their services and resources.

Coordinating policies preventing misuse of the Internet

As we have seen, organisations such as the RIRs, TLD registries, ICANN and the IETF all have very specific roles. It is neither within their charters, nor within their capabilities, to take on responsibility for all areas of Internet Coordination—particularly that of preventing inappropriate use of the Internet. For example, areas such as "cyber crime" (for example, fraud and child pornography) require coordinated global attention by lawmakers—and not by those responsible for the equitable coordination of the underlying Internet infrastructure. Security matters also need to be addressed by organisations providing Internet access (not only by standards developers), and intellectual property iss ues may best be handled by organisations such as the *World Intellectual Property Organization* (WIPO).

In discussions about these broader Internet policy issues there is cooperation between all the organisations mentioned above. ICANN for example works with WIPO to implement its *Uniform Domain Name Dispute Resolution Policy* (UDRP). And the Internet Society, with technical advice from the IETF, works with Governments and policy makers to explain the effects and possibilities of new Internet technologies.

The way forward: Make your voice heard

Existing consensus-based processes have given us the Internet and have successfully coordinated its phenomenal growth: thousands of new networks, new policy procedures, new top-level domain names, new protocols etc. All of them constantly balance the needs and stability of today's Internet with future demands.

An open debate is now needed to move towards common, globally acceptable policies, processes and technologies to prevent misuse of the Internet. Governments have a vital role to play here as a concerted effort on the part of the Internet community, non-governmental organisations and Governments can help strengthen and extend today's successful coordination processes.

The successful continued development of the Internet for the benefit of everyone can be ensured by participation in these proven processes rather than by attempting to create new untested mechanisms that are inappropriate to the unique characteristics of the Internet.

The Internet Society remains dedicated to providing information and orientation about Internet structures and processes. We encourage broad participation in the activities of each of the organisations involved in Internet coordination. For more information on ISOC, visit: **www.isoc.org**

From The Editor

The operational stability of the global Internet (or any network based on TCP/IP technology) is in large part the result of a carefully configured routing system. Routing continues to be one of the most complex topics in Internet engineering. In our first article, Russ White describes some mechanisms for the design of large-scale, stable routing systems. The article is entitled "High Availability in Routing."

Security continues to be a high-priority item in computer networks and in society in general. One aspect of security is the identification system by which an individual is given authorized access to a particular facility, be it physical or virtual. Edgar Danielyan gives us an overview of one key element of identification, namely *biometrics*.

The Internet is "going where no network has gone before." The *National Aeronautics and Space Administration* (NASA) has been working on the *Interplanetary Internet Project* (**http://www.ipnsig.org/**). We hope to bring you an in-depth article about this project in a future issue. An important demonstration of this system took place recently. To quote from the press release:

> "A pioneering demonstration of communications between NASA's Mars Exploration Rover *Spirit* and the *European Space Agency* (ESA) *Mars Express* orbiter has succeeded. On February 6, 2004, while Mars Express was flying over the area Spirit was examining, the orbiter transferred commands from Earth to the rover and relayed data from the robotic explorer back to Earth. The commands for the rover were transferred from Spirit's operations team at NASA's *Jet Propulsion Laboratory* (JPL), in Pasadena, California, to ESA's European Space Operations Centre in Darmstadt, Germany, where they were translated into commands for Mars Express. The translated commands were transmitted to Mars Express, which used them to successfully command Spirit. Spirit used its ultra-high frequency antenna to transit telemetry information to Mars Express. The orbiter relayed the data back to JPL, via the European Space Operations Centre."

We often receive requests for back issues of IPJ. Although we cannot provide paper copies, all of our previously published editions are available in both PDF and HTML format from the IPJ Website: **www.cisco.com/ipj**.

High Availability in Routing

by Russ White, Cisco Systems

A network is a complex system of interacting pieces, as anyone who has ever worked with a large-scale network "in the wild" can tell you. So, when businesses begin asking for a network that can converge in something under 1 second, especially in a large network, network engineers begin to scratch their heads, and wonder what their counterparts in the business world are thinking about. Just about everyone in the network engineering business knows scale and speed are, generally speaking, contradictory goals. The faster a network converges, the less stable it is likely to be; fast reactions to changes in the network topology tend to create positive feedback loops that result in a network that simply will not converge.

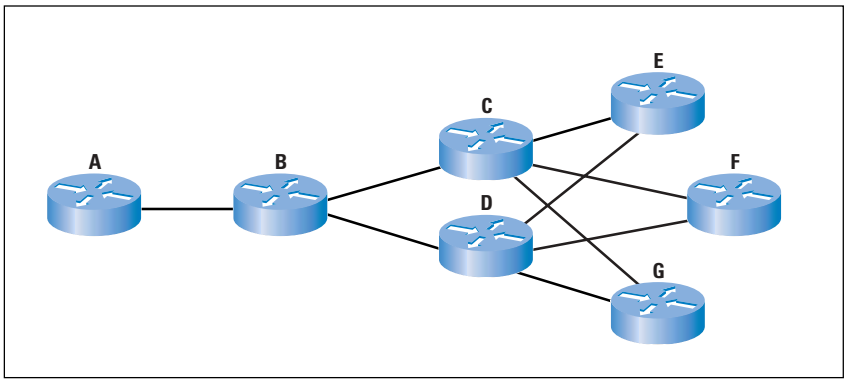
But recent experience has shown that subsecond convergence in a network—even a large network in the wild—is definitely possible. How do we go about building a large-scale network that can converge in times that were, before recently, considered impossible, or improbable, at best? We approach the problem the same way network systems, themselves, are approached. We break the problem down into smaller pieces, and try to solve each piece individually. When we have solved each of the smaller pieces, we recombine them, and see what needs to be adjusted to make it all work together properly.

What pieces of a network do we need to be concerned about when considering subsecond (fast) convergence? Generally, we are concerned with the physical layer (how fast can a down link be detected?), routing protocol convergence (how fast can a routing protocol react to the topology change?), and finally, forwarding (how fast can the forwarding engine on each router in the network adjust to the new paths calculated by the routing protocol?). This article focuses on routing protocols convergence, with some discussion of fast down detection as well, specifically the interior gateway protocols, *Enhanced Interior Gateway Routing Protocol* (EIGRP), *Intermediate System-to-Intermediate System* (IS-IS), and *Open Shortest Path First* (OSPF).

Network Meltdowns

Before beginning to work on a network so it will converge quickly, we need to set some realistic expectations. As mentioned previously, a routing protocol configured to react very quickly to changes in network topology tends to develop positive feedback loops, which result in a network that will not converge at all. Using the following example, consider how a single problem can produce feedback that causes a failure to cascade through the network.

Figure 1: Positive Feedback Loops in a Network



Suppose the link between routers D and G flaps, meaning that it cycles between the down and up states slow enough for a routing adjacency to be formed across the link, or for the new link to be advertised as part of the topology, but too quickly for the link to actually be used. In this situation, the adjacency (or neighbor relationship) between routers D and G forms and tears down as quickly as the routing protocol will allow.

While this is occurring, the routing information at routers E, F, and G is changing as quickly as the adjacency between D and G can form and tear down. This change in routing information is, in turn, passed on to C, which then must process it as fast as it possibly can. It is possible that the routing information presented to router C will overcome the ability of its processor to process the information, causing router C to fail, or drop its neighbor adjacencies.

At the same time, the constantly changing routing information at router B will also cause problems, possibly causing it to periodically drop its adjacencies, specifically with routers C and D. At this point, if the routers B, C, and D are all three consuming a large amount of memory and processing power adjusting to apparent topology changes because of changing adjacency states, the flapping link between routers D and G, which originally caused the problem, can be removed from the network, and the routing protocol will still not converge. This is what network engineers consider a classic *meltdown* in the routing system.

Solving the Meltdown

Typically, when a network engineer faces a network in this condition, the first step is to simply remove routing information from the system until the network "settles." This typically involves removing parallel (redundant) links from the view that the routing protocol has of the topology until the routing protocol converges. At this point, the network would be examined, routers reloaded as needed, and the parallel links brought back up. The network design might then be reviewed, in an attempt to prevent recurrence of a meltdown.

Routing protocol designers and developers would also like to move the point at which a routing protocol "melts" as far along the curve of network design as possible.

Of course, it is impossible to prevent all network meltdowns through protocol design; there are limits in any system where the implementation steps outside the "state machine," and the system will simply fail. But how would a routing protocol designer work around this sort of a problem in the protocol itself? The answer is actually very simple: Slow down.

The main problem here, from a protocol designer's point of view, is that routers D and G are simply reacting too fast to the changing topology. If they were to react more slowly, the network would not fall into this positive feedback loop, and the network would not melt. And, in fact, slowing down is really quite simple. Various methods of slowing down include:

- Not reporting all interface transitions from the physical layer up to the routing protocol. This is called *debouncing* the interface; most interface types wait some number of milliseconds before reporting a change in the interface state.
- Slow neighbor down timers. For instance, the amount of time a router waits without hearing from a given neighbor before declaring that a neighbor has failed is generally on the order of tens of seconds in most routing protocols. The dead timer does not impact down-neighbor detection on point-to-point links, because when the interface fails, the neighbor is assumed to be down, but there are other "slow-down" timers here, as well.
- Slow down the distribution of information about topology changes.
- Slow down the time within which the routing protocol reacts to information about topology changes.

All four of these methods are typically used in routing protocols design and implementation to provide stability within a routing system. For instance:

- In IS-IS, a timer regulates how often an intermediate system (router) may originate new routing information, and how often a router may run the *shortest path first* (SPF) algorithm used to calculate the best paths through the network.
- In OSPF, similar timers regulate the rate at which topology information can be transmitted, and how often the shorter path first algorithm may be run.
- In EIGRP, the simple rule: "no route may be advertised until it is installed in the local routing table" dampens the speed at which routing information is propagated through the network, and routing information is also paced when being transmitted through the network based on the bandwidth between two routers.

It seems like the simplest place to look when trying to decrease the time a routing protocol requires to converge, then, is at these sorts of timers. Reduce the amount of time an interface waits before reporting the transition to a down state, reduce the amount of time a router must wait before advertising topology information, etc. But when we consider implementing such changes, we remove much of the stability we have all come to expect in routing systems—the size a network can be built without melting down decreases below an acceptable threshold, even with modern processors, more memory, and implementation improvements in place.

There is another place to attack this problem: the frequency of changes within the network. This is the same concept—speed—from a different angle. How does looking at it from a different angle help us? By allowing us to see that it is not the speed of the network changes that causes the positive feedback loop, but rather how often the changes take place. If we could report the changes quickly when they occur slowly, and report them more slowly when they occur quickly, or if we could just not report some events at all, routing could converge much faster, and still provide the stability we expect.

The two options we want to examine, then, are not reporting every event, and slowing down as the network speeds up. First we will discuss these two options, and then discuss speeding up the reporting of network events, which plays a large role in decreasing convergence times.

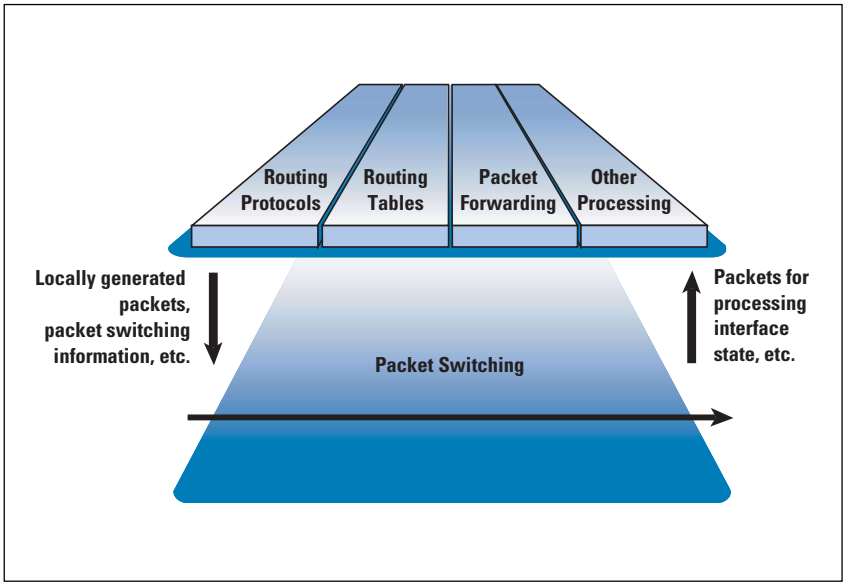
Do Not Report Everything You See (NSF and GR)

It sounds simple just to say that a router should not report every event within the network it is aware of, but it becomes more complicated as we consider the issues involved. What we need to do is sort out which events are important, in some sense, and which are not. For instance, if a router loses contact with an adjacent router because the adjacent router restarted for some reason, do not report the resulting change in topology until you are certain the neighbor is not coming back.

But the classic questions follow: How long do you wait before deciding the problem is real? And what happens to traffic you would normally forward to that neighbor while you are waiting? Finally, how do you reconnect in a way that allows the network to continue operating correctly? A technology recently incorporated in routing protocols called *Graceful Restart* (GR), combined with another technology called *Non-Stop Forwarding* (NSF), can combine to answer these questions.

Let's start at the bottom of the *Open Systems Interconnection* (OSI) model, at the physical and data link layers, and discuss the second question, what happens to traffic that would normally be forwarded while a router is restarting? Normally, this traffic would be dropped, and any applications impacted would need to retransmit lost data. How could we prevent this? We can take advantage of the separation between the control plane and the forwarding plane in a large number of modern routers.

Figure 2: Control and Data Plane Interaction in a Router



In some routers, such as the Cisco® 12000, 10000, 7600, and others, the actual switching, or forwarding, of packets is performed by different processors and physical circuitry than the control plane processes run on (such as routing protocol processes, routing table calculation, and other processes). Therefore, if the control plane fails or restarts for any reason, the data plane could continue forwarding traffic based on the last known good information.

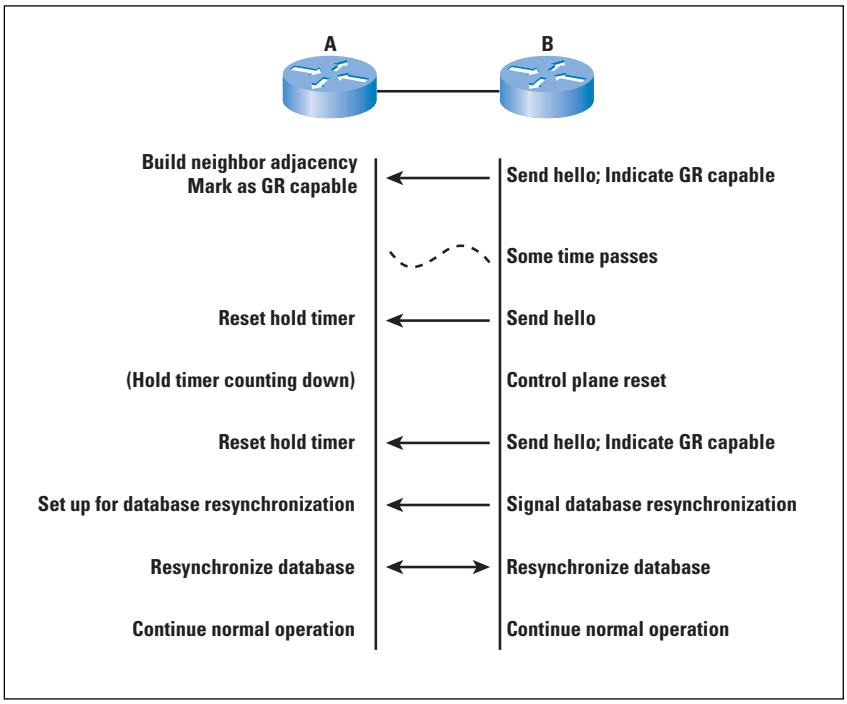
NSF, implemented through *Stateful Switchover* (SSO) and *Stateful Switchover+* (SSO+) in Cisco products, allows this continuous forwarding, regardless of the state of the control plane, to take place. Normally, when the control plane resets, it sends a signal to the data plane that it should clear its tables out, and reset, as well. With NSF enabled, this signal from the control plane simply acts as a signal to mark the current data as stale, and to begin aging the information out.

Now we need to be able to bring the control plane back up, resynchronize the routing protocol databases, and rebuild the routing table, all without disturbing the packets still being switched by the data plane on the router. This is accomplished through GR. GR starts by assuming two critical things:

- The normal hold times are acceptable, within this network environment, for reporting a network event or topology change. In other words, if a router's control plane fails, the event wouldn't be reported until the routing protocol's default hold or dead timers expire, whether or not GR is configured.
- The control plane on the router can reload and begin processing data within the hold or dead time of the routing protocol.

Let's examine how, in principle, GR works, so we can put these two requirements into context, and understand where GR is best deployed in a live network. Consider the following chart to understand how GR works between two peers of any generic routing protocol.

Figure 3: The Process of Graceful Restart



When two routers begin forming an adjacency (or neighbor relationship, or begin peering, depending on which routing protocol is being run between them), they exchange some form of signaling noting that they are capable of understanding GR signaling, and responding to it correctly.

[Note that this does not imply the router is GR-capable, only that it can support a neighboring router performing a GR. For instance, the Cisco 7200 supports switching modes only where the control and data planes are not cleanly separated, so it cannot fully support GR. It can, however, support the signaling necessary for a neighboring router to gracefully restart.]

Assume some time passes, and router B is transmitting Hello packets to router A normally, on a periodic basis. Each time router A receives one of these Hello (or *keepalive*) packets, it resets the hold, or dead, timer on router B, indicating that it should wait that amount of time before declaring router B down if it stops receiving Hellos. Now, at some point, after sending a Hello packet, the router B control plane resets. While the control plane is down, the router A hold timer is still counting down; the routing protocol does not reset the session. This is, in fact, normal routing protocol operation, which normally results in the packets forwarded by router A toward router B to be dropped. Because router B is NSF-capable, however, its data plane is still forwarding this traffic to the correct destination, even though the control plane is down.

If the router B control plane does not come back up within the dead or hold timer allowed by the routing protocol, router A declares the adjacency down, and begins routing around router B. This explains why the router B control plane must come back up within the hold interval of the routing protocol, one of the two assumptions we outlined GR as making at the beginning of this section. For this case, we assume that the router B control plane comes back up before the router A hold timer expires, and router B sends a Hello with no information other than indicating it is restarting.

When router A receives this Hello, it acts as though it has received a normal Hello, and simply keeps its adjacency with router B up. In other words, although router B may not know what the network it is connected to looks like at this point, router A does not report this failure to the rest of the network. Convergence time is, from a network standpoint, effectively reduced to 0.

When the router B control plane completes its reset, it then signals router A to begin resynchronizing their databases. The two routers then use some method specific to each protocol to resynchronize their databases, and begin operating normally, in a stable condition once again.

Slow Down When the Network Speeds Up

The second option we discussed originally was to attack the problem by reducing the frequency, rather than the number, of updates. What we want to do is to slow down the reporting of events when they occur more frequently (or when they occur rapidly), and speed up the reporting of events when they occur less frequently (or when they occur slowly). This is possible through a series of features built into Cisco IOS® Software within the last year or two, applying the concept of the *exponential timers*.

An exponential timer changes the amount of delay between an event occurring and the reporting of that event by the frequency at which the event occurs—possibly not reporting the event at all, in some situations. Two implementations of exponential timers are *exponential backoffs* and *dampening*. Let's examine each of these individually, and then consider where they are implemented in Cisco IOS Software.

Exponential Backoffs

Consider the following figure to examine how exponential backoff works.

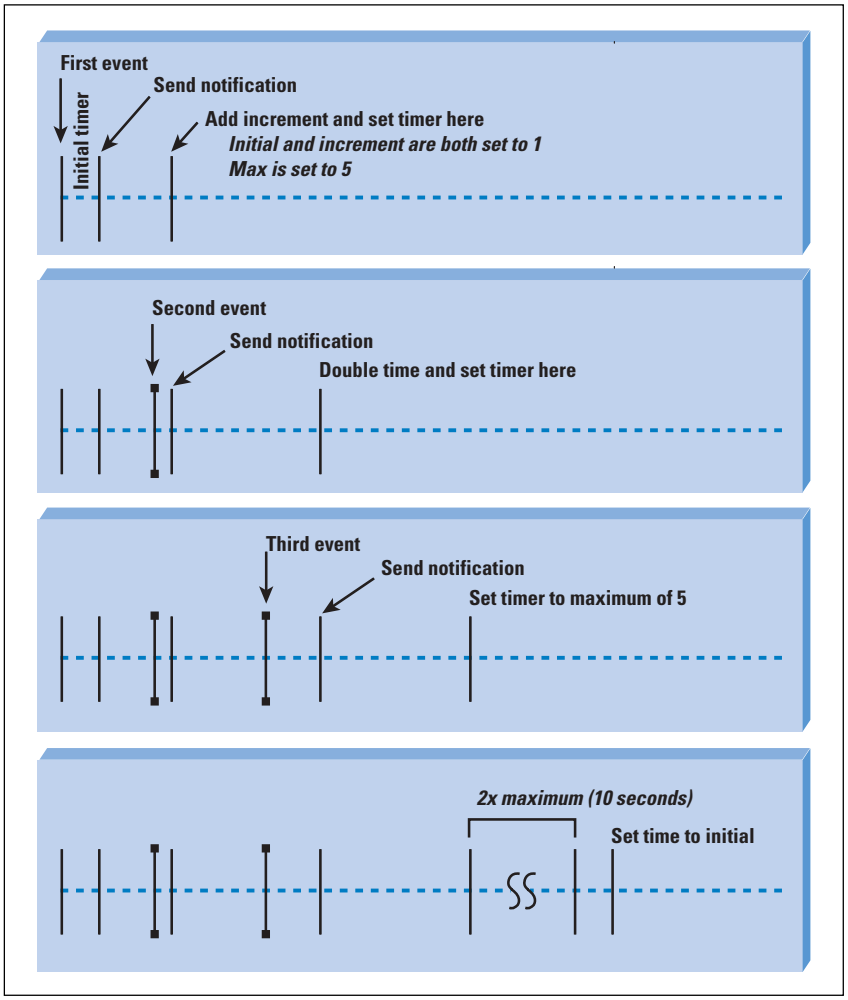


Figure 4: Exponential Backoff

When the first event occurs, a timer is set to the initial time, 1 second in this case, meaning that the router waits for one second before notifying other routers in the network about the event. When the notification is sent, the router adds the initial timer to the increment, and sets a timer for this period. We call this timer the *backoff timer*.

When the second event occurs, the backoff timer is still running; the router waits until this timer expires to send the notification about this event occurring. When this notification is sent, the backoff timer is set to twice the previous setting or the maximum backoff time, whichever one is shorter. In this case, doubling the backoff timer results in 4 seconds, so it is set to 4 seconds.

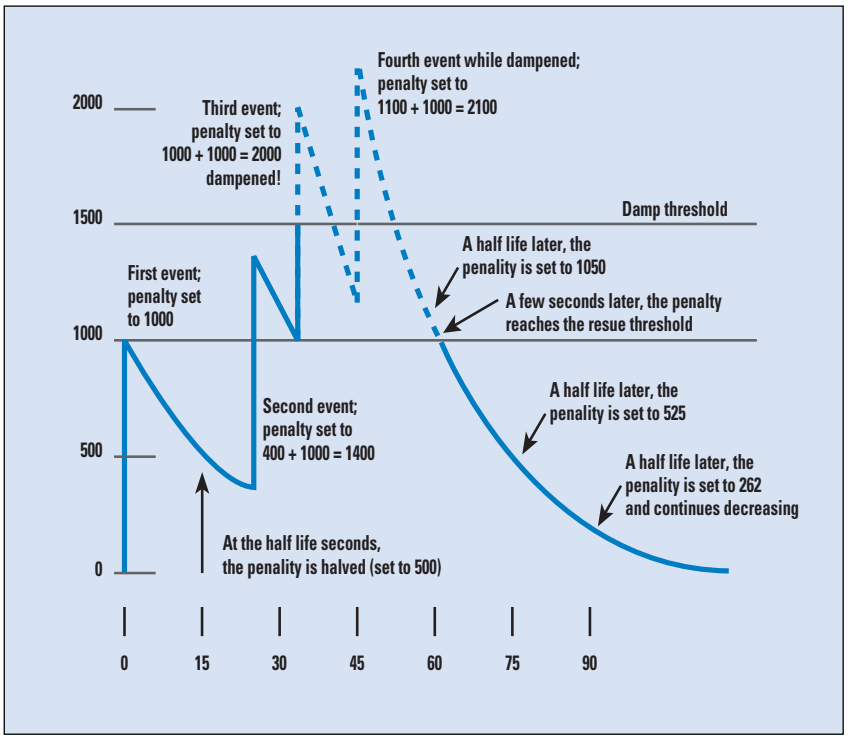
When the third event occurs, the backoff timer is still running; the router waits until the timer expires before sending any notification of the event occurring. Again, the timer is doubled, this time to 8 seconds, and compared to the maximum time, which is 5 seconds. The shorter of the two times is taken, so the backoff timer is now set for 5 seconds.

At this point, any future events will be reported only at 5-second intervals, as long as one event occurs at least every 5 seconds. If no events occur for an interval of 10 seconds, the timers are all reset to their initial condition, so the initial timer is set to 1 second, and the backoff timer is not set at all.

Dampening

Dampening, or damping, is also an exponential backoff mechanism similar to the exponential backoff algorithm we examined previously. The primary difference is that dampening is applied to events that have a Boolean component; a route that is either advertised or withdrawn, an interface that is either up or down, etc. Exponential backoff simply deals with events in general, whereas dampening adds value based on the type of event, as well as the frequency at which the event occurs. Consider the following figure to understand dampening.

Figure 5: Dampening Over Time



In dampening, the desirability of reporting an event is set using the *penalty*; the higher the penalty applied to a given item, such as a route or an interface, the less desirable it is to advertise changes in the state of that item. Dampening always leaves the item in the "off," or "down," state, when it stops reporting state changes; this is called the *dampened* state. A penalty is normally added when transitioning from "down" to "up" in most dampening systems.

Here, we start at time 0, with a penalty of 0; when the first event occurs, a penalty of 1000 is added, making the total penalty 1000. As time passes without another event occurring, the penalty is decreased, based on the *half life*. Each time the half life passes, in this case 15 seconds, the current penalty is halved, so after 15 seconds, the half life is set to 500.

A few seconds later, while the penalty is still decreasing, the second event occurs; 1000 is added to the current penalty, making the total penalty 1400. Again, as time passes, the penalty decays exponentially, reaching 1000 before the third event occurs. When the third event occurs, 1000 is again added to the total penalty, so it reaches 2000—which is above the *damp threshold*, so future events are dampened by simply leaving the interface or route in the down state.

Again, as time passes, the penalty is cut in half for each passing half life, reaching 1100 before the fourth event occurs. When the fourth event occurs, 1000 is again added, making the penalty 2100, and leaving us in the dampened state until the penalty can be reduced again. Over time, the penalty finally drops to 1000 (at around 60 seconds in the example), which is the *reuse threshold*. At this point, state changes in the item being tracked are once again reported as they occur, unless the penalty reaches the dampening threshold at some future point.

So, dampening reacts to events by simply not reporting events if they occur too frequently, whereas exponential backoff reacts to events by reporting each event that occurs, but slowing down the reporting of events as they occur more frequently.

Speeding Up the Reporting of Events

When we have some methods in place to prevent a network meltdown when events occur, we can consider ways to discover events faster. Primarily, these techniques are used in conjunction with exponential backoff and dampening.

There are two ways to detect a down neighbor or link: *polling* and *event driven*. We will briefly discuss each of these, and some various techniques available in both cases.

Polling

One method commonly used for detecting a link or adjacency failure is polling, or periodically sending Hello packets to the adjacent device, and expecting a periodic Hello packet in return. The speed at which Hello packets are transmitted and the number of Hello packets missed before declaring a link or adjacency as failed are the two determining factors in the speed at which polling can discover a failed link or device.

Normally, a neighbor or link is declared down if three Hello packets are lost, meaning that the hold time, or the dead time, will always be about three times the Hello time, or polling interval. Normally, for Layer 2 links and routing protocols, the Hello interval is measured in seconds. For instance:

- EIGRP running over a point-to-point link sends one Hello every 5 seconds, and declares a neighbor down if no Hellos are heard for 15 seconds.
- EIGRP running over a lower-speed point-to-multipoint link sends one Hello every 60 seconds, and declares a neighbor down if no Hellos are received in 180 seconds.

- OSPF normally sends a Hello every 10 seconds, and declares a neighbor down if no Hellos are heard for 40 seconds.
- *Frame Relay Local Management Interface* (LMI) messages, the equivalent of a Hello, are transmitted every 10 seconds. If an LMI is not received in 30 seconds, the circuit is assumed to have failed.
- *High-Level Data Link Control* (HDLC) keepalive messages are transmitted every 10 seconds. If a keepalive message is not received within 30 seconds, the circuit is assumed to have failed.

Fast Hellos can decrease these timers to Hello intervals on the order of 300 milliseconds, and dead timers of around 1 second.

The primary problem with fast Hellos is scaling, particularly in receiving and processing fast Hellos from a large number of neighboring routers. For instance, if a router has 1000 neighbors and is using a Hello interval of 330 milliseconds, the router has to be able to receive and process 3000 Hellos per second and send 1000 Hellos per second. Timers in this range leave little room for processes that consume a router processor for long periods of time, short-term packet loss on a link due to congestion, and other factors.

Event Driven

Rather than polling at a fast interval, event-driven notifications rely on devices within the network that can sense the state of a link through lower layers (electrical, electronic, or optical state) to notify the routers attached to the link when the link has failed. SONET links are probably the best example of media with built-in capabilities for sensing link failures and notifying attached devices. This Tech Note on Cisco Online:

`http://www.cisco.com/en/US/tech/tk482/tk607/technologies_tech_note09186a0080094522.shtml`

... provides information about SONET alarms. There are also techniques that can be used to speed up the reporting of failed links in Frame Relay circuits, and techniques are being developed for allowing switches to notify devices attached to an Ethernet VLAN about a loss of connection to an attached device.

Implementations

Now that we have discussed what exponential backoff and dampening are, we can consider how they are implemented, and how their implementation helps you build highly available networks (through fast convergence) without risking major network instability along the way. We start by examining where dampening is implemented, and then follow that with a discussion about where exponential backoff is implemented. These sections do not provide a great deal of detail on the implementation of these features; vendor documentation and other sources of information (such as the forthcoming book *Designing to Scale*) should be consulted for technical details.

Dampening

Dampening is currently implemented in two places:

- *Border Gateway Protocol* (BGP) route flap dampening
- Interface dampening

BGP route flap dampening is a well-known technology, deployed in the Internet on a wide scale to increase the stability of the Internet routing table.

Interface dampening allows the network engineer to prevent rapidly flapping interfaces from having a wide-ranging impact on the entire network. When an interface fails and comes back up numerous times within a short time period, the interface is placed in the down state from an IP perspective, and not advertised within routing protocols, or used for forwarding packets.

It is important to note that the interface is allowed to change states freely at Layer 2; an interface that continues to change state rapidly continues to accumulate penalties, and continues to show down to the IP subsystem.

Exponential Backoff

Exponential backoff is implemented in several places in link state protocols at this point, including:

- The ability to exponentially back off the amount of time between a change in the network topology being detected and the transmission of a link state packet being transmitted to report the change; exponential backoff has been applied to the link state generation timer.
- The ability to exponentially back off the amount of time between receiving a link state packet reporting a change in the network topology, and running SPF to recalculate the path to each reachable destination in the network; exponential backoff has been applied to the SPF timer.

Fast Hellos

Each routing protocol has a different limit on how Fast Hellos can be transmitted and how often they must be received for a neighbor to be considered alive. OSPF and IS-IS have both implemented the fastest Hellos, with a minimum of 330 millisecond Hellos, and a dead interval of 1 second.

EIGRP can run with Hellos as fast as one per second, with a 3-second dead time. BGP can use similar timers, with a keepalive interval of 1 second.

Caution should be used when configuring Fast Hellos on a network. Congestion, high processor use, and other problems can cause false down indications that may cause higher rates of network failure than would normally occur.

Deploying GR and Fast Convergence Technologies

We now have a full range of options we can use to improve network availability, including GR and NSF, event dampening, and fast convergence techniques. How can we deploy these in a real network to improve network uptime? Generally, the technologies can be placed in one of three categories:

- *Fast reaction to node or link failure, to route around the failure.* We use Layer 2 techniques and Fast Hellos to quickly determine when an adjacent node, or a link to that node, has failed.
- *Slow reaction to node of link failure, combined with routing through the failure.* We rely on moderate speed reactions to node failures to allow resynchronization of routing data while forwarding of traffic continues.
- *Fast recalculation of the best path when a topology change has been reported.*

As we can see, the first two are complementary; we could not deploy both of them in the same place in the network. The third one, fast recalculation, can be deployed with either (or both) fast reaction and slow reaction techniques to increase network availability. The primary question then becomes: which of these two techniques do you deploy in your network, and where?

The basic premise behind making this design decision follows:

- If there is a fast, online backup available to a node or a link, it probably makes more sense to route around any problems that occur as rapidly as possible.
- If any existing backup is going to take a good deal of time to bring online, or there is no backup path (such as a single homed remote office, or a remote office with dial backup), it probably makes more sense to route through any problems.

In general, then, we want to deploy techniques that improve network convergence time everywhere—techniques that bring down the time a network is down when a failure occurs, is detected, and a new path calculated. At the same time, we want to evaluate each point in the network we would like to protect from failure, and determine the best means to protect that point of failure: redundancy with fast down detection, GR, or NSF.

Fast, stable networks are possible with today's techniques in routing; some large networks, with several hundred routers, measure their convergence times in the milliseconds, with 1 second as their outside convergence goal.

RUSS WHITE is on the Cisco Systems Routing DNA Team in Research Triangle Park, North Carolina, specializing in the deployment and architecture of routing protocols. He has coauthored books on routing protocols, network design, and router architecture, regularly speaks at the Cisco Networkers conference, and is active in the Internet Engineering Task Force. Russ can be reached at **riw@cisco.com**. This article offers a high-level overview of material covered in depth in a forthcoming network design book, *Designing to Scale,* being published through Cisco Press.

The Lures of Biometrics

by Edgar Danielyan, Danielyan Consulting LLP

This article introduces biometrics and discusses some of the complex issues associated with use of biometrics for identification and authentication of individuals and its impact on both standalone and networked information systems, as well as on physical security. The agenda is not to show whether biometrics is your best investment or a useless thing—these two polar viewpoints share the same quality of being oversimplifications, to say the least. It also certainly does not purport or try to tell everything there is to tell about biometrics or its applications. Legal and social implications of biometrics are also not discussed in this article because these would differ considerably, depending on the legislation and cultural traditions of countries concerned; we also do not consider the complex performance, design, and implementation questions, because these are of too specialized nature—for more in-depth coverage of these topics a list of biometrics organizations and publications are provided at the end of this article, along with a list of references.

Before we continue, it would be useful to examine the current deployment of biometrics outside testing laboratories and the corporate perimeter. With the U.S. government fingerprinting and taking photographs of some of the visitors coming to the United States beginning January 5, 2004, under the US-VISIT program, biometrics and associated issues such as privacy and personal data protection are bound to get unprecedented levels of publicity[1]. Although it is too early to judge whether this innovation will actually contribute to overall security of the country or rather increase the general confusion surrounding security procedures, it has already resulted in more questions asked than answered. To some of its proponents, biometrics is a magic technology that would contribute to the security of their societies, to others the same technology heralds the coming of a police state and erosion of personal privacy and liberties and discrimination against (potentially not only) foreign citizens. Indeed, that was the opinion of Julier Sebastiao da Silva, a federal judge in Mato Grosso state of Brazil, who ordered similar measures to be taken in the case of U.S. citizens visiting Brazil[2]. Despite the announcement of Brazil's federal police that they may well seek to have this judgment overturned, this is a significant event because it illustrates that the use of biometrics is not only a technical procedure but also has its far-reaching social, legal, and international implications. It is immaterial whether this judgment will be upheld or overruled—it is the fact that introduction of the mandatory use of biometrics at borders resulted in such a response that is important.

Earlier announcement by the U.S. authorities that they expect the visa-waiver countries whose citizens currently may enter the U.S. without visas, simply upon presentation of their passports, to provide biometric data in newly issued passports also resulted in different reactions, ranging from support for the measure to outright condemnation[3].

Aside from the huge technological and logistical work that must be done in order to introduce biometrics into passports, these requirements also pose considerable legal and social issues in countries with strong personal privacy and data protection legislation in place. However, one thing is clear—biometrics ceases to be an exotic and little-used technology and is bound to be increasingly used in one way or another.

This article is organized as follows. First biometrics and related concepts are introduced, along with descriptions of the most widely used and understood physiological and behavioral biometrics. We will also see how biometric systems fail when inadequately designed or implemented. Later we describe the system and design issues of biometrics, such as security, accuracy, speed, resilience, privacy, and cost of biometric identification and verification systems, as well as practical applications of biometrics in network authentication and international travel documents.

Definition of Biometrics

A *biometric* is a physiological or behavioral characteristic of a human being that can distinguish one person from another and that theoretically can be used for identification or verification of identity. For a biometric to be practically useful, ideally it should be unique, universal, permanent, recordable, and acceptable—more on these properties of practical biometrics later.

Authentication in General

Authentication is the second step in the identify-authenticate-authorize process, which is done countless times every day by humans and computers alike. When speaking about human authentication, basically we have three choices: using something we know (such as passwords and passphrases), something we have (such as access tokens, smart cards, and so on) or something we are (biometrics). There is no "best" authentication method; each has its pros and cons, depending on the application, the users, and the environment. Whatever authentication method we use, we can make it stronger by using one or both of the other methods. An example of strong authentication would be a system that requires possession of a smart card, knowledge of a password or *Personal Identification Number* (PIN), and biometric verification. Obviously to steal or fake all three would be much more difficult than to steal or fake any one of these—however, more expensive and laborious to operate as well. The other two factors—the time of access and the location of subject—may also be used for access control, but usually only as auxiliary factors.

What You Know

Unquestionably the most widely used method of authentication, passwords, passphrases, and PINs share both pros and cons with each other. Moreover, an advantage in one situation easily becomes a problem in another—an example being the ease of password sharing. Passwords are easy to change, but are also easy to intercept. Systems can force the use of strong passwords, but the user may respond by storing or transmitting them in such a way that the added security is effectively reduced to nil.

Unauthorized disclosure of a password is not usually detected until after unauthorized access has already taken place. Passwords are also vulnerable to guessing, dictionary, and brute-force attacks. On the other hand, they require no additional hardware, they are an accepted method of authentication, and they are well-understood—even by the most technologically challenged part of human species.

What You Have

Smart cards, access tokens (both challenge-response and time-based), and other "what you have" authentication methods solve some of the problems associated with "what you know" authentication, but they create a set of different problems. Unlike theft of a password, theft of a smart card or access token can, of course, be easily detected. Unlike passwords, smart cards usually cannot be used simultaneously by two or more parties in different places. However, "what you have" authentication devices may be lost, damaged, and stolen. They may also run out of power (if self-powered) or may be prone to power-, synchronization- and time-based attacks if externally powered. They may also be subjected to reverse engineering and other treatment, which may compromise their security.

What You Are: Biometric Authentication

There are two biometric authentication methods: biometric verification and biometric identification of identity. Biometric identification is also sometimes referred to as *pure biometrics* because it is based only on biometric data and is more difficult to design and operate—but alas, pure biometrics is not the most secure, useful, or efficient one. Also, both methods can not always be used with all biometrics—some biometrics can only be used in verification mode because of their intrinsic properties.

Verification

Biometric verification uses entity IDs and a biometric—in this case biometric merely serves to prove identity already declared by the entity—which may be done using something you know (a username) or something you have (a smart card). Biometric (something you are) works to actually complete the authentication process. Hence, the biometric database keeps a list of valid entity IDs (which may be said to serve as primary keys to the database) and corresponding biometric templates, and compares ("matches") the stored template with the biometric provided. The result of this comparison is either an accept or reject decision based on a complex algorithm and system settings (refer to the section "Matching").

Identification

Unlike biometric verification of identity, biometric *identification* is based solely on biometrics. The biometric serves as both the identifier and the authenticator. The biometric database contains the enrolled biometric templates, and they all are compared against the provided biometric to find a match. Biometric identification may be described as "putting all your eggs in one basket," partly because somehow faking or stealing a biometric compromises both the ID and the authenticator.

A biometric identification system may operate in one of the two modes: positive identification or negative identification. In a positive identification biometric system, the provided biometric must be in the database and there must be only one match to positively identify the person. The risks present in a biometric system are false acceptance and false rejection, whereas unauthorized subjects are incorrectly accepted, or authorized ones are denied identification, resulting in a denial of service. A negative identification system, in contrast, works by determining whether the provided biometric is not in the database.

Enrollment

Regardless of the type of a biometric system, *enrollment* is a mandatory part of the process. Biometric enrollment is the registration of subjects' biometrics in a biometric database. Positive enrollment results in a database of recognized persons' biometric templates that may be later used for positive identification or verification. Negative enrollment results in a database of "excluded" persons, a black list if you wish. Security and reliability of the enrollment process and the biometric database are fundamental to the security of the entire system, but in practice they are difficult to achieve because of the myriad of issues that affect collection, transmission, storage, and usage of biometric data (see "Security" and "Privacy," later in this article for an overview of just some of the risks).

Matching

After an individual is enrolled—that is, the individual's biometrics are scanned and registered in the biometric database—*matching* is the next step. Biometric matching is essentially the comparison of the enrolled person's known biometric data stored in the biometric database in the form of biometric templates—binary representation of biometric sample—with the biometric provided by the individual at the identification or verification time. However, biometric matching is a pattern-recognition problem and not a simple bit-by-bit comparison—representation of the same biometric taken by two input sensors or taken at two different points in time does not match bit by bit because of numerous factors such as sensor resolution, system noise, and so on. Therefore, a degree of likeness (usually referred to as the *matching score*) is used to express how like the stored biometric is to the provided biometric. A *threshold level* is used to decide whether the matching score is high enough to be considered a match—if the score is at or below the threshold level, matching fails. This threshold level is one of the many variables that affect the accuracy—and hence security—of biometric authentication systems.

For biometric identification applications, the provided biometric is compared against all entries in the database and should result in only one successful match to result in positive identification. In biometric verification systems, the provided biometric is compared only with the biometric template or templates corresponding to the specified identity. As a result of biometric matching, the following system errors may occur:

- *False match or acceptance:* This occurs when the system decides that the two biometrics (the one stored in the database and the one provided now) are the same, when in reality they are not. The rate of false matches is known as *False Matching Rate* (FMR) or *False Acceptance Rate* (FAR). False acceptance is a confidentiality and integrity risk.
- *False nonmatch or rejection:* This is expressed as *False Rejection Rate* (FRR), and *False Nonmatching Rate* (FNMR). False nonmatch is when the system erroneously decides that biometrics are from different identities while in reality they are from the same person. False rejection is an availability risk.

In practice, both FRR and FAR do not equal zero, and in different applications one of them may be more important than the other. In an application that requires higher security (and hence as low FAR as possible), users may be troubled with high false rejection rates; whereas in an application that can accept somewhat higher false acceptance rates (such as public transport), false rejection rate is of more concern because of convenience and manual processing concerns. When FAR and FRR meet, that is the *Cross-over Error Rate* (CER). The lower the CER, the better—hence it is frequently used to express accuracy of biometric systems (although it is not the infallible measure as some suppose). Additionally, *Failure to Acquire* (FTA) errors occur when an individual does not have the required biometric or the biometric cannot be read by the sensor; and *Failure to Enroll* (FTE) is when a part of the targeted population may not be enrolled for whatever reason (such as a FTA). These errors directly affect the practicality of biometrics and must be accounted for with regard to the projected population of users.

Practicality of Biometrics

Writing in the December 1994 issue of *Information Technology & People* ("Human identification in Information Systems: Management Challenges and Public Policy Issues")[4] ten years ago, Roger Clarke proposed some criteria that should be met in order for a biometric to be practically usable:

- *Universality:* Every relevant person should have an identifier.
- *Uniqueness:* Each relevant person should have only one identifier, and no two people should have the same identifier.
- *Permanence:* The identifier should not change, nor should it be changeable.

- *Indispensability:* The identifier should be one or more natural characteristics, which each person has and retains.
- *Collectibility:* The identifier should be collectible by anyone on any occasion.
- *Storability:* The identifier should be storable in manual and in automated systems.
- *Exclusivity:* No other form of identification should be necessary or used.
- *Precision:* Every identifier should be sufficiently different from every other identifier that mistakes are unlikely.
- *Simplicity:* Recording and transmission should be easy and not error-prone.
- *Cost:* Measuring and storing the identifier should not be unduly costly.
- *Convenience:* Measuring and storing the identifier should not be unduly inconvenient or time-consuming.
- *Acceptability:* Its use should conform to contemporary social standards.

Although some of these criteria may be argued over, this set is nevertheless a useful reference. An interesting point is that no known biometric completely satisfies all of these criteria, perhaps proving that these are not strict "must haves" but instead guidelines to be accounted for.

Types of Biometrics

Two broad categories of biometrics exist: *physiological* biometrics (such as fingerprints, hand geometry, iris recognition) and *behavioral* biometrics (such as signature and voice biometrics). Physiological biometrics is based on direct measurements and data derived from measurements of a part of the human body, whereas behavioral biometrics is based on measurements and data derived from human actions, and indirectly measures characteristics of the human body over a period of time.

Physiological Biometrics

Relatively widely understood and used physiological biometrics are fingerprint recognition, face recognition, hand geometry, and iris recognition. These methods are introduced in the following sections.

Fingerprint Recognition

It is believed that no two persons share the same fingerprints—not even identical twins—because the fingerprint patterns are part of a person's phenotype and do not apparently depend on genetics[5]. Fingerprints have been used to identify humans for a long time—there is some evidence that thousands of years ago ancient Chinese were aware of the uniqueness of fingerprints[6], not speaking about their current use in forensic science and law enforcement. The traditional fingerprint acquisition mechanism—finger into ink and then on to paper—obviously is not usable in many—if not most—noncriminal applications.

Currently there are four known inkless fingerprint acquisition mechanisms considered suitable for use in practical biometrics.

Optical Sensing

Optical fingerprint sensing works by acquiring light reflected from the finger surface through a special prism. The result is an image of the finger surface. The downside of this method is that wet, dirty, or dry finger skin may result in a bad image.[7]

Thermal Sensing

With the thermal sensing method, a thermogram of the finger surface is taken and the resulting image is used.[8]

Capacitance Sensing

Because of differing capacitance of the ridges and valleys of fingers, a *Complementary Metal-Oxide Semiconductor* (CMOS) capacitance sensor can obtain an image of the finger when it is touched. However, like optical sensing, cpacitance sensing may be negatively affected by dry, dirty, or wet skin. [9]

Ultrasound Sensing

Ultrasound sensing works by using an ultrasound beam to scan the skin surface. Ultrasound sensing is not affected much by dry, dirty, or wet skin but takes longer to perform and the ultrasound sensing equipment is usually not compact and consequently not widespread.[10]

In addition to the mentioned issues of wet, dry, or dirty skin, numerous other factors may also affect the quality or the very possibility of taking a fingerprint. For example, although the absolute majority of people have at least one finger, many people may also have damaged skin or skin illnesses that may degrade the quality of fingerprints or render them unusable. Fingerprint matching approaches may be broadly categorized into three classes: feature techniques, imaging techniques, and hybrids of the two. In feature-based fingerprint matching techniques, a symbolic representation of the fingerprint, defined by so-called *minutiae*, is created from the fingerprint image, and it is this representation that is later stored and used to match fingerprints—not the raw fingerprint image itself[11]. Imaging techniques use the fingerprint images directly—image correlation algorithms are then used to compare the fingerprints[12].

The Mighty Fingers

If the defending technology is expensive and complex, it does not mean the attacking technology will also be complex and expensive—this has been proven by many successful security attacks. Tsutomu Matsumoto of the Yokohama National University successfully fooled numerous fingerprint readers into accepting fake fingers made of gelatin with a 80-percent success rate, sending a shock wave among biometrics proponents[13].

In a paper ambiguously entitled "Impact of Artificial Gummy Fingers on Fingerprint Systems," co-authored with H. Matsumoto, K. Yamada, and S. Hoshino and presented at the Optical Security and Counterfeit Deterrence Techniques IV conferene (Proceedings of the *International Society for Optical Engineering,* 2002), Matsumoto describes relatively easy ways to create artificial clones of fingers using cheap and freely available materials such as gelatin, free molding plastic, and photosensitive printed circuit boards.

Not only was he able to create a copy of a live finger that was good enough to fool most fingerprint readers used in the experiment, he also created an artificial finger using a latent fingerprint left on a glass, which was also accepted as genuine. In addition, Matsumoto mentions several other attack vectors against fingerprint systems, including instances where the registered finger is presented by an armed criminal, under duress, or on a sleeping drug; a severed fingertip of the registered finger; or a genetic clone of the registered finger.

Even if we disregard the last possibility as too expensive and unlikely, the others are indeed very real and must be disturbing to current users of fingerprint-based identification or verification systems. After this research was published, Bruce Schneier wrote in the May 2002 issue of his monthly newsletter CRYPTO-GRAM[14]:

> "There's both a specific and a general moral to take away from this result. Matsumoto is not a professional fake-finger scientist; he's a mathematician. He didn't use expensive equipment or a specialized laboratory. He used $10 of ingredients you could buy, and whipped up his gummy fingers in the equivalent of a home kitchen. And he defeated eleven different commercial fingerprint readers, with both optical and capacitive sensors, and some with "live finger detection" features. (Moistening the gummy finger helps defeat sensors that measure moisture or electrical resistance; it takes some practice to get it right.) If he could do this, then any semi-professional can almost certainly do much much more. More generally, be very careful before believing claims from security companies. All the fingerprint companies have claimed for years that this kind of thing is impossible. When they read Matsumoto's results, they're going to claim that they don't really work, or that they don't apply to them, or that they've fixed the problem. Think twice before believing them. "

Face Recognition

One of the most powerful drivers behind the use of face recognition is the fact that we all use face recognition every day to recognize people—so it seems to be one of the most acceptable biometrics we have (unlike, for example, fingerprints, which are often associated with criminal prosecution), not speaking about photographs that have been used for identification for many years[15]. However, despite progress in this area of biometrics, face recognition is still not accurate and dependable enough, and factors such as aging, changing hairstyles, beards, and moustaches only make reliable face recognition more difficult. Bruce Schneier, in his recent book *Beyond Fear,* had the following to say about the usefulness of face recognition systems[16]:

> "I'll start by creating a wildly optimistic example of the system. Assume that some hypothetical face-scanning software is magically effective (much better than is possible today)—99.9% accurate. That is, if someone is a terrorist, there is a 1-in-1000 chance that the software fails to indicate "terrorist" and if someone is not a terrorist, there is a 1-in-1000 chance that the software falsely indicates "terrorist." In other words, the defensive-failure rate and the usage-failure rate are both 0.1%. Assume additionally that 1 in 10 million stadium attendees, on average, is a known terrorist (this system won't catch any unknown terrorists who are not in the photo database). Despite the high (99.9%) level of accuracy, because of the very small percentage of terrorists in the general population of stadium attendees, the hypothetical system will generate 10,000 false alarms for every one real terrorist. This would translate to 75 false alarms per Tampa Bay football game and one real terrorist every 133 or so games."

Of course these issues do not apply exclusively to face recognition systems, but we get the idea—a system that generates so many false alarms and catches so few terrorists is not going to be successful. This was proven on several occasions. First at the Palm Beach International Airport, where a face recognition system failed by providing less than 50-percent recognition rate and generating a large number of false positives, resulting in a decision by the airport not to use the system at all[17]. Almost the same happened in the second case, at a face recognition system trial at the Boston Logan International Airport[18].

Hand Geometry

Features measured and used by hand geometry biometrics typically include length and width of fingers, different aspect ratios of palm and fingers, thickness and width of the palm, and so on[19]. Existing hand geometry systems mostly use images of the hand. Like face recognition, hand geometry is a user-friendly technology that scores higher on the acceptability test than, for example, fingerprints. It is also relatively more easily measurable and recordable than some other biometrics. Several patents have been issued for hand geometry systems, but there is not as much research as on fingerprints[20]. However, because of its biometric properties, hand geometry is not suitable for use in the identification mode.

Iris Recognition

Iris recognition-based biometric systems are believed to be very reliable and accurate[21]. Like fingerprints, the iris image is a part of human phenotype and is believed to be unique in every individual. Perhaps one of the most known cases of deployment of the iris recognition system is the Privium at Amsterdam's Schiphol International Airport. Frequent travelers may enroll in the system to enjoy fast border crossing by simply looking at the iris scanner, which authenticates the person and opens the gate[22]. In February 2004, an iris recognition system will also be piloted at the Frankfurt International Airport, and if the six-months-long trial concludes successfully, the system may be installed and deployed in 18 European countries[33]. Obviously, iris recognition would not work for people who are missing both eyes or who have serious eye illnesses that affect the iris.

Behavioral Biometrics

Two of the most used behavioral biometrics are signature- and voice-based systems. Another behavioral biometric, keystrokes (where the timing between successive key pressings is used), seems to receive increasing attention and use.

Signature

In use for centuries, signatures enjoy a high degree of acceptance, largely because of their everyday use and familiarity, but as a behavioral biometric, signatures lack permanence: they may change at the will of a person, or under influence from such factors as illness, mental state, medicines, emotions, or age. For these and other reasons, signature-based biometric systems function in the verification and not in the identification mode.

Two subtypes of signature verification systems exist: static signature verification systems, where only the graphical representation (image) of the signature is used, and dynamic signatures, where the dynamics, pressure, and speed of the movement of a special pen are used for verification. Although the first method does not require any special hardware, the dynamic signature verification requires the use of special electronic signature readers or high-quality tablets. It is understood that dynamic signature verification is more secure and reliable than static signatures[23]. However, some people do not have consistent signatures, resulting in increased false rejection rates to unacceptable levels and severely affecting the practical use of signature-based biometric systems.

Voice

Voice recognition systems (not to be confused with speech recognition systems, which are concerned with the actual words said and not the identity of the speaker) depend on numerous characteristics of a human voice to identify the speaker. Voice recognition holds much potential because it is acceptable and it does not require expensive input devices, unlike some other biometrics. Like face recognition, voice recognition is something we humans do many times a day; additionally, voice recognition is ideal for many practical and widespread telephony applications, and in theory voice recognition systems may even function in the background without forcing the users to go through a separate identification and verification process, saving us from another password to remember. But as usual, voice recognition systems also have their fair share of potential problems. As we all know, some people with exceptional vocal abilities may skillfully imitate others' voices, potentially defying such systems. Another issue is the ease of sound recording and replay, so any voice recognition system must be designed to withstand "record and replay" attacks.

Voice recognition also is influenced by the usual suspects—illness, mental state, emotions, age—which may substantially modify an enrolled subject's voice to a degree that it does not match the stored templates anymore. Several voice recognition models varying in accuracy and complexity exist.

The *fixed-text* model involves a person saying a word or phrase previously recorded and enrolled in the biometric database. The verification process is the simple comparison, possibly accounting for some allowable differences. However, if this word or phrase can be recorded, the entire system fails, because it is fairly easy to reproduce words and phrases.

Another model is *text-dependent,* meaning the system instructs the person to speak words or phrases—naturally this system is less prone to replay attacks because supposedly the person does not know in advance what words or phrases the system will ask for. A hybrid system, also known as *conversational voice verification,* combines something you are—your voice—and something you know—such as a password—to provide a higher degree of verification accuracy and reliability, and this system may well be the best choice in practice[24], so multimodal biometrics may hold the key to more accurate and practical biometric authentication. Again, we should keep in mind that some people cannot use this biometric for one reason or another.

System and Design Issues

The following is a quick overview of only some of the most important biometric system design and implementation considerations:

Security

Biometrics is invariably associated with security, hence the biometric system itself should be reasonably secure and trustworthy. Not only should the system provide the required functionality, but we also should have a degree of security assurance. Keeping in mind our track record of creating secure complex systems (almost an oxymoron), we should not really have high expectations this time either. If we have learned a lesson, it is that systems fail and malfunction, so recovery and compensating mechanisms should be in place from the beginning, and even the most sophisticated system should be expected to fail sooner or later, one way or another. Some of the biometrics security issues are discussed in the following section.

Rogue Sensors and Unauthorized Acquisition (theft) of Biometric Samples

One of the risks associated with the use of biometrics for identification or verification is that a biometric cannot be changed by definition—your fingerprint is your fingerprint and there is no easy way to change it—so if it is stolen and used to create a fake finger to impersonate you, there is not much you can do about yours. Therefore, the issue of mutual authentication of the individual and the sensor is of much importance. In practice, however, as illustrated by numerous stories about rogue *Automated Teller Machines* (ATM) harvesting unsuspecting victims' card and PINs, this would prove to be a difficult task. Unlike, for example, smart cards, which may use cryptographic protocols to establish with whom they are communicating, we humans have no secure way to ascertain whether the biometric reader attached to a computer somewhere is indeed under control of (let's say) a genuine Internet banking application and will not relay or store our biometric template without authorization.

In contrast, bank customers asked to authenticate themselves at a bank counter may have a reasonable expectation that their biometric will be used by the same bank for lawful purposes only—because of their and the sensor's physical location (so called location-based authentication). Still, unauthorized acquisition and use of biometrics remains one of the issues to be considered in any practical implementation.

The fact that not all biometrics require placing your finger on a fingerprint reader (such as face recognition systems) and that some biometric samples may be obtained without any action on part of the subject is further food for thought because one's biometrics may be acquired without knowledge or authorization.

Communications Security Between Sensors, Matchers, & Biometric Database(s)

Although as important as the previous issue, communications security between sensors, matchers, and biometric databases is easier to provide than to solve the problems of mutual authentication of humans and biometric sensors. Well-designed and well-implemented secure cryptographic protocols may provide the required security for sensitive data exchange between parts of a biometric identification or verification system, and they are unlikely to be the weak link in the biometrics chain.

Accuracy

A biometric system must be reasonably accurate—otherwise why would we need it? The widely used FAR and FRR, and their product, CER, are not really exact measures but often estimates made using assumptions—and these assumptions may not be reasonable in all circumstances.

Speed

Although the question of how fast the system works may not be a pressing issue in, say, a nuclear reactor access control system, it will be a crucial factor at installations such as airports or border crossing points where a large number of people needs to be reliably and quickly identified and authenticated.

Scalability

Biometric verification systems are significantly and inherently more scalable than biometric identification systems particularly because only one-to-one matching is required. A distributed, combined system using smart cards that store the owner's biometric template and compare the provided biometric in card is an example of a scalable distributed biometric verification system. However, as the previously described face recognition system experiences at airports show, system properties such as FRR must be considered in context—one false rejection a month may be acceptable, but a hundred false rejections a day clearly would not. Another scalability issue is the nature of biometrics. A scalable biometric—such as the iris—can theoretically be deployed on a large scale (with thousands or millions of enrolled users), but a biometric with weak scalability could provide acceptable error rates and performance only in small installations. Therefore, scalability is directly linked with the particular type of biometric used, and this seems to be accounted for by the International Civil Aviation Organization (see the section "Biometrics and Passports").

Resilience

A biometric system should be able to handle exceptions. An exception in this context might be a person without the required biometric or a person whose biometric may not be usable for some reason. In many cases exception handling means resorting to a manual process, which of course brings all the issues of human intervention (speed and social engineering, to name only two) with it and may mean life or death for a particular system or application.

Cost

Because laws of economics apply to almost every human activity, a biometric system should be reasonable in cost. Of course reasonableness of cost is a very subjective concept and would vary greatly between different environments and different uses.

Privacy

As mentioned in the beginning of this article, biometrics is argued to be one of the threats to privacy and anonymity in the modern age. The *Electronic Frontier Foundation* (EFF) lists the following as being the most important privacy concerns:

- Biometric technology is inherently focused on individuals and interfaces easily to database technology, making privacy violations easier and more damaging.
- Biometric systems are useless without a well-considered threat model.
- Biometrics are no substitute for quality data about potential risks.
- Biometric identification is only as good as the initial ID.
- Biometric identification is often overkill for the task at hand.
- Some biometric technologies are discriminatory.
- Biometric systems accuracy is impossible to assess before deployment.
- The cost of failure is high.

Indeed it is very depressing to imagine a society—or even worse, a world order—where everyone is forced into a biometric database and total control over all your actions and whereabouts during your entire life is maintained—and where you can never "change your username" or "log out." One cannot help but remember Benjamin Franklin's immortal statement that those who are willing to trade liberty for security deserve neither. However depressing, this image hopefully will not materialize—and to achieve that, biometric systems should provide reasonable privacy and specific use guarantees to the enrolled subjects; in addition, they must have effective systems of checks and balances to audit and assure conformance with these guarantees.

Standards in Biometrics

As Andrew Tanenbaum once supposedly said, the good thing about standards is that there are so many to choose from—regardless of whether he did or not, this statement perhaps does not yet seem to apply to biometrics standards.

- The *Common Biometric Exchange File Format* (CBEFF) describes a set of data elements necessary to support biometric technologies in a unified way, and provides for the exchange of security, processing, and biometric data in a single file. The U.S. *National Institute for Standards and Technology* (NIST) describes CBEFF as facilitating interoperability between different systems or system components, forward compatibility for technology improvement, and software/hardware integration[26].
- *BioAPI and Human Authentication API.* BioAPI and HA-API efforts merged in 1999 under the umbrella of the BioAPI Consortium. The current version of the BioAPI Specification is Version 1.1, which aims to provide a "standardized *Application Programming Interface* (API) that will be compatible with a wide range of biometric applications and a broad spectrum of biometrics technologies"[27].
- The Open Group's *Human Recognition Services* (HRS) is a module of the *Common Data Security Architecture* (CDSA), which in particular is used in Apple's Mac OS X. HRS is compatible with the CBEFF and, thanks to the CDSA modular and layered approach, can use services provided by other CDSA modules[28].
- *Biometrics Management and Security for the Financial Services Industry* (ANSI X9.84-2000) specifies minimum security requirements for effective use of biometrics data in the U.S. financial services industry, including collection, distribution, and processing of biometrics data. In particular, it specifies the security of the physical hardware used throughout the biometric life cycle; the management of the biometric data across its life cycle; the use of biometric technology for verification or identification of bank clients and employees; and other aspects. The data objects specified in X9.84 are compatible with CBEFF[29].
- The *American Association of Motor Vehicle Administrations* (AAMVA) *Driver's License and Identification* (DL/ID) standard provides a uniform way to identify holders of driver license cards within the United States and Canada. This standard specifies identification information on drivers' license and ID card applications, provides for inclusion of fingerprint data, and is compatible with BioAPI and CBEFF[30].
- *ANSI/NIST Data Format for the Interchange of Fingerprint, Facial, Scar Mark, and Tattoo Information* (ANSI/NIST-ITL 1-2000). This standard defines the content, format, and measurement units for the exchange of the specified information that may be used for identification of persons, and it is mainly directed at U.S. law enforcement agencies and government.[31]

Additionally, one of the groups of the *International Organization for Standardization* (ISO) is working toward inclusion of biometrics specifications in the widely used ISO 7816 standard for smart cards (Part 11: personal verification through biometric methods)[32].

Practical Uses of Biometrics

Because there may be as many practical uses of biometrics as users, we address just two of them: the use of biometrics for network authentication and the use of biometrics in international travel documents.

Biometrics for Network Authentication

As we saw earlier in this article, the accepted and widely used *what you know* and *what you have* authentication methods are not always—nor are they necessarily—secure or convenient, and they have their share of weaknesses.

The additional challenge of using biometrics for network authentication is the fact that the subject and the object of access are separated by a (usually uncontrolled, untrusted, and possibly hostile) network, which does not add to the simplicity or security of the system as a whole. As illustrated by the case of gelatin fingers described earlier, the question of whether a live person provided the biometric to a remote biometric sensor is even more important in network authentication applications when there are no preventive or detective controls, such as a watching guard, in place.

Although we have relied mostly on passwords to serve as the only or the main authentication mechanism until today, it has been clear for a while that passwords do not provide strong authentication. Keeping this lesson in mind, a biometric network authentication system should not depend solely on biometrics but should use one of the other authentication methods (what you know or what you have) as well.

The remote biometric sensors required in any biometric network authentication system are one of the most vital parts of the entire system, yet they are most vulnerable ones as well. For our purposes, we define the remote part of a centralized network authentication system as including a human user who needs to be authenticated as being physically present at the site and time of authentication, a general-purpose computer running a general-purpose operating system, and a special-purpose biometric sensor device directly connected to the general-purpose computer. This setup, therefore, includes the following high-level potential points of attack:

1. User
2. Path from the user to the sensor
3. Biometric sensor
4. Path from sensor to the general-purpose computer
5. Network
6. The central database

Even if the central authentication database is left out of the picture, the most simple risk assessment would reveal, among others, the following issues:

1. The user should be accurately identified or the declared identity should be verified; the sensor should be able to differentiate between a live human being providing live biometric and a biometric replica, such as an iris photograph or a gelatin finger. This includes, inter alia, reasonable assurance of the physical presence of the whole individual and not just the particular biometric at a particular point in time (hence, in part, the need for multimodal authentication involving not only what you are but also what you know or what you have).
2. The sensor should be sufficiently tamper-proof to withstand a defined set of attacks by a defined class of attackers, which would of course differ from environment to environment.
3. The communication protocol used between the sensor and the general-purpose computer should be simple, well-defined, and verified.
4. The role of the (untrusted) general-purpose computer and its software in such a system should be kept to a minimum. The biometric data acquired by the sensor should be cryptographically protected (encrypted and signed with the device key, for instance) inside the same sensor, without any dependence on action or inaction of the general-purpose computer. Their only role in this play should be to relay the bits from the sensor to the central authentication server for verification. Confidentiality and integrity of the biometric data should not be affected by a malicious, general-purpose computer or its software; the worst that can happen is the nondelivery of such data to the central authentication database.

An example of this approach would be a tamper-resistant fingerprint reader able to accurately recognize live human fingers (and reject fake ones), extract the required information, append a time stamp from an internal independent time source, encrypt and sign the resulting minutiae + time stamp data block using some digital signature algorithm, and send the resulting information through, for example, a *Universal Serial Bus* (USB) connection to the general-purpose computer. The general-purpose computer may then use the provided token to seek authentication from the central authentication database, provided all other requirements have been met.

Today a variety of network authentication systems that use or can use biometrics are available from numerous vendors. Aside from the objectively subjective information provided by vendors of such systems, little evidence of assurance exists that could enable potential users to evaluate them for their particular environments. The fact that most of these systems run as applications on the most widespread and arguably the least secure of operating systems perhaps speaks for itself.

Biometrics and Passports

For many years now more than 110 nations have issued machine-readable travel documents (mainly passports and visas) that conform to the *International Civil Aviation Organization* (ICAO) standard 9303. ICAO, a United Nations specialized agency, in addition to being responsible for international civil aviation matters, is also mandated to develop and adopt international standards on customs and immigration documents and procedures under the Chicago Convention. These machine-readable travel documents include a two-line area printed in *Optical Character Recognition* (OCR) B format, which contains information usually required for international travel (such as a person's name, date of birth, citizenship, document validity dates, and other information). These documents have greatly reduced the time necessary to check passports and visas by border officials, and have contributed to smoother international travel. In May 2003, the ICAO adopted a set of documents on integration of biometrics into machine-readable passports, choosing three most suitable for these purposes[2.5]. The main biometric chosen was a digitized face image, followed by two optional biometrics: fingerprints and irises. The ICAO also selected high-capacity, contactless smart cards as the storage method for this biometric data and gave other recommendations related to integration and use of biometrics in passports and other documents. It remains to be seen if or how and when 188 member states of the ICAO will integrate biometrics into their passports.

New Biometrics

It would be unreasonable to assume that we are aware of all possible biometrics. It may very well be the case that new biometrics are discovered and possibly, in the fullness of time, considered fit for practical use. An example would be a behavioral biometric proposed by Ross Anderson of Cambridge University, author of the already classic *Security Engineering:*

> "Are there any completely new biometrics that might be useful in some circumstances? One I thought up while writing this chapter, in a conversation with William Clocksin and Alan Blackwell, was instrumenting a car so as to identify a driver by the way in which he or she operated the gears and the clutch."

Summary

Biometrics is a promising and exciting area, where different disciplines meet and provide an opportunity for a more secure and responsible world. However, the same biometrics, if misused or poorly engineered, may instead bring many hassles—if not troubles. Some biometrics are less usable than others, and different environments warrant different biometrics and design considerations. The best advice would be to differentiate between market-ready biometric technologies and technologies that are not yet (if ever) ready for deployment outside testing grounds. However much fervent proponents and keen vendors of biometric solutions market their wares, the guiding factor should be proven reliability and appropriateness of these solutions to specific uses, not marketing hype, which seems at times to dominate this arena.

Organizations and Publications

The following organizations and publications may be useful sources of further information on biometrics and biometric applications:

The International Biometric Society: **www.tibs.org**

Biometric Consortium: **www.biometrics.org**

BioAPI Consortium: **www.bioapi.org**

International Biometrics Industry Association: **www.ibia.org**

International Association for Identification: **www.theiai.org**

Journal of the International Biometric Society: **stat.tamu.edu/Biometrics**

Biometric Digest: **www.biodigest.com**

Biometric Technology Today: **www.biometrics-today.com**

Additionally, the following books may serve as good introductions to biometrics:

Guide to Biometrics, by Bolle, Connell, Pankanti, Ratha, Senior, ISBN 0-387-40089-3, Springer Verlag, 2003

Practical Biometrics, Julian Ashbourn, Springer Verlag, 2003

One of the best publicly available works on security engineering is *Security Engineering: A Guide to Building Dependable Distributed Systems,* by Ross Anderson (Wiley, 2001).

Book Reviews

The Unicode Standard

The Unicode Standard, Version 4.0, by The Unicode Consortium, ISBN: 0-321-18578-1, Addison Wesley Professional, 2003.

The Unicode 4.0 book is a thick, heavy one, but it is good. If you work with the Unicode character set, you should have this book on your bookshelf.

This book consists of four parts:

- Background and explanation of terms (103 pages)
- Implementation guidelines (29 pages)
- Technical specifications (60 pages)
- The Unicode Character Tables (1150 pages)

A review must describe each of these sections by itself, because they are important for different reasons. Unfortunately, however, the sections in the book are not clearly divided into sections as I outlined, so you don't necessarily know where to start. You don't need to read the characters section—just the sections you are interested in.

You should read the "Preface" (Section 0), because this section describes the rest of the book. It starts on page xxxi (before chapter 1).

You can then immediately go to the section you are interested in. Each section more or less stands by itself, and the book is easy to read. If something is not clear, you should look for text in another section that describes the subject. Reading from start to finish is possible, but I use this book as reference material, like an encyclopedia (except for the characters).

The background material is easy to read. It covers basic concepts such as differences between *characters* and *glyphs,* definition of terms such as *equivalence,* character encoding schemes and implication of things such as bidirectional text (mixed right-to-left and left-to-right text). Knowing how these things work is essential for anyone who either implements text engines of any kind or works on developing protocols or standards. This background material is easier understood read on paper and not electronically. It also is the part of the book I return to most often.

The second very good part concerns implementation guidelines. Even though it is (relatively) short, it is very important material. It discusses selection algorithms and other user interface guidelines, as well as other algorithms needed for, for example, comparison (what is called "Normalization"). I like this section as well, because it really describes the details you need to know when implementing anything Unicode related.

Unicode is a *large* character set. You see that in the more-than-1000 pages of "just characters." Of course, the tables themselves can be found on the Unicode Consortium Web site, but this book gives you a good overview. Part of this overview is a description of the *scripts* that Unicode covers, one at a time before the *codepoints* that come from those scripts. Still, this is the part that makes this book heavy, and a version without the codepoints would have been interesting by itself.

The book ends with more technical material, consisting mostly of references to, for example, *Unicode Technical Notes* and other standards documents that the Unicode Consortium produces, in addition to the Unicode Standard itself.

Useful reference

In summary, the first 130 pages (well, starting at page 40) in the book are very good. If you work at all with Unicode, you should read those pages. The rest of the book is good reference material.

Even though I have been working with Unicode for almost 10 years now, and for the last 8 years have weekly reviewed Unicode-related standards in the Internet Engineering Task Force, I see myself opening this book now and then. There is always something I need to check, and to be honest, I like encyclopedias on paper.

As reference material, this is a must-have item. If you want to read only the 140 interesting pages once, well, the book is possibly overkill.

iSCSI: The Universal Storage Connection

iSCSI: The Universal Storage Connection, by John L. Hufferd, ISBN 0-201-78149-X, Addison-Wesley, 2003.

I have to come clean straightaway and say that when I received this book to review I had never even heard of *Internet Small Computer System Interface* (iSCSI) and, to be honest, I have never heard it mentioned by anyone again since the day the book arrived. This is, of course, not a criticism of this book, just a comment on the current state of penetration of iSCSI into everyday computing discourse. In fact, if you search Google for "iscsi," you get only 465,000 hits—very few indeed these days, though this does have the decided advantage that the links you get are generally pretty useful. I'm sure that this will change because there are lots of big names behind the protocol, and certainly when vendors start really selling kit that uses it. *Storage Area Networks* (SANs) are important (though also not yet at the forefront of most computing people's minds)—and iSCSI will probably make them bigger.

However, to the book. And, really, if you want to know pretty well everything about iSCSI and don't want to read lots of Web sites, then this book is for you. It covers everything from the background behind the protocol, to how and where it might be applied, to all the low-level information that most of us hope that we never need to see. I'm not going to list it all and go into detail: the whole thing is here, from soup to nuts.

As to the presentation of the material, it is excellent—clear diagrams and useful tables. The layout is spacious without huge amounts of wasted white space on every page—making a change from many textbooks you see today.

The writing is clear too, though I did find myself becoming a bit bogged down in all the abbreviations (no, not acronyms—most of them are not words), which seem to pile up in the sentences. I got a bit tired of seeing iSCSI everywhere after a while too. I wasn't keen on the end-of-chapter summaries, finding them a bit redundant.

Good Reference

All in all, if you are in a position where you need to know about iSCSI and may have to be involved in working with it at a low level, this book is a good reference. I doubt that there is anything more comprehensive or better written at the present time.

—Lindsay Marshall, University of Newcastle upon Tyne
lindsay.marshall@newcastle.ac.uk

Read Any Good Books Lately?

Then why not share your thoughts with the readers of IPJ? We accept reviews of new titles, as well as some of the "networking classics." In some cases we may be able to get a publisher to send you a book for review if you don't have access to it. Contact us at **ipj@cisco.com** for more information.

Fragments

NRO Comments Concerning ICANN and WSIS

The *Number Resource Organization* (NRO) is the coalition of *Regional Internet Registries* (RIRs) which operate in the world today. The NRO is an organization representing the collective experience of individual RIRs and their communities. While the prime subject of its work are matters of joint interest relating to Internet numbering resources, the NRO provides an efficient interface to other parties interested in these issues. As the Internet continues to evolve, the NRO will ensure continuity of the operational infrastructure of Internet number resource allocation.

The RIRs are responsible for distribution of *Internet Number Resources* [IPv4 and IPv6 addresses and *Autonomous System Numbers*]. These number resources are the most fundamental of the identifiers on which the Internet relies: the Internet can operate without domain names; but it cannot operate without numbers. The RIRs have carried the responsibilities associated with managing these critical resources collectively for over 10 years, since well before the start of ICANN. This has been done very effectively through the entire "modern history" of today's Internet which includes both the "dot com boom" and the "dot com bust."

The RIRs have participated in the *World Summit on the Information Society* (WSIS) processes for over a year, including regional Prepcoms and the Summit itself. This is probably longer than any other Internet organization. The RIRs have attended as observers, and as subject matter experts with a genuine aim to assist in debates and discussions around issues related to Internet Number Resources in general and to IP addresses in particular.

The RIRs participated in the WSIS Phase I process as full supporters of ICANN as the model which represents not only the fundamental and critical aspects of Internet development to date, but also the means of community self-regulation to administer and manage Internet Number Resources. It must be understood that this is not given by the RIRs as mere components of ICANN, dependent upon it for support; but rather as independent components of the broader Internet administrative framework which ICANN itself is intended to support.

In the second round of WSIS, the NRO speaking for the collective RIRs will assert an active role vis-à-vis ICANN in order to aid that organization to address the genuine questions that it faces. The principle of these issues within the WSIS context is that of the independence and genuine internationalization of ICANN.

Therefore the NRO calls on ICANN to continue its work in this area, not by building a multinational organization, but rather by including and gaining the genuine support of its significant base of core stakeholders, namely those in the DNS, IP address, and protocol communities. Furthermore, the NRO calls on ICANN to work with the US Government to demonstrate a genuine and unambiguous plan for its independence and to commit to this plan before the conclusion of the second phase of the WSIS.

Finally, the NRO rejects any concept of an alternative Internet administrative model located within any governmental or intergovernmental structure. The NRO acknowledges that there is a valid role for governments in the administration of the Internet but this must be in the context of the current model. There is a need for the continual improvement of the current model of industry self-regulation to the extent that the ultimate solution may look little like today's ICANN.

The Internet Protocol Journal

June 2004 Volume 7, Number 2

A Quarterly Technical Publication for Internet and Intranet Professionals

In This Issue

You can download IPJ back issues and find subscription information at: **www.cisco.com/ipj**

From The Editor

The Internet Protocol Journal continues to be a forum for discussion of current and emerging technologies. In this issue, we first look at *content networking*. One can describe the Internet as a system of interconnected devices, but equally as a collection of information, called *content*, that resides on a distributed set of *servers* and is accessed by numerous *clients*. Our first article is by Christophe Deleuze.

Engineers are hard at work planning for an eventual transition to the next version of IP — IPv6. We've published several articles about IPv6 in previous editions. This time, François Donzé describes the automatic address configuration feature of IPv6. Of note is also the increasing global support for IPv6 deployment, (refer to "Fragments" on page 31).

Our final article returns to our recurring theme: adding security to existing Internet protocols. Because many malicious attacks on the Internet are perpetrated by "spoofing" information in one form or another, it makes sense to look at the *Domain Name System* (DNS), a critical component of the Internet infrastructure. Today, it is possible to create systems which provide fake answers to DNS queries. Miek Gieben explains what is being done to address this issue in his tutorial on DNSSEC, the secure version of the DNS protocols.

Please take a moment to renew or update your subscription to this journal. You can do so by visiting **www.cisco.com/ipj** and clicking on the "Subscription Information" link on the left. You will need to supply your subscription ID and e-mail address in order to gain access to your database record. If you have any questions, please send a note to **ipj@cisco.com**.

This is the 25th edition of IPJ. The journal now has more than 32,000 subscribers world-wide, and is available on paper and electronically on our Website in PDF and HTML format. The Website, located at **www.cisco.com/ipj**, contains all our back issues, and will soon offer a cumulative index in ASCII format that will make it easier to find particular articles. As always, we welcome your feedback.

Content Networks

by Christophe Deleuze

The Internet is constantly evolving, in both usage patterns and underlying technologies. In the last few years, there has been a growing interest in *content-networking* technologies. Various differing systems can be labelled under this name, but they all share the ability to access objects in a location-independent manner. Doing so implies a shift in the way communications take place on the Internet.

The Classic Internet Model

The Internet protocol stack comprises three layers, shown in Figure 1. The network layer is implemented by IP and various routing protocols. Its job is to bring datagrams hop by hop to their destination host, as identified by the destination IP address. IP is "best effort," meaning that no guarantee is made about the correct delivery of datagrams to the destination host.

The transport layer provides an end-to-end communication service to applications. Currently two services are available: a reliable ordered byte stream transport, implemented by the *Transmission Control Protocol* (TCP), and an unreliable message transport, implemented by the *User Datagram Protocol* (UDP).

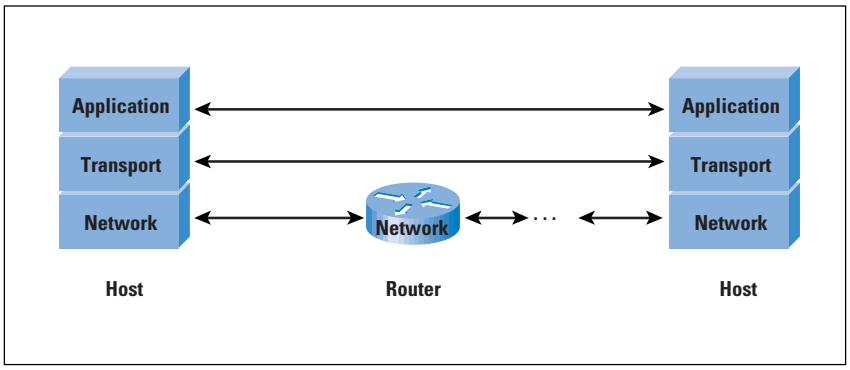

Figure 1: The Three Layers of the Internet Protocol Stack

Above the transport layer lies the application layer, which defines application message formats and communication semantics. The Web uses a client-server application protocol called *Hypertext Transfer Protocol* (HTTP)[10].

A design principle of the Internet architecture is the "end-to-end principle," which states that everything that can be done in the end hosts should be done there, and not in the network itself[8]. That is why IP service is so crude, and transport and application layer protocols are implemented only in the end hosts.

Application objects, such as Web pages, files, etc. (we will simply call those "objects") are identified by URLs. (Actually URLs identify "resources" that can be mapped to different objects called "variants." A variant is identified by a URL and a set of request header values, but in order to keep things simple, we will not consider this in the following.) URLs for Web objects have the form **`http://host:port/path`**. This means that the server application lives on a host with *hostname* (or possibly IP address) on port *N* (with default value of 80), and knows the object under the name *path*. Thus URLs, as their name implies, tell where the object can be found. To access such an object, a TCP connection is open to the server running on the specified host and port and the object named path is requested.

Content Networks

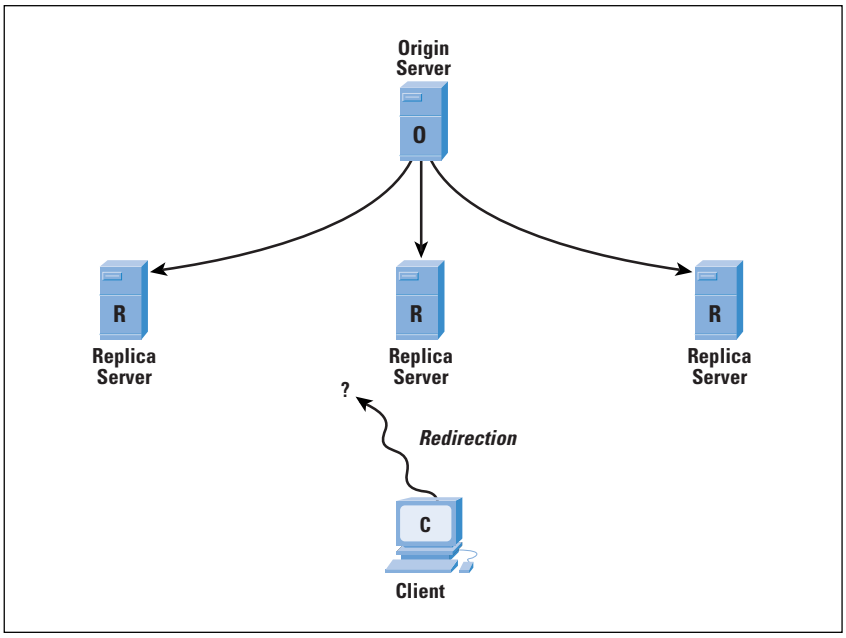
Content networks aim to provide location-independent access to an object, most commonly because they handle some kind of (possibly dynamic) replication of the objects. By design, URLs are not suited to identify objects available on several places on the network.

Handling such replication and location-independent access usually involves breaking the end-to-end principle at some point. Communication is no more managed end to end: intermediate network elements operating at the application layer (whose most common types are "proxies") are involved in the communication. (Content networks are not the only case where this principle is violated.)

In the same way that IP routers relay IP datagrams (that is, network layer protocol data units), routing them to their destination according to network layer information, those application layer nodes relay application messages, using application layer information (such as content URLs) to decide where to send them. This is often called *content routing*.

So the goal of a content network is to manage replication, handling two different tasks: *distribution* ensures the copying and synchronization of the instances of an object from an *origin server* to various *replica servers,* and *redirection* allows users to find on instance of the object (possibly the one closest to them.) (By "replica," we mean any server of any kind other than the origin that is able to serve an instance of the object. This term often has a narrower meaning, not applying, for example, to caching proxies.) This is illustrated in Figure 2.

Figure 2: Elements of a Content Network



Various kinds of content networks exist, differing in the extent to which they handle these tasks and in the mechanisms they use to do so. There are many possible ways to classify them. In this article, we use a classification based on who owns and administers the content network. We thus find three categories: content networks owned by network operators, content providers, and users.

Network Operators' Content Networks

Network operators (also called *Internet Service Providers*, or ISPs) often install caching proxies in order to save bandwidth[11]. Clients send their requests for objects to the proxy instead of the origin server. The proxy keeps copies of popular objects in its cache and can answer directly if it has the requested object in cache. (To be precise, such a caching proxy does not cache objects, but server responses.) If this is not the case, it gets the object from the origin server, possibly stores a copy in its cache, and sends it back to the client.

This caching proxy scheme can be used recursively, making those proxies contact parent proxies for requests they cannot fulfill from their local store. Such hierarchies of caching proxies actually lead to constructing content-distribution trees. This makes sense if the network topology is tree-like, although there are some drawbacks, including the fact that less popular objects (those not found in any cache) experience delays, which increase with the depth of the tree. Another problem is with origin servers whose closest tree node is not the root.

The Squid caching proxy[5] can be configured to choose the parent proxy to query for a request based on the domain name of the requested URL (or to get the object directly for the origin server). This allows setting up multiple logical trees on the set of proxies, a limited form of content routing.

Such manual configuration is cumbersome, especially because domain names do not necessarily (and actually most do not) match network topology. Thus the administrator must know where origin servers are in the network to use this feature effectively.

The same effects can be achieved, to some extent, in an automatic and dynamic fashion using ICP, the *Internet Cache Protocol* [16, 15]. ICP allows a mesh of caching proxies to cooperate by exchanging hints about the objects they have in cache, so that a proxy missing an object can find a close proxy that has it. One advanced feature of ICP allows you to select among a mesh of proxies the one that has the smallest *Round-Trip Time* (RTT) to the origin server.

One design flaw of ICP is that it identifies objects with URLs. We mentioned previously that a URL actually identifies a resource that can be mapped to several different objects called variants. Thus information provided by ICP is of little use for resources that have multiple variants. However, in practice most resources have only one variant, so this weakness does little harm.

Users normally configure their browsers to use a proxy, but automatic configuration is sometimes possible. Multiple proxies can be used by a client with protocols such as the *Cache Array Routing Protocol* (CARP)[14]. To avoid configuration issues, a common trend is for ISPs to deploy *interception proxies*. Network elements such as routers running the Cisco *Web Cache Communication Protocol* (WCCP)[6,7] redirect HTTP traffic to the proxy, without the users knowing. The proxy then answers client requests pretending to be the origin server. This poses numerous problems, as discussed in [12].

Caching proxies have limited support for ensuring object consistency. Either the origin server gives an expiration date or the proxy estimates the object lifetime based on the last modification time, using an heuristic known as *adaptive TTL* (time to live).

Content Providers' Content Networks

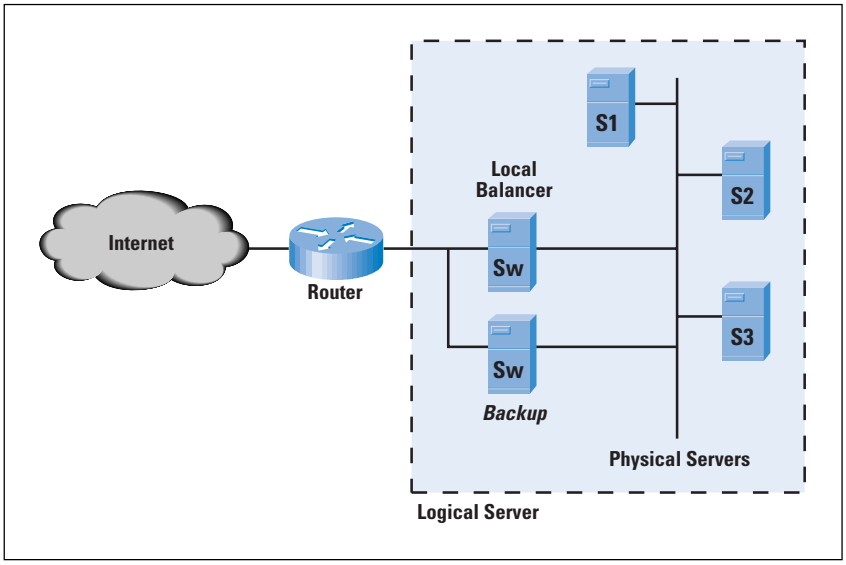
Contrary to ISPs whose main goal is to save bandwidth, content providers want to make their content widely available to users, while staying in control of the delivery (including ensuring that users are not delivered stale objects). We can again roughly classify such content networks in three subcategories:

- *Server farms:* Locally deployed content networks aimed at providing more delivery capacity and high availability of content
- *Mirror sites:* Distributed content networks making content available in different places, thus allowing users to get the content from a close mirror
- *Content-Delivery Networks* (CDNs): Mutualized content networks operated for the benefit of numerous content providers, allowing them to get their content replicated to a large number of servers around the world at lower cost.

Server Farms

Server farms are made of a load-balancing device (we will call it a *switch*) receiving client requests and dispatching them to a series of servers (the *physical* servers). The whole system appears to the outside world as a single *logical* server. The goal of a server farm is to provide scalable and highly available service. The switch monitors the physical servers and uses various load metrics in its dispatching algorithm. Because the switch is a single point of failure, a second switch is usually set up in a hot failover standby mode, as shown in Figure 3.

Figure 3: Server Farm



Some switches are called *Layer 4 switches* (4 is the number of the transport layer in the *OSI Reference Model*), meaning they look at network and transport layer information in the first packet of a connection to decide to which physical server the incoming connection should be handed. They establish a state associating the connection with the chosen physical server and use it to relay all packets of the connection. The exact way the packets are sent to the physical servers varies. It usually involves some form of manipulation of IP and TCP headers in the packets (like *Network Address Translation* [NAT] does) or IP encapsulation. These tricks are not necessary if all the physical servers live on the same LAN.

More complex *Layer 7 switches* (7 is the number of the application layer in the OSI Reference Model) look at application layer information, such as URL and HTTP request headers. They are sometimes called *content switches*. On a TCP connection, application data is available only after the connection has been opened. A proxy application on the switch must thus accept the connection from the client, receive the request, and then open another connection with the selected physical server and forward the request. When the response comes back, it must copy the bytes from the server connection to the client connection.

Such a splice of TCP connections consumes much more resources in the switch than the simple packet manipulation occurring in Layer 4 switches. Bytes arrive at one connection and are handed to the proxy application, which copies them to the other connection—all of this involving multiple kernel mode-to-user mode memory copy operations and CPU context switches. Various optimizations are implemented in commercial products. The simplest one is to put the splice in kernel mode. After it has sent the request to the physical server, the proxy application asks the kernel to splice the two connections, and forgets about them. Bytes are then copied between the connections directly by the kernel, instead of being given to the proxy application and back to the kernel.

It is even possible to actually merge the two TCP connections, that is, simply relay packets at the network layer to establish a direct TCP connection between the client and the physical server. This requires manipulating TCP sequence numbers (in addition to addresses and ports) when relaying packets, because the two connections will not have used the same initial sequence numbers. This can be much more complex (or even impossible) to perform if TCP options differ in the two connections.

Mirror Sites

In such a content network, a set of servers are installed in various places in the Internet, and they are defined as *mirrors* of the master server. Synchronization is most commonly performed periodically (often every night), using FTP or specialized tools such as *rsync*[4].

Redirection is performed by the users themselves for most sites. The master server, to which the user initially connects, displays a list of mirrors with geographic information and suggests that users choose a mirror close to themselves, by simply clicking on the associated link.

This process can be automated sometimes. One trick is to store the user's choice in a *cookie*, such that the next time the user connects to the master site, the information provided in the cookie will be used to issue an *HTTP redirect* (an HTTP server response asking the client to retry the request on a new URL) to the previously selected site.

Other schemes involve trying to find which of the mirrors is closest to the user based on information provided in the user request (such as preferred language) or indicated by network metrics. Such schemes were not very common for simple mirror sites, but today many commercial products allowing for this kind of "global load balancing" are available.

In any case (except if redirection is automatic and *Domain Name System* [DNS] based—this is discussed in the next section) the URLs of objects change across mirrors.

CDNs

Most content providers cannot afford to own numerous mirror sites. Having servers in different places around the world costs lots of money. Operators of CDNs own a large replication infrastructure (Akamai, the biggest one, claims to have 15,000 servers) and get paid by content providers to distribute their content. By mutualizing the infrastructure, CDNs are able to provide very large reach at affordable costs.

CDN servers do not store entire sites of all the content providers, but rather cache a subset according to local client demand. Such servers are called *surrogates*. They manage their disk store like proxies do, and serve content to clients like mirrors do (that is, contrary to proxies, they act as the authoritative source for the content they deliver).

Because the number of surrogates can be so large, and because of the argument that "no user configuration is necessary," CDNs typically include complex redirection systems that allow them to perform automatic and user-transparent redirection to the selected surrogate. The selection is based on information about surrogate loads and on network metrics collected by various ways such as routing protocol information, RTTs measured by network probes, etc. The client is made to connect to the selected surrogate either by sending it an HTTP redirect message, or by using the DNS system: when the client tries to resolve the host name of the URL in an IP address to connect to, it is given back the address of the selected surrogate instead. Using the DNS ensures that the URL is the same for all object copies. In this case, CDNs actually turn URLs into location-independent identifiers.

In addition to proxy-like on-demand distribution, content can also be "pushed" in surrogates in a proactive way. Synchronization can be performed by sending invalidation messages (or updated objects) to surrogates.

CDN principles are also being used in private intranets for building *Enterprise CDNs* (ECDNs).

Users' Content Networks

User-operated content networks are better known as *Peer-to-Peer* (P2P) networks. In these networks, the costly replication infrastructure of other content networks is replaced by the users, who make some of their storage and processing capacities available to the P2P network. Thus, no big money is needed, and no one has control over the content network.

One advantage P2P networks have over other content networks is that they are usually built as overlay networks and do not strive for transparent integration with the current Web. Thus they are free to build new distribution (some of them allow downloading files from multiple servers in parallel) and redirection mechanisms from scratch, and even to use their own namespace instead of being stuck with HTTP and URLs.

P2P networks basically handle the distribution part of replication in a straightforward way: the more popular an object is, the more users will have a copy of it, thus the more copies of the object will be available on the network. More complex mechanisms can be involved, but this is the basic idea.

The redirection part of replication is more problematic with most current P2P networks. It can be handled by a central directory as in *Napster:* every user first connects to a central server, updates the directory for locally available objects, and then looks up the directory for locations of objects the user wants to access. Of course, such a central directory poses a major scalability and robustness problem.

Gnutella and *Freenet,* for example, use a distributed searching strategy instead of a centralized directory. A node queries neighbors that themselves query neighbors, and so on until either one node with the requested object is found or a limit on the resources consumed by the search has been hit. Although there is no single point of failure, such a scheme is no more scalable that the central directory. It seems easy to perform denial-of-service attacks by flooding the network with requests. Additionally, you can never be sure you have found the object even if someone has it.

These examples are primitive and have serious flaws, but much research work is being performed on this topic; refer to [13] for a summary.

Although they are currently used mainly for very specific file-sharing applications, P2P networks do provide new and valuable concepts and techniques. For example, *Edge Delivery Network* is a commercially available software-based ECDN inspired by Freenet. Various projects use a *scatter/gather* distribution scheme, useful for very large files: users download several file chunks in parallel from other currently downloading users, thus refraining from using server resources for long periods of time.

Some projects attempt to integrate P2P principles in the current Web architecture and protocols. Examples are [3] and [1].

Conclusion

Current networks have been designed and deployed as ad-hoc solutions of specific problems occurring in the current architecture of the network. Caching proxies lack proper means to ensure consistency, but CDNs tricks the DNS to turn URLs into location-independent identifiers. P2P networks are mostly limited to file-sharing applications.

Content networks implement mechanisms to ensure distribution of content to various locations, and redirection of users to a close copy. They often have to break the end-to-end principle in order to do so, mainly because current protocols assume each object is available in only one statically defined location.

Probably the first step in building efficient distribution and redirection mechanisms for providing an effective replication architecture is the setting up of a proper replication-aware namespace. Applications would pass an object name to a name resolution service and be given back one or more locations for this object. The need for such a location-independent namespace was anticipated a long time ago. URLs are actually defined as one kind of *Uniform Resource Identifier* (URI), another one being *Uniform Resource Names* (URNs) intended to provide such namespaces. A URN IETF working group [2] has been active for a long time, and recently published a set of RFCs (3401 to 3406).

Work on the topic of content networking has also been performed by the now closed *Web Replication and Caching* (WREC) IETF working group, which issued a taxonomy in [9]. An interesting survey of current work on advanced content networks is [13].

IPv6 Address Autoconfiguration

by François Donzé, HP

Since 1993 the *Dynamic Host Configuration Protocol* (DHCP)[1] has allowed systems to obtain an IPv4 address as well as other information such as the default router or *Domain Name System* (DNS) server. A similar protocol called DHCPv6[2] has been published for IPv6, the next version of the IP protocol. However, IPv6 also has a stateless autoconfiguration protocol[3], which has no equivalent in IPv4.

DHCP and DHCPv6 are known as *stateful* protocols because they maintain tables within dedicated servers. However, the stateless autoconfiguration protocol does not need any server or relay because there is no state to maintain.

This article explains the IPv6 stateless autoconfiguration mechanism and depicts its different phases.

Scope of IPv6 Addresses

Every IPv6 system (other than routers) is able to build its own unicast global address. A *unicast* address refers to a unique interface. A packet sent to such an address is treated by the corresponding interface—and *only* by this interface. This type of address is directly opposed to the multicast address type that designates a group of interfaces. Most of this article deals with unicast addresses. For simplicity, we will omit the unicast qualifier when there is no ambiguity.

Address types have well-defined destination scopes: *global*, *site-local* and *link-local*. Packets with a link-local destination must stay on the link where they have been generated. Routers that could forward them to other links are not allowed to do so because there has been no verification of uniqueness outside the context of the origin link.

Similarly, border-site routers cannot forward packets containing site-local addresses to other sites or other organizations. The IETF is currently working on a way to remove or replace site-local addresses. Hence, this article will refrain from any other reference to this address type. Finally, a global address has an unlimited scope on the worldwide Internet. In other words, packets with global source and destination addresses are routed to their target destination by the routers on the Internet. A fundamental feature of IPv6 is that all *Network Interface Cards* (NICs) can be associated with several addresses.

At minimum, a NIC is associated with a single link-local address. But in the most common case a NIC is assigned a link-local and at least one global address. The following command displays the configuration of network interface **`eth1`** on a Red Hat system. This interface is associated with two IPv6 addresses. One of them starts with **`fe80::`** and the other with **`3ffe:`**. The scope of the first one is the link and the second has a global scope.

```
root# ip address list eth1
3: eth0: <BROADCAST,MULTICAST,UP mtu 1500 qdisc pfifo_fast qlen 100
link/ether 00:0c:29:c2:52:ff brd ff:ff:ff:ff:ff:ff
inet6 fe80::20c:29ff:fec2:52ff/10 scope link
inet6 3ffe:1200:4260:f:20c:29ff:fec2:52ff/64 scope global
```

Creation of the Link-Local Address

An IPv6 address is 128 bits long. It has two parts: a *subnet prefix* representing the network to which the interface is connected and a *local identifier*, sometime called token. In the simple case of an Ethernet medium, this identifier is usually derived from the EUI-48 *Media Access Control* (MAC) address using an algorithm described later in this article. The subnet prefix is a fixed 64-bit length for all current definitions. Because IPv4 manual configuration is a well-known pain, one could hardly imagine manipulating IPv6 addresses that are four times longer. Moreover, a DHCP server is not always necessary or desired; in the case of a remote control finding the DVD player, a DHCP environment is not always suitable.

Because the prefix length is fixed and well-known, during the initialization phase of IPv6 NICs, the system builds automatically a link-local address. After a uniqueness verification, this system can communicate with other IPv6 hosts on that link without any other manual operation.

For a system connected to an Ethernet link, the build and the validation of the link-local address is the following:

1. An identifier is generated, supposedly unique on the link.
2. A tentative address is built.
3. The uniqueness of this address on the link is verified.
4. If unique, the address from phase 2 is assigned to the interface. If not unique, a manual operation is necessary.

Although a local policy can decide to use a specific token, the most common method to obtain a unique identifier on an Ethernet link is by using the EUI-48 MAC address and applying the modified IEEE EUI-64 standard algorithm. A MAC address (IEEE 802) is 48 bits long. The space for the local identifier in an IPv6 address is 64 bits. The EUI-64 standard explains how to stretch IEEE 802 addresses from 48 to 64 bits, by inserting the 16 bits **`0xFFFE`** at the 24th bit of the IEEE 802.

By doing so, transforming MAC address **`00-0C-29-C2-52-FF`** using the EUI-64 standards leads to **`00-0C-29-FF-FE-C2-52-FF`**. Using IPv6 notation, we get **`000C:29FF:FEC2:52FF`**. Recall that the notation of IPv6 addresses requires 16-bit pieces to be separated by the character "**`:`**". Then, it is necessary (RFC 3513) to invert the universal bit ("u" bit) in the 6th position of the first octet. Thus the result is: **`020c:29ff:fec2:52ff`**.

Universal uniqueness of IEEE 802 and EUI-64 is given by a "u" bit set to 0. This global uniqueness is assured by IEEE, which delivers those addresses for the entire planet. Inverting the "u" bit allows ignoring it for short values in the manual configuration case, as explained in paragraph 2.5.1 of RFC 3513[4].

The second phase of creating automatically a link-local address is to prepend the well-known prefix **`fe80::/64`** to the identifier resulting from phase one. In our case we obtain **`fe80::20c:29ff:fec2:52ff`**. This address is associated with the interface and tagged "tentative." Before final association, it is necessary to verify its uniqueness on the link. The probability of having a duplicate address on the same link is not null, because it is recognized that some vendors have shipped batches of cards with the same MAC addresses.

This is the goal of the third phase, called *Duplicate Address Detection* (DAD). The system sends ICMPv6 packets on the link where this detection has to occur. Those packets contain *Neighbor Solicitation* messages. Their source address is the undefined address "**`::`**" and the target address is the tentative address. A node already using this tentative address replies with a *Neighbor Advertisement* message. In that case, the address cannot be assigned to the interface. If there is no response, it is assumed that the address is unique and can be assigned to the interface.

We are reaching the last step of the automatic generation of a link-local address. This phase removes the "tentative" tag and formally assigns the address to the network interface. The system can now communicate with its neighbors on the link.

Global Prefixes

In order to exchange information with arbitrary systems on the global Internet, it is necessary to obtain a global prefix. Usually (but not necessarily), the identifier built during the first step of the automatic link-local autoconfiguration process is appended to this global prefix.

However, before assigning this global address, the system verifies again that no duplicate address exists on the link. DAD is performed for all addresses before they are assigned to an interface, because uniqueness in one prefix does not automatically assure uniqueness in any other available prefixes.

Generally, global prefixes are distributed to the companies or to end users by *Internet Service Providers* (ISPs).

Random Identifiers

The EUI-48-to-EUI-64 transform process is attractive because it is simple to implement. However, it generates a privacy problem. Global unicast as well as link-local addresses may be built with an identifier derived from the MAC address. A Website tracking where a node frequently attaches can collect private information such as the time spent by employees in the enterprise or at home.

Because a MAC address follows the interface it is attached to, the identifier of an IPv6 address does not change with the physical location of the Internet connection. Hence it is possible to trace the movements of a portable laptop or *Personal Digital Assistant* (PDA) or other mobile IPv6 device.

RFC 3041[5] allows the generation of a *random* identifier with a limited lifetime. Because IPv6 architecture permits multiple suffixes per interface, a single network interface is assigned two global addresses, one derived from the MAC address and one from a random identifier. A typical policy for use of these two addresses would be to keep the MAC-derived global address for inbound connections and the random address for outbound connections. A reason for not using it for inbound connections is the need to update the DNS just as frequently as it is changes.

Such a system, with two different global addresses—one of which changes regularly—becomes very difficult to trace.

By default, Microsoft enables this feature on Windows XP and Windows Server 2003. The random-identifier-based global addresses of Microsoft systems have the address type "temporary." EUI-64 global addresses have type "public." Those types as well as other information can be displayed in a **`cmd.exe`** DOS-box with the command line:

```
netsh interface ipv6 show address
```

IPv6 Routers

By definition, a router is a node that forwards IP packets not explicitly addressed to it. IPv6 routers are certainly compliant with this definition but, in addition, they regularly advertise information on the links to which they are connected—provided they are configured to do so. These advertisements are *Internet Control Message Protocol Version 6* (ICMPv6) *Router Advertisement* (RA) messages, sent to the multicast group **`ff02::1`**. All the systems on a link must belong to this group, and nodes configured for autoconfiguration, among other things, analyze the option(s) of those messages. They might contain any routing prefix(es) for this segment.

Router Solicitation

Upon reception of one of those RA messages and according to local algorithm policy, an autoconfiguring node not already configured with the corresponding global address will prepend the advertised prefix to the unique identifier built previously.

However, the advertisement frequency, which is usually about ten seconds or more, may seem too long for the end user. In order to reduce this potential wait time, nodes can send *Router Solicitation* (RS) messages to all the routers on the link. Nodes that have not configured an address yet use the unspecified address "**`::`**". In response, the routers must answer immediately with a RA message containing a global prefix. This router solicitation corresponds to ICMPv6 messages of type RS, sent to the all-router multicast group: **`ff02::2`**. All routers on the link must join this group.

Thus, a node soliciting on-link routers in such a way is able to extract a prefix and build its global address. Note that this method using an advertised prefix is possible only for end nodes. Today IPv6 routers are usually manually configured. The reason is obvious: a stateless automatic configuration requires the advertisement of a prefix. This prefix is sent by a router. The router sending the prefix must be fully configured to do so. The easiest way to break this seemingly unsolvable problem is to manually configure IPv6 routers. However, some automatic methods are being developed[6].

Conclusion

Stateless address autoconfiguration is a new concept with IPv6. It gives an intermediate alternative between a purely manual configuration and stateful autoconfiguration. In addition to ease of use with no dedicated server or relay, this mechanism removes problems that have not been discussed here, such as the mismatch between the DCHP server and the router (prefix topology) or the IPv4 need to readdress subnets that have outgrown their prefix. Moreover, automatic renumbering (prefix change) is also possible on nodes using stateless autoconfiguration.

DNSSEC: The Protocol, Deployment, and a Bit of Development

by Miek Gieben, NLnet Labs

> "One Key to rule them all,
> one Key to find them,
> one Key to bring them all
> and in the Resolver bind them."
> —Modified from *Lord of the Rings*.

The *Domain Name System* (DNS) (RFCs 1034 and 1035) is a highly successful and critical part of the Internet infrastructure. Without it the Internet would not function. It is a globally distributed database, whose performance critically depends on the use of caching.

Unfortunately the current DNS is vulnerable to so-called *spoofing attacks* whereby an attacker can fool a cache into accepting false DNS data. Also various man-in-the-middle attacks are possible. The *Domain Name System Security Extension* (DNSSEC) is not designed to end these attacks, but to make them detectable by the end user. Or more technically correct: detectable by the security-aware *resolver* doing the work for the end user. This saves users from doing online banking on the wrong server even if a secured connection is used and the address in the browser looks correct.

DNSSEC is about protecting the end user from DNS protocol attacks. In order to make it work, zone owners (such as **`.com`**, **`.net`**, **`.nl`**, etc.) need to deploy DNSSEC in their zones. End users then need to update their resolvers to become security-aware (that is, understand DNSSEC) and add some trusted keys. These keys are called *anchored keys;* they are configured in the resolver and cannot be changed or updated very easily. If this is all configured, the end user will (finally) be able to detect attacks.

DNSSEC, as defined in (hopefully soon-to-be-obsoleted) RFC 2535, adds data origin authentication and data integrity protection to the DNS. The *Public Key Infrastructure* (PKI) in DNSSEC may be used as a means of public key distribution, which may be used by other protocols. *IP Security* (IPSec) and the *Secure Shell* (SSH) protocol, for example, are already considering the use of DNSSEC to carry their keying material.

In the course of early-deployment experiments carried out by various organizations, it became evident that RFC 2535 introduced an administrative key-handling and maintenance nightmare. This in turn would mean the DNSSEC deployment would never start (or be successful, for that matter).

The IETF DNSEXT working group decided to fix this problem, and to incorporate all drafts and RFCs written since RFC 2535 into a new DNSSEC specification.

This (still ongoing) effort became known as the *RFC 2535bis* DNSSEC specification. This work has resulted in three drafts, each handling a specific part of the new specification. These drafts follow:

1. dnssec-intro[1] provides an introduction into DNSSEC.
2. dnssec-records[2] introduces the new records for use in DNSSEC.
3. dnssec-protocol[3] is the main document, which details all the protocol changes.

The documents are now almost ready (July 2004) to be submitted to the *Internet Engineering Steering Group* (IESG) for review. It is hoped that soon after this is done the drafts will become RFCs. It could be that 2004 will be the year of DNSSEC.

In this article I use the terms *domain* and *zone*. These are important concepts in the DNS and in DNSSEC. The difference between a zone and a domain is worth highlighting. A domain is a part of the DNS tree. A zone contains the domain names and data that that domain contains *except* for the domain names and data that are delegated elsewhere. Also refer to [4].

Consider, for instance, the **`.com`** *domain,* which includes everything that ends in **`.com`**. **`CNN.com`** is in the **`.com`** domain. The **`.com`** *zone,* however, is the entity handled by VeriSign.

One other important concept in DNS is the *Resource Record* (RR) and the *Resource Record Set* (RRset). An RR in DNS is, for instance:

```
www.example.org.  IN   A    127.0.0.1
```

... where **`www.example.org`** is the "ownername" or "name." **`IN`** is the class (IN stands for Internet). **`A 127.0.0.1`** is the type (together with its rdata). **`A`** stands for "address." This 3-tuple (name, class, type) together make up the resource record. RRset are all the RRs that have an identical name, class and type. Only the rdata is different. Thus:

```
www.example.org.  IN   A    127.0.0.1
www.example.org.  IN   A    192.168.0.1
```

... together form a RRset, but:

```
www.example.org.  IN   A    127.0.0.1
www.example.org.  IN   MX   mail.example.org.
```

... do not (their type is different). In the DNS an RRset is considered *atomic* and the smallest data item. In DNSSEC each RRset gets a signature.

What Is DNSSEC?

DNSSEC adds data origin authentication and data integrity to the DNS. To achieve this, DNSSEC uses public key cryptography; (almost) everything in DNSSEC is digitally signed.

Public key cryptography uses a single key split in two parts: a private and a public component. The *private* component, also known as the *private key,* must be kept secret. The *public* component (the *public key*) can be made public. Both these keys can be used for cryptographic operations, albeit with different goals.

If a message is scrambled with the public key, it can be decrypted only with the private key. This is called *encryption* of the message and it ensures that only the holder of the private key can read the original message. When the private key is used to scramble a message, everybody can use the available public key to decipher the message. This last operation is called (digitally) *signing* a message (for increased speed usually a hash of the message is signed). In this case you know where the message comes from (*authenticated data origin* in cryptographic jargon). An added benefit of signing messages is that when the data is mangled during transport the signature is no longer valid. This last property is called *authenticated data integrity*. A more lengthy introduction on public key cryptography can be found at [10]. In DNSSEC only digital signatures (signing) are used, and nothing is ever encrypted.

For every secure zone there must be a public key in the DNS for use by DNSSEC. Each zone administrator generates a key to be used for securing a zone. The private key is (of course) kept private and is used in the "signing process" to create the signatures. The public key is published in DNSSEC as a DNSKEY record, which is the zone key. The generated signatures are published as RRSIG records.

If RRsets in DNSSEC do not have a valid signature, they are labeled bogus by the resolver. Bogus data should not be trusted, because probably somebody is trying to conduct a spoof attack. DNSSEC further distinguishes between:

- Verifiable secure—The data has signatures that are valid.
- Verifiable unsecure*—The data has no signatures.
- Old-style DNS—A non-DNSSEC lookup is done.

* Yes, Unsecure. This word has somehow evolved from "insecure."

Verifiable secure data is data that has valid signatures, and the key used to create those signatures is trusted (anchored in the resolver). Verifiable unsecure data is data for which we know for sure we do not need to do signature validation. Old-style DNS is the current (insecure) method of getting DNS data.

The signing of data in DNSSEC is comparable to the *Gnu Privacy Guard* (GPG) signing of e-mail. If I trust a public key from someone, I can use that key to verify the GPG signature and authenticate the origin of the e-mail.

The problem with both DNSSEC and GPG lies in the "...If I trust the public key from someone." GPG solves this with public key servers, key signing parties at various events and thus the creation of a web of trust. For DNSSEC such solutions are impractical. DNSSEC uses a different, but very elegant mechanism called the *chain of trust*.

The chain of trust makes it possible to start with a root zone key, the highest possible key in the DNS tree, and following cryptographic pointers to lower zones. Each pointer is validated with the previous validated zone key. (The root key is the key used in the root zone of the Internet; it is the key used in the **.** (dot) zone. It could take a while before the root is signed.)

By using this mechanism only the root key is needed to validate *all* DNSSEC keys on the Internet. With these DNSSEC keys the DNS data in each zone can then be validated. So, unlike GPG, we need to distribute only one key. This can be done by publishing it on the World Wide Web or in a newspaper or putting an ad on TV, etc.

One of the current items in the DNSSEC community is to outline procedures and guidelines on how to update this root and other keys.

Chain of Trust

To start securely resolving in DNSSEC, a root key must be anchored in the resolver at your local computer or nameserver. Only when a resolver knows and trusts a zone key can it validate the signatures belonging to that zone. Because of the chain of trust, a resolver has to carry only a few zone keys to be able to validate DNSSEC data on the Internet.

The chain of trust works by following "secured pointers," which are called *secured delegation* in DNSSEC. A special, new record called the *Delegation Signer* (DS) record delegates trust from a parental key to a child's zone key.

The DS record holds a hash (*Secure Hash Algorithm 1* [SHA-1]) of a child's zone key. This DS record is signed with the zone key from the parent. By checking the signature of the DS record, a resolver can validate the hash of the child's zone key. If this is successful, the resolver can compare this (validated) hash with the (yet-to-be-validated) hash of the child's zone key. If these two hashes match, the child's real zone key can be used for validation of data in the child's zone. Note: by successfully following a secured delegation, the amount of trust a resolver has in the parental key is transferred to a child's key. This is the crux of the chain of trust.

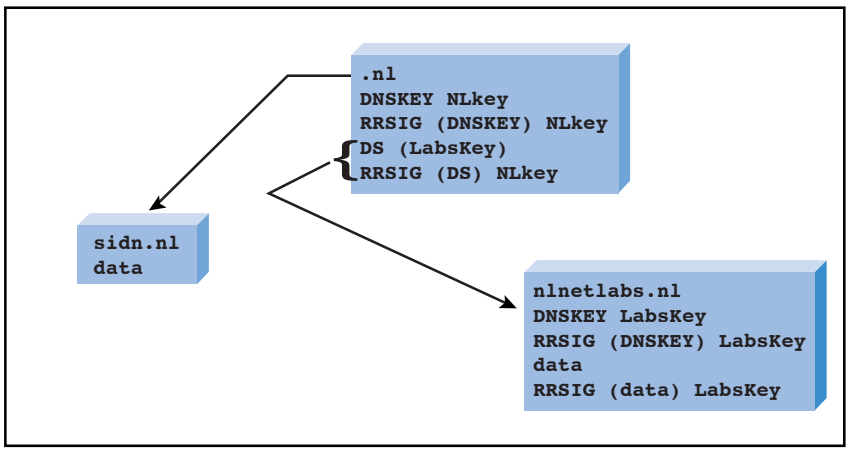

Figure 1: **nlnetlabs.nl** *is a secured delegation under* **.nl**. *RTSIG(x)y denotes that a signature over a data x is created with key y.*

In Figure 1 the following takes place.

The **.nl** zone contains the following:

```
nl.   IN    SOA (soa-parameters)
; the zone key
nl.   IN    DNSKEY NLkey
nl.   IN    RRSIG(DNSKEY)NLkey
nl.   IN    RRSIG(SOA)NLkey

nl.   IN    NS ns5.domain-registry.nl.
; this NS is authoratitive
nl.   IN    RRSIG(NS) NLkey

nlnetlabs.nl.   IN   NS open.nlnetlabs.nl.
; no RRSIG here (nonauthoritative data is not signed)

; DS record with a hash of the child's zone key
nlnetlabs.nl.   DS  hash(LabsKey)
; The signature of the parent
nlnetlabs.nl.   RRSIG(DS)NLkey
```

Note: It is important to see that we now have linked a parental signature to something that is *almost* the key of the child.

And the **nlnetlabs.nl** zone has the following:

```
nlnetlabs.nl.    IN    SOA (soa-parameters)
; The zone key
nlnetlabs.nl.    IN    DNSKEY LabsKey
nlnetlabs.nl.    IN    RRSIG(SOA)Labskey
; The (self) signature of the zone key
nlnetlabs.nl.    IN    RRSIG(DNSKEY)Labskey
nlnetlabs.nl.    IN    NS open.nlnetlabs.nl.
nlnetlabs.nl.    IN    RRSIG(NS)LabsKey
```

So the chain of trust looks like the following:

```
.nl DNSKEY –> nlnetlabs.nl DS –> nlnetlabs.nl DNSKEY
```

... and with that last key we can validate the data in the **nlnetlabs.nl** zone.

With this "trick" all keys from all the secure **.nl** zones can be chained from the **.nl** "master" key. So instead of one million (the number of zones in **.nl** currently) we need to configure only one key.

As you might have guessed, getting the root zone signed as soon as possible will make it possible to have one key that validates all other keys on the Internet.

We can also look at it from the resolver side. A resolver wants to get an answer. With DNSSEC it has to deal with signatures, keys, and DS records, but those are "side issues"; it still wants an answer.

Suppose **.nl** is secured and a secure delegation to **nlnetlabs.nl** exists. Our resolver has the key of **.nl** anchored. The nameservers of the root zone are also known to the resolver. We further assume the root is not signed. The resolver wants to resolve the address (A record) of **www.nlnetlabs.nl**. What does the actual resolving process look like in DNSSEC? Numerous steps need to be performed:

1. Go to a root server and ask our question.
2. The root server does not know anything about **www.nlnetlabs.nl**, but it *does* know something about **.nl**. The root nameserver refers us to the **.nl** nameservers. This kind of answer is called a *referral*.

3a. Notice that we have a key for **.nl** anchored.

3b. Go to the **.nl** nameserver and ask the **.nl** DNSKEY.

4a. Compare the two DNSKEYs. Continue with the secure lookup only if they match.

The **.nl** DNSKEY is now validated.

4b. Optionally, the RRSIG on the DNSKEY also can be checked.

5. Ask a **.nl** nameserver our question.
6. The **.nl** nameserver is also oblivious about **www.nlnetlabs.nl**, but it does know something about **nlnetlabs.nl**. It returns a secure referral consisting of a DS record plus the RRSIG and some nameservers.
7. The resolver now checks the signature on the DS record. If the signature is valid, the hash of the **nlnetlabs.nl** zone key is ok. The nameservers in the referral do not have any signatures on them.

   The hash of the **nlnetlabs.nl** DNSKEY is validated with the **.nl** DNSKEY.

8. Go to the nameserver as specified in the referral and ask for the **nlnetlabs.nl** DNSKEY.
9. Hash the DNSKEY of **nlnetlabs.nl** and compare this hash with the hash in the DS record. If they match continue with the secure lookup.

   The **nlnetlabs.nl** DNSKEY is now validated.

10. Ask the nameserver of **nlnetlabs.nl** our question.

11. The nameserver now responds with an answer consisting of the A record of **`www.nlnetlabs.nl`** and an RRSIG made with the **`nlnetlabs.nl`** DNSKEY.
12. The resolver now uses the already validated **`nlnetlabs.nl`** DNSKEY to check the RRSIG. If that signature is valid the RR with the answer is ok and can be given to the application.
13. After these steps we find out that the address of **`www.nlnetlabs.nl`** is 213.154.224.1. We also know it is not a spoofed answer.

This looks like a lot of work and it is—a recursive resolver is a complicated piece of software. Keep in mind, though, that only steps 3ab, 4ab, 7, 8, 9, and 12 are needed for DNSSEC; the rest is how resolving is done in the DNS today.

Deployment

As mentioned earlier, each zone owner generates its own key. To make the secure delegation actually work, this key must somehow be securely transferred to the parent, which is usually the local registry. The registry must have procedures in place to determine whether or not the uploaded key really belongs to the domain it claims to come from. During the *Secure Registry* (SECREG) experiment[5] NLnet Labs has researched the impact DNSSEC has on registries.

But even before the key can be actually uploaded to the parent, a zone administrator still has to do some work; the DNS zone must be signed. This process, called *zone signing,* turns a DNS zone into a DNSSEC zone.

The signing is done offline; first you sign, and then you load the zone. This setup was chosen because at the time (late 1990) computers were not fast enough to generate the signature in real time. Currently it would be possible to do this, but having a server sign every answer it gives is a *Denial-of-Service* (DoS) attack waiting to happen. Especially root servers will be unable to do this.

In DNSSEC a zone can have multiple keys. The signed zone then has multiple signatures per RRset (one for each key). There is no protocol limit on the number of keys. Here we sign with only one zone key. Also signatures in DNSSEC have a start and end date, that is, before and after a certain date interval the signature can no longer be used for validation.

If you use DNSSEC, you must re-sign your zone to generate new signatures with a new validity interval.

The signing of a zone consists of the following steps:

1. The zone key is added to the zone file.
2. The zone file is sorted.

3. Each owner name (for example, a host name) in the zone gets a *Next SECure* (NSEC) record. (Refer to the section "Authenticated Denial of Existence.")
4. For each secured delegation, a DS record is added.
5. The entire zone is then signed with the private key of the zone. Each authoritative RRset gets a signature, including the newly generated NSEC records.

Berkeley Internet Name Domain (BIND)[6] version 9—a popular implementation of the DNS protocols—contains a tool *dnssec-signzone,* which does steps 2 through 5 automatically; we only (manually) need to add the zone key to the zone file. The net result is that we have a bigger, signed, DNSSEC zone. A typical DNSSEC zone is 7 to 10 times larger than its DNS equivalent.

Experiments have shown that this does not pose much of a problem, even for such so-called country code *Top Level Domains* (ccTLDs) as **`.nl`**. The signed **`.nl`** zone was 350 megabytes, slightly more than a half a CD-ROM. And even if scaling problems are occurring, 64-bit machines would certainly help.

A few years ago there was much concern about the signing time. There was fear that it would be impossible to sign large zones, such as **`.com`**.

Experiments disproved this fear. Furthermore, a zone can be split up in pieces and each piece can be signed on a different machine. Later all the signed pieces can be put back together. Signing DNS zones is a highly parallel process.

After signing the zone, it can be loaded in the nameserver. If a resolver is DNSSEC-aware and has been configured with a trusted key that has a chain of trust to the zone key, it can validate the answers. If an answer does not validate, something is wrong and the DNS data must not be used.

The actual Internet-wide deployment of DNSSEC can happen incrementally. Each zone can decide to join independently. It is expected that initially DNSSEC is deployed in subsections of the Internet. These so-called *Islands of Trust* can appear anywhere on the Internet or even in intranets. The only requirement is that the key of the island of trust is distributed to the resolver. Resolvers configured with the key of a certain island of trust are called the *resolvers of interest.* Of course when DNSSEC is widely deployed on the Internet all resolvers are resolvers of interest and will have that key preconfigured.

Authenticated Denial of Existence

As mentioned previously, all records are signed offline. When a nameserver receives a query it looks up the answer plus the signature and returns the two (RRSIG + RRset) to the resolver. The signature is thus not created in real time. How can a secure-aware nameserver then respond to a query for something it does not know (that is, give an NXDOMAIN answer)? The only way to have offline signing and NXDOMAIN answers work together is to somehow sign the data you do not have.

In DNSSEC this is accomplished by the *Next SECure* (NSEC) record. This NSEC record holds information about the next record; it spans the nonexistence gaps in a zone, so to say. For this to work, a DNSSEC zone must be sorted (this is where that requirement stems from). To clarify this, consider an example.

We have a DNS zone, with (for the sake of clarity only the NSEC records are shown):

a.nl
d.nl
e.nl

Next we generate (with the signer) our DNSSEC zone:

a.nl
a.nl NSEC d.nl (span from **a.nl** to **d.nl**)

d.nl
d.nl NSEC e.nl (span from **d.nl** to **e.nl**)

e.nl
e.nl NSEC a.nl (loop back to **a.nl**)

1. If a resolver asks information about b.nl, the nameserver tries to look up the record fails. Instead it finds **a.nl**. It must then return: **a.nl NSEC d.nl** together with the signature. The resolver must then be smart enough to process this information and conclude that **b.nl** does not exist. If the signature is valid, we have an *authenticated denial of existence*. These NSEC records together with their signatures are the major cause of the zone size increase in DNSSEC.

Road to the DS Record

This section briefly considers the history of DNSSEC and, in particular, why the DNSEXT working group has invented this peculiar DS record, which can only exist at the parent side of a zone cut.

In RFC 2535 the DS record did not exist, and this is the reason that the key management in RFC 2535-DNSSEC is very, very cumbersome. In 2000 NLnet Labs ran its first experiment to test deployment of DNSSEC in the Netherlands. Because **.nl.nl** was chosen as the zone under which the secure tree would grow, this experiment became known as the *nl-nl-experiment*. With this experiment it was shown that the current DNSSEC standard (the soon-to-be-obsoleted RFC 2535) was difficult to deploy[7].

An update of a zone key in a child zone required up to 11 (coordinated and sequential) steps with the parent zone. The **.nl** zone now has more than 1 million delegations, so updating all the child zones would require more than 11 million steps. Because these updates could be quite frequent (once a month is typical), this is clearly an administrative nightmare.

Worse yet, if **.nl** lost its private key, all child-zone administrators would have to be notified and they would have to resubmit their public key for re-signing with the new **.nl** key. And because under these conditions the DNS may have been hacked and is thus untrusted, **.nl** is limited in its communication through the Internet; e-mail may not be the preferred method. A telephone call would be more safe, but what kind of organization can make up to one million phone calls in a few days ..?

After various failed attempts (sig@parent[8]) to fix this behavior, the DS record was introduced[1,3]. With this record the administration nightmare is solved, because DS introduces an indirection from the parent zone to a child's zone key.

If **.nl** loses its private key, it can easily resign its own zone, *without* contacting all its children. The DS to child key indirection is still valid, and only the signature of the DS record needs to be updated. This is a local operation.

To test this new DNSSEC specification, a new experiment was set up, which would build a shadow DNSSEC tree in the **.nl** zone. This experiment, called *SECREG,* was to test the new procedures in DNSSEC and, of course, the new DS record. Detailing the conclusions of this experiment is beyond the scope of this article, but in short the conclusion was that the new DNSSEC procedures do not pose much difficulty. At some point, more than 15,000 zones were delegated from the secure tree. A writeup of the experiment and the conclusions can be found in "DNSSEC in NL"[5].

Settings and Parameters in DNSSEC

DNSSEC brings many new parameters to the DNS, including cryptographic ones such as key sizes, algorithm choices, and key and signature lifetimes. Because DNS never has involved cryptography, the best values for these parameters are still open for debate. There is, however, some documentation and knowledge available on this topic (refer to [9] for instance).

One of the major issues is how large (bit length) to make a zone key and how often to re-sign a zone file. The current view is that a parent zone should use larger keys and re-sign more often than a child zone. Also the signature lifetime should be shorter in a parent zone.

Because a parent zone has a DS record (and signature) of a child's zone key, it can decide how long this DS RRSIG must be valid. The shorter this validity interval is, the better protected the child. If a cracker steals a child's zone key, it can forge DNS data. This data looks genuine because the cracker has access to the private key. As long as there is a valid chain of trust to this hijacked key, the child is vulnerable. This chain of trust is broken as soon as the RRSIG of the DS record expires. This argues in favor of a very short parental RRSIG over the DS record.

However, making this interval too short opens the door for accidental mishaps. If a child zone makes an error and somehow the chain of trust is broken, it has until the RRSIG expires to fix the problem. This would recommend a longer signature lifetime. In DNSSEC these and other trade-offs have to be made.

The IETF DNSOP working group is currently addressing these parameters and their trade-offs. The current data came (and comes) from workshops and early test deployments.

Outlook and Prospects

Because DNSSEC requires some additions to the (cc/g)TLD registration process, it could be a while before ccTLDs are capable of deploying DNSSEC. If the protocol is completed this year (2004), it will probably take a few years before registries can advertise DNSSEC domain names.

It is important to consider what DNSSEC actually wants to accomplish; it makes spoofing attacks in the DNS visible—and nothing more. It is not a PKI with all the extra features because key revocation is, for instance, not implemented in DNSSEC. Seen in this light, the protection of private keys in DNSSEC is important, but when a private key is compromised we are just back to plain old DNS.

On the other hand, because DNSSEC does introduce cryptographic material in the DNS and allows for the addition of other (non-DNS) keys, some interesting possibilities emerge. Many technologies on the Internet want to have some kind of simple key distribution mechanism in place; for example: SSH and IPSec. What DNSSEC promises is a system in which we can validate the SSH key from an unknown host with only one key. If the validation is successful, we are quite certain the SSH host key comes from the host from which it claims to come. We get this without any extra effort or cost (from a client's perspective at least). The possibilities are probably endless.

Book Review

Network Management

Network Management, MIBs and MPLS by Stephen B. Morris, ISBN 0131011138, Prentice Hall, June 2003.

Few people would question the need for good network management, and books about the *Simple Network Management Protocol* (SNMP) have been circulating for more than ten years now. But the key differentiator of this book is well recognized in its title—it's about SNMP in the context of a *Multiprotocol Label Switching* (MPLS) network. MPLS is now recognized as the convergence technology, and an increasing number of mission-critical services are being deployed over it. World-class network management is vital to keep these services running to the "five nines" level we've all come to expect.

Organization

In this book, Stephen Morris offers a very approachable and comprehensive look at SNMP and the methodology behind the all-important *Management Information Base* (MIB). The first chapter gives the obligatory justification for network management and sets the scene nicely for the rest of the book.

It's amazing to think that SNMP has been around since the late 1980s, and yet if you ask any MPLS operations person, the odds are that person is still using a *Command-Line Interface* (CLI) to actually configure boxes. CLI is a man-machine interface, not a machine-machine interface like SNMP. Even centralized provisioning platforms, such as the former Orchestream (now Metasolve) VPN Manager, simply created a friendly *Graphical User Interface* (GUI) front end for the provisioning procedure, and then ran CLI scripts frantically in the background. The drawbacks of CLI configuration are too numerous to list here, but the basic solution to the problem is to create a scalable and secure machine-to-machine interface. In the IP world the candidate technology for this is SNMPv3, and Morris discusses both the MIB structure (the key to scalability) and the security model in Chapter 2. Because premium MPLS-based services demand secure and robust provisioning, SNMPv3 is the technology of choice.

Chapter 3 describes what Morris calls the "Network Management Problem," although in fact this is described as a whole set of problems, some of which are caused by deficiencies in the SNMP architecture, whereas others are caused by the scale and pace of operations in a modern network. A specific problem that Morris addresses very sensibly is the way that the rapid pace of network technology development impacts the ability to manage these networks. In other words, new technologies tend to appear too quickly for management mechanisms to be optimized for these protocols. To solve this problem, Morris (a software engineer by training) presents a series of "Linked Overviews" (these describe the properties of a given network technology—MPLS, *Asynchronous Transfer Mode* (ATM), etc.—in a procedural framework. In essence this is a kind of recipe for the software developer. In addition, the text is liberally sprinkled with "Developers Notes" that I'm sure will provide invaluable help for people trying to write management system code.

Chapter 4 then takes the approach of solving the "Network Management Problem" to a higher, and perhaps longer-term level, with the proposed development of smarter network management components and more integrated data frameworks. This culminates in a description of *Directory Enabled Networking,* a technology that seemed to flower briefly in the context of network management a few years ago, but then was buried when the telecom recession hit the industry. My own feeling is that the time is right for a rebirth of this approach in modern, converged networks.

Chapter 5 looks at some real *Network Management System* (NMS) issues, using the HP OpenView Network Node Manager as a worked example. Morris is quick to point out that this is not an endorsement of the product, but because it is the most well-known and widely used product in this class, it is the logical choice.

Chapters 6 and 7 look at software components, and Morris's background in software development shines through here in the level of detail, coupled with well-structured explanations.

Chapter 8 describes a very useful case study of using SNMP to provision a tunnel through an MPLS network—a task that is typically performed today using crude CLI techniques.

Chapter 9 contrasts theory and practice in network management, and deals with the loose ends of various topics such as end-to-end security and the integration of a third-party *Open Source Software* (OSS) using standardized northbound *Element Management System* (EMS) interfaces.

Recommended

Overall this is an excellent book that really does deliver what it claims—a comprehensive and practical look at the latest SNMP technologies and techniques. In this regard it stays highly focused, and doesn't waste time with irrelevant discussion on other topics. For example, at first I was disappointed to note that only a page or two of brief explanation is devoted to topics such as *Common Object Request Broker Architecture* (CORBA) and *Extensible Markup Language* (XML). But in the context of what this book is trying to tell us, it makes perfect sense. Each of these topics really needs it own book to cover the topic in similar detail to Morris's work.

Similarly, if you're expecting a description of emerging IP/MPLS *Operations, Administration, and Maintenance* (OA&M), then this book is not for you. Again, I would defend Morris's use of Occam's Razor because OA&M protocols are usually demanded by network staff, and not by OSS operatives. In my own opinion, this situation will gradually change in the next few years, as OA&M is recognized as the "eyes and ears" of the OSS. Perhaps this would be a good place for Mr. Morris to start his next book.

Cooperative Support for Global IPv6 Deployment

The *Regional Internet Registries* (RIRs), the *IPv6 Task Forces* and the *IPv6 Forum* are working in cooperation to support global IPv6 deployment.

The four RIRs, APNIC, ARIN, LACNIC and the RIPE NCC, are responsible for the management of global Internet numbering resources, including IPv4 and IPv6 address space, throughout the world. The RIRs confirm their commitment and continued support towards the deployment of IPv6 in cooperation with the IPv6 Task Forces and with the support of the IPv6 Forum.

The IPv6 Task Forces are focused on rapid IPv6 deployment. They see the adoption of IPv6 by industry, governments, schools and universities is particularly important. The extra address space offered by IPv6 will facilitate the deployment of widespread "always-on" Internet services including broadband access for all. In addition, IPv6's built-in encryption will help improve Internet security and is promoted by many government institutions globally.

The cooperation among the RIRs and the IPv6 Task Forces includes key aspects such as:

- Supporting awareness, education and deployment of IPv6;
- Disseminating information on the progress of IPv6 deployment;
- Encouraging dialogue and ensuring the necessary cooperation between all involved parties;
- Benchmarking IPv6 deployment progress;
- Supporting the adoption of Domain Name Service infrastructure necessary for IPv6;
- Encouraging the participation of all those who are interested in the IPv6 policy development process.

This cooperative effort between the RIRs and the IPv6 Task Forces recognises that while IPv4 address space will be available for many years, new users and usages of the Internet have the potential to rapidly increase the utilisation of IPv4 address space. With the advent of multiple always-on devices, wireless handhelds and 3G mobile handsets, the Internet community needs to prepare for a sharp increase in IP address space utilisation. In order to prevent future operational problems, the global rollout of IPv6 is essential for enabling the development and adoption of new applications and services.

The rollout of IPv6 on this scale requires significant preparation, particularly in terms of training and planning. The RIRs and the IPv6 Task Forces encourage early evaluation by network operators and industry players, in order to promote the necessary technical dialogue and to facilitate widespread adoption. *Internet Service Providers* (ISPs) can already deploy IPv6 in non-disruptive ways that do not require additional investment while providing added value to their customers.

"The RIPE NCC has supported IPv6 from an early stage. We are committed to ensuring that IPv6 resources are provided to RIPE NCC members whenever they are required. We will continue to use the long-established system of address distribution where IP addresses are allocated according to demonstrated need wherever that need is demonstrated," stated Axel Pawlik, Managing Director of the RIPE NCC. "The RIPE NCC is already providing IPv6 training to our members and other tools required to facilitate IPv6 deployment," he added.

Jordi Palet, Founding Member of the EU IPv6 Task Force and co-chair of the IPv6 Forum's Awareness and Education Working Group, sees the formalisation of this cooperative support of IPv6 deployment as an important development. "This cooperative effort ensures the global recognition of the strategic importance of IPv6 in enabling the continued development of the Internet and the worldwide information society. This ongoing coordination will have a positive global benefit for end users and the industry, by reinforcing the resilience of the Internet while allowing for the development of ever-improving applications and services," he said.

Paul Wilson, APNIC Director General, noted that significant advances have been taking place in all the RIR regions with respect to IPv6 allocation and policy. "The RIRs are already working with the IANA and large ISPs to facilitate the delegation of large blocks of IPv6 address space," he stated. "In the Asia Pacific region, a number of countries are taking the lead in terms of IPv6 deployment, and APNIC will continue to offer its support in these areas, and elsewhere, to allow the entire region to benefit from IPv6."

"In the ARIN region, we have received clear direction from the community to make all necessary preparations for IPv6 deployment. This includes work on the allocation policies and procedures, as well as making our own services available via IPv6," stated John Curran, Acting President of ARIN

"LACNIC is involved in the formation of the Latin American and Caribbean IPv6 Task Force and is active in encouraging the participation of its members and the community in IPv6 deployment and policy, and our services are already available over IPv6," said Raúl Echeberría, CEO of LACNIC.

"This global cooperation signals another historic milestone to further accelerate take-up of IPv6 for the global good," applauded Latif Ladid, President of the IPv6 Forum.

"The North American IPv6 Task Force supports the worldwide collaboration with the RIRs to further support the deployment of IPv6 and the next generation Internet mobile society using IPv6," stated Jim Bound, Chair NAv6TF and IPv6 Forum CTO.

As an IPv6 Forum Board member and an ICANN Address Council member, Takashi Arano of the Asia Pacific IPv6 Task Force steering committee supports this collaboration. "Address management, which the RIRs are in charge of, is one of the crucial components for the commercial deployment of IPv6 and its stable operation."

"I hope collaboration between IPv6 Task Forces and the RIRs will result in the advent of an IPv6-powered 'everything-everywhere-every time' networking world," he stated.

IPv6 is a new version of the data networking protocols on which the Internet is based. The *Internet Engineering Task Force* (IETF) developed the basic specifications during the 1990s. The primary motivation for the design and deployment of IPv6 was to expand the available "address space" of the Internet, thereby enabling billions of new devices (PDAs, cellular phones, appliances, etc.), new users and "always-on" technologies (xDSL, cable, Ethernet-to-the-home, fibre-to-the-home, Power Line Communications, etc.).

The existing IPv4 protocol has a 32-bit address space providing for a theoretical 232 (approximately 4 billion) unique globally addressable network interfaces. IPv6 has a 128-bit address space that can uniquely address 2^{128} (340,282,366,920,938,463,463,374,607,431,768,211,456) network interfaces.

The *European IPv6 Task Force* is a volunteer organisation, with over 500 members, open to all the interested parties in advancing the IPv6 deployment in the European region, in cooperation with the rest of the world and other related entities. Further information is available on the IPv6 Task Forces website: **http://www.ipv6tf.org**

Four RIRs exist today. They provide number resource allocation and registration services that support the operation of the Internet globally. The RIRs are independent, not-for-profit organisations that work together to meet the needs of the global Internet community. They facilitate direct participation by all interested parties and ensure that the policies for allocating Internet number resources (such as IP addresses and *Autonomous System Numbers*) are defined by those who require them for their operations.

The RIRs ensure that number resource policies are consensus-based and that they are applied fairly and consistently. The RIR framework provides a well-established combination of bottom-up decision-making and global cooperation that has created a stable, open, transparent and documented process for developing number resource policies.

The RIR framework contributes to the common RIR goal and purpose of ensuring fair distribution, responsible management and effective utilisation of number resources necessary to maintain the stability of the Internet. The RIRs currently consist of:

APNIC: *Asia Pacific Network Information Centre*
http://www.apnic.net

ARIN: *American Registry for Internet Numbers*
http://www.arin.net

LACNIC: *Latin American and Caribbean Internet Addresses Registry*
http://www.lacnic.net

RIPE NCC: *RIPE Network Coordination Centre*
http://www.ripe.net

The *IPv6 Forum* is a world-wide consortium of over 160 leading Internet service vendors, National Research & Education Networks and international ISPs, with a clear mission to promote IPv6 by improving market and user awareness, creating a quality and secure New Generation Internet and allowing world-wide equitable access to knowledge and technology. The key focus of the IPv6 Forum today is to provide technical guidance for the deployment of IPv6. IPv6 Summits are hosted by the IPv6 Forum and staged in various locations around the world to provide industry and market with the best available information on this rapidly advancing technology. **http://www.ipv6forum.org**

The *North American IPv6 Task Force* is an all-volunteer non-vendor/service/provider or other entity interest with the IPv6 mission of assisting the North American geography as sub task force of the IPv6 Forum for deployment, education, awareness, technical analysis/direction, transition analysis, political/business/economic/social analysis support and other efforts as required. The members see IPv6 as more important than their own self-interests. **http://www.nav6tf.org**

Upcoming Events

The *Internet Corporation for Assigned Names and Numbers* (ICANN) will meet in Kuala Lumpur, Malaysia, July 19–23, 2004, and in Cape Town, South Africa, December 1–5, 2004. For more information see: **http://www.icann.org**

ICANN and *The International Telecommunications Union* (ITU) will be jointly hosting a workshop on *country code Top Level Domains* (ccTLDs), in Kuala Lumpur on 24 July. The purpose of this joint ICANN/ITU-T open workshop is to focus on the operation and practical operational issues facing the ccTLDs and to give the opportunity for ccTLD operators and ITU Member States to share their experiences. The Workshop is not a policy meeting, but rather it is intended as a forum for the exchange of views and discussions. Written presentations are encouraged, but not required. Written presentations can be submitted to **ICANN-ITU-T-Workshop@icann.org**. Additional information can be found at the ITU-T website: **http://www.itu.int/ITU-T/worksem/cctld/kualalumpur0704/index.html**

The IETF will meet in San Diego, CA, August 1–6, 2004 and in Washington, DC, November 7–12, 2004. For more information, visit: **http://ietf.org**

From The Editor

Network Address Translators (NATs) were designed to allow multiple devices in a private address realm to dynamically share a single public IP address. NATs are widely deployed in today's Internet. They provide an effective way of IPv4 address conservation while simultaneously offering some level of security because individual IP addresses on the "inside" are hidden from the "outside," or global Internet. But NATs also present a challenge to existing Internet applications that may depend on globally unique IP addressing for proper operation. To further complicate matters, not all NATs are created equal, leading to unpredictable behavior. This edition of IPJ is almost entirely devoted to an in-depth look at NATs. Geoff Huston looks inside the NAT, and explains the complexities behind each variation of NAT implementation. It seemed only natural that he would name such an exposé "Anatomy."

Many IPJ subscriptions had an official expiration date of September 30, 2004, but I am pleased to report that all these subscriptions have been extended for another year. You should still make sure your delivery address and e-mail is up-to-date in our database by using the link at **www.cisco.com/ipj** or sending e-mail to **ipj@cisco.com** with your updated information.

If you're hungry for even more networking-related reading material, look at the Internet Society's publication page at **http://isoc.org/pubs/**. Here you will find The ISP Column, Member Briefings, Articles of Interest, and links to other material.

We didn't have room for a book review in this issue, but we have several in store for future editions. If you'd like to contribute a book review for publication in IPJ, please contact me.

Anatomy: A Look Inside Network Address Translators

by Geoff Huston, APNIC

Over the past decade numerous IP-related technologies have generated some level of technical controversy. One of these is the *Network Address Translator,* or NAT. This article describes the inner workings of NATs in some detail, and then looks at the issues that have accompanied the deployment of NATs in the Internet that appear to have fueled this technical controversy. NATs are a very widespread feature of today's Internet, and this article attempts to provide some insight as to how they operate, why there is such a level of technical controversy about NATs, and perhaps some pointers to what we have learned about technology and the process of standardization of technology along the way.

NAT Motivation

The first RFC document describing NATs was by Kjeld Egevang and Paul Francis in 1994[1]. The original motivation behind the NAT work was based on efforts in the early 1990s associated with a successor protocol to IPv4. The overall effort of a successor protocol to IPv4 was to devise a protocol that would directly address the issues of accelerating address consumption in IPv4 that appeared to be leading to the prospect of imminent address exhaustion. Although IPv4 was capable of uniquely addressing some 4.4 billion devices, it was evident by as early as 1992 that the world was heading down a path of very intensive deployment of devices that included communications capabilities, and that IPv4 was not going to be able to extend across the full range of future device deployment. The objective with NAT was to define a mechanism that allowed IP addresses to be shared across numerous devices. In addition, it was intended that NATs could be deployed in a piecemeal fashion within the Internet, without causing changes to hosts or other routers. Other forms of address-sharing technologies relied on intermittent connectivity, whereas NATs were intended to allow a collection of connected devices to share an address pool dynamically. The original RFC portrays this approach as being a measure that can "provide temporarily relief while other, more complex and far-reaching solutions are worked out."

So, as documented, the original intent of NATs was to be a possible short-term response to address exhaustion while longer-term solutions were being devised. NATs were also intended to be unmanaged devices that are transparent to end-to-end protocol interaction, requiring no specific interaction between the end systems and the NAT device.

A decade later NATs are attaining a status of near-ubiquitous deployment across the Internet, and although IPv6 has been defined and deployment is commencing, NATs appear to be a very well-entrenched part of the network landscape. And, for the most part, NATs continue to function as unmanaged devices.

They can be transparent to some forms of protocol interaction, but, as the voice-over-IP folks are finding out, they can be very obvious to the point of being highly disruptive to other forms of protocol operation.

NAT Operation

The operation of NATs is deceptively easy to describe in general terms. They are active units placed in the data path, usually as a functional component of a border router or site gateway. NATs intercept all IP packets, and may forward the packet onward with or without alteration to the contents of the packet, or may elect to discard the packet. The essential difference here from a conventional router or a firewall is the discretional ability of the NAT to alter the IP packet before forwarding it on. NATs are similar to firewalls, and different from routers, in that they are topologically sensitive. They have an "inside" and an "outside," and undertake different operations on intercepted packets depending on whether the packet is going from inside to outside, or in the opposite direction.

NATs are IP header translators, and, in particular, NATs are IP *address translators*. The header of an IP packet contains the source and destination IP addresses. If the packet is being passed in the direction *from* the inside *to* the outside, a NAT rewrites the source address in the packet header to a different value, and alters the IP and TCP header checksums in the packet at the same time to reflect the change of the address field. When a packet is received *from* the outside destined *to* the inside, the destination address is rewritten to a different value, and again the IP and TCP header checksums are recalculated (Figure 1). The "inside" does not use globally unique addresses to number every device within the network served by the NAT. The inside (or "local") network may use addresses from private address blocks, implying that the uniqueness of the address holds only for the site. Let's look at this using an example.

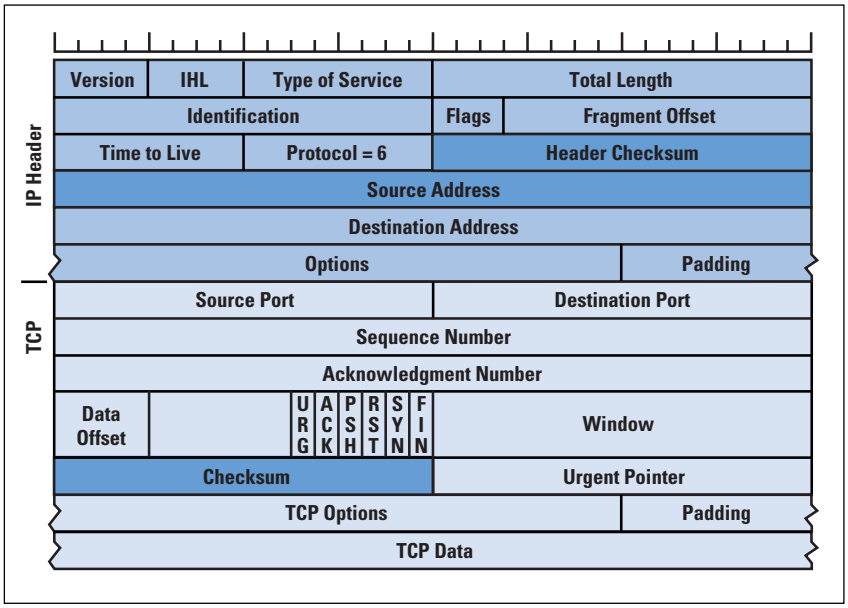

Figure 1: TCP/IP Header Fields Altered by NATs (Outgoing Packet)

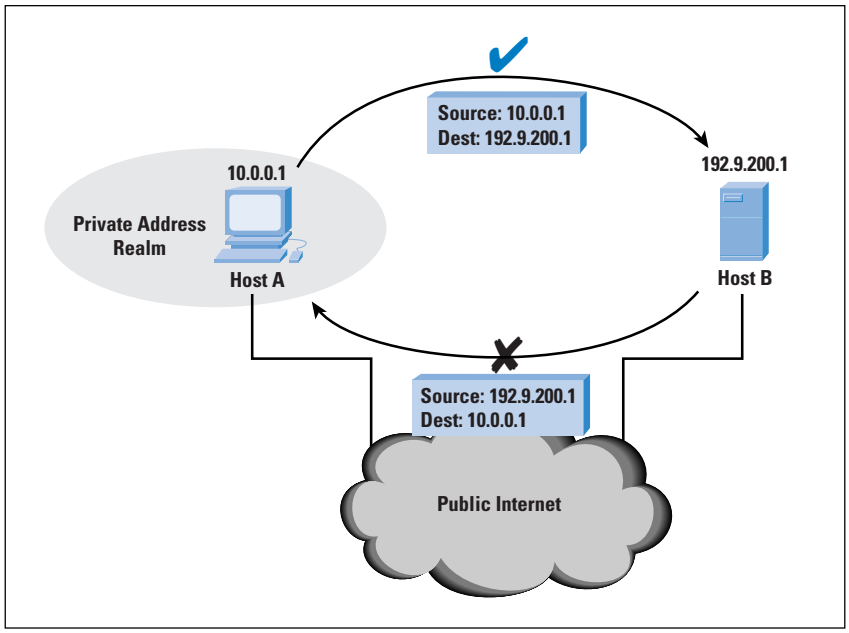
As shown in Figure 2, how can local (private) host A initiate and maintain a TCP session with remote (public) host B? Host A first uses the *Domain Name System* (DNS) to find the public IP address for host B, and then creates an IP packet using host B's address as the destination address and host A's local address as the source, and passes the packet to the local network for delivery. If the packet was delivered to host B without any further alteration, then host B would be unable to respond. The public Internet does not (or should not at any rate!) carry private addresses, because they are not globally unique addresses.

Figure 2: Public/Private Communication



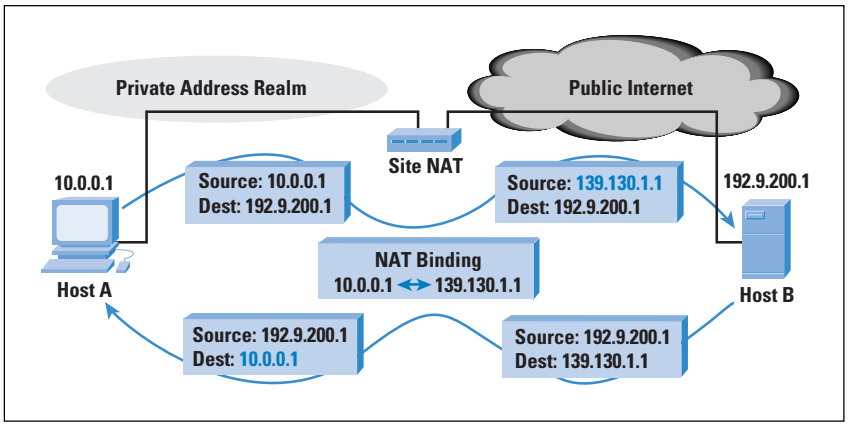
With a NAT between hosts A and B, the NAT intercepts host A's outgoing packet and rewrites the source address with a public address. NATs are configured with a pool of public addresses, and when an "inside" host first sends an outbound packet, an address is drawn from this pool and mapped as a temporary alias to the inside host A's local address. This mapped address is used as the new source address for the outgoing packet, and a local session state is set up in the NAT unit for the mapping between the private and the public addresses.

After this mapping is made, all subsequent packets within this application stream, from this internal address to the specified external address, will also have their source address mapped to the external address in the same fashion.

When an incoming packet arrives on the external interface, the destination address is checked. If it is one of the NAT pool addresses, the NAT box looks up its translation table. If it finds a corresponding table entry, the destination address is mapped to the local internal address, the packet checksums are recalculated, and the packet is forwarded. If there is no current mapping entry for the destination address, the packet is discarded.

The mode of operation of a NAT is shown in Figure 3. So, continuing our example, the local host at address A is directing packets to the external server host at address B. Because the NAT is in the path, the NAT has altered the packets so that address A is translated to address X. Host A is aware that it is communicating with host B, and from host A's perspective this is a normal session. Host B believes that it is communicating with a host at address X, and is entirely unaware of address A. From host B's perspective this is a normal session with a host at address X.

Figure 3: NAT Traversal

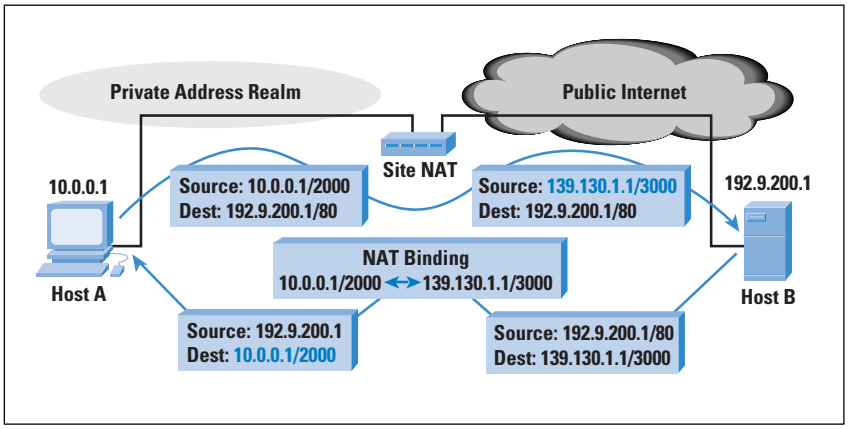


Dynamically created mapping entries (or "bindings") are typically maintained by the NAT with a *timer*. If no packets that use the mapping are received by the NAT within a certain time window, then the binding is removed from the NAT and the public address is returned to the NAT pool.

NAPTs

A variant of the NAT is the *Port-Translating NAT*, or NAPT. This form of NAT is used in the context of TCP and *User Datagram Protocol* (UDP) sessions, where the NAT maps the local source address and source port number to a public source address and a public-side port number for outgoing packets. Incoming packets addressed to this public address and port pair are translated to the corresponding local address and port. Again, the binding is maintained by a NAT idle timer, and upon expiration of the timer the public address and port pair are returned to the NAT pool (Figure 4).

Figure 4: NAPT Traversal



Again the NAPT is attempting to be transparent in terms of providing a consistent view of the session to each end, using a symmetric binding of a local address and port pair to an external address and port pair.

A reasonable question to ask is: Why should NAPTs bother with port translation? Are straight address translations not enough? Surprisingly, NATs can be relatively profligate with addresses. If each TCP session from the same local host is assigned a different and unique external pool address, then the peak address demands on the external address pool could readily match or exceed the number of local hosts, in which case the NAT could be consuming more public addresses than if there were no NAT at all! NAPTs allow concurrent outgoing sessions to be distinguished by the combination of the mapped address and mapped port value. In this way each unique external pool address may be used for up to 65,535 concurrent mapped sessions.

For a while the terminology distinction between NATs and NAPTs was considered important, but this has faded over time. For the remainder of this article we use current terminology, and look at NATs and NAPTs together and refer to them collectively as "NATs."

NAT Behavior

The use of NATs involves two basic issues: One is that NATs make applications "brittle" in that NATs support a particular style of application operation, and if the application deviates in any way from this style then the application no longer works. The second is of much more concern, and that is that NATs differ from each other in quite fundamental ways. What works across one NAT may not work at all for another class of NAT. It has also been reported that NATs differ not only on a vendor-by-vendor basis, but even on a model-by-model basis within a single vendor's range of NAT units. The implication here is that such differences of behavior become a matter for discovery by applications rather than something applications can predict in advance. This section explores this behavioral aspects of NATs in further detail.

Symmetry and Sessions

NATs can manage address mapping in numerous ways, and many implementations of NATs use a form of binding termed a "symmetric" binding.

A *symmetric* binding is where the mapping of a local address to a public address is exclusively tied to the destination address used in the initial trigger outgoing packet for the lifetime of the binding. Incoming external packets with the mapped public address as their destination are translated to the local address only if the source address of the incoming packet matches the destination address of the original mapping. Multiple sessions to different public hosts may use the same mapped public address, or may use different public addresses for each session. This mapping is "endpoint" sensitive. Symmetric NATs represent a restricted model of operation, where each NAT binding represents a window through the NAT that is visible only to the destination host (Figure 5).

By comparison, a *full-cone* NAT allows any external host to use this opened window, where all incoming packets addressed to the mapped external address are translated to the mapped internal address and forwarded through the NAT. Symmetric NATs represent the most restrictive form of behavior, whereas full-cone NATs represent a far more permissive mode of operation.

In the context of NATs, this symmetric mode of operation refers to the session state 5-tuple, made up of Transport Protocol, the local IP address and port number, and the destination IP address and port number. When a session is opened from the local host to a remote service port on a remote host, then only that remote service can pass packets back through the NAT to the local host on that port. As with NATs, a full-cone NAT allows any remote service entity to direct packets back through the port window.

NATs can be further refined by having different behaviors for TCP and UDP transports. A NAT may behave in a symmetric manner for TCP sessions, and operate in a full-cone mode for UDP transactions. The variations in NAT behavior has led to an exercise in categorizing NAT behaviors and developing a discovery protocol whereby a pair of cooperating systems can discover if one or more NATs is on the network path between them, as well as attempting to establish the type of NAT.

Discovering NAT Behaviors and STUN

NAT behavior has not been the topic of any industry standardization efforts, and it should not be surprising to learn that, given that a range of possible NAT behaviors exist under certain conditions, the market contains NAT offerings that cover the full spectrum of possibilities. In the absence of common specifications or standards, implementers have been placed in the position of having to make some creative guesses as to what the "right" behavior should be under such circumstances. This is a significant problem for the application designer, given the prospect that in today's Internet any popular application must have a means of being able to function correctly in the face of one or more NATs on the path between two hosts that are communicating using the application.

One of the more pressing problems here is that NATs commonly enforce an application model where the local "hidden" host must initiate a transaction in order to create a window in the NAT to allow the packets of the remote host back into the local network.

Some applications may wish to undertake "referral," where the correspondent host on the external side may want to pass the externally presented address and port details of the local host to a third party in order to commence a further part of the transaction. Other application transactions may simply want to be initiated from the external side. Although this may have been thought of as a relatively obscure condition, it was brought into the forefront of attention when various forms of voice-over-IP and peer-to-peer applications gained popularity. In particular, the question of "how can the external side initiate a packet flow in the presence of a NAT?" has become increasingly important.

Given that the application needs to perform some additional gymnastics in such a case, there is the additional question that the application must answer, namely: "How does the application learn that there are NATs in the path in the first place?"

At this point the application is placed in the role of performing a forensic exercise of establishing whether or not its packets are being altered by one of more NATs when it attempts to establish an end-to-end packet transaction. If so, what types of implementation decisions have been made by the NAT in terms of the way in which packets are being systematically modified? In others words, what is the anatomy of the particular NATs that have been discovered along the path? This anatomy exercise is further complicated by the observation that NATs are silent devices, so the application cannot directly interrogate the NAT to establish its behavior. All that is left is a somewhat unsatisfying guessing game for the application. It is forced to send particular types of test packets through the NAT to some pre-defined counterpart on the other side. The application must then compare the self-view of the IP address and port number of the local host to the remote view of its IP address and port number, and then attempt to guess the nature of the systematic transforms that the NAT is applying.

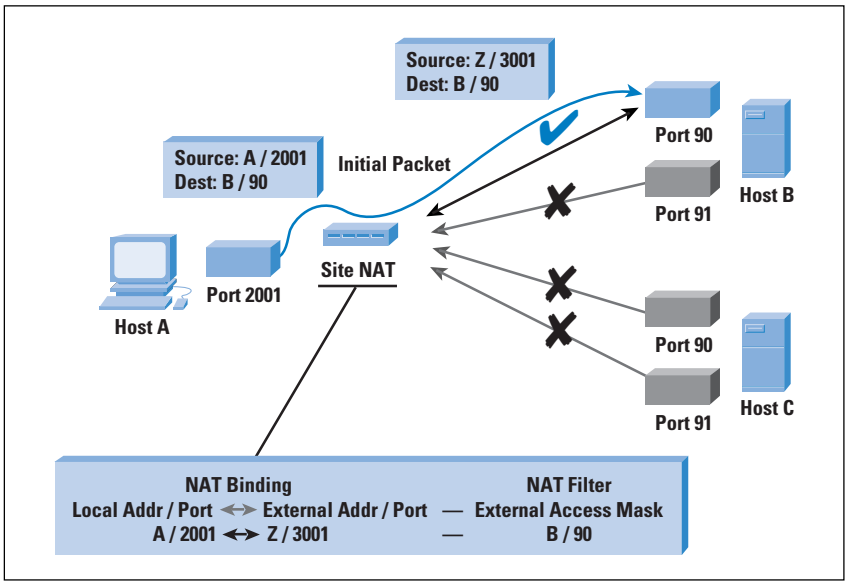
In the case of TCP it appears that the prevalent NAT behavior is that of a symmetric NAT based on address and port bindings. This implies that when the local host opens up a TCP session with a remote host, the NAT address and port bindings for the local host are coupled with the address and port of the destination host. Only packets with a source field of the destination host can pass packets back through the NAT to the TCP session of the local host. In other words, when a TCP session has been established within a NAT, only the two endpoints of the TCP session can access the NAT bindings, and attempts by others to direct packets to the external-side presented address and port meet with the NAT discard response. The fine-grained behavior of NATs with respect to TCP sessions can vary according to the amount of TCP state maintained by the NAT. At a basic level, the NAT can maintain a binding based on the local address and port and the remote address and port. The NAT also can keep the binding timer at a high value until a **`FIN`** exchange is observed, or until the session is reset through the **`RST`** flag being set, at which point the binding timer can be reduced to a very short interval. The NAT can also track the sequence number windows of the two sides and associated window sequence number scaling values and not adjust the binding timer of the session for TCP packets with sequence numbers outside the sequence number window with their **`FIN`** or **`RST`** flags set.

These NAT behaviors are based on the explicit signaling of changes in session state within the TCP packet exchange, and the consequent ability of the NAT to track the session state and adjust the associated binding timer in response to this state information. UDP is not so straightforward, because there is no explicit session state within a UDP packet exchange, and various NATs behave differently with respect to UDP-based bindings.

Various classes of NAT behavior relate to how UDP bindings are managed within a NAT. These have been classified into four types of behaviors[11]:

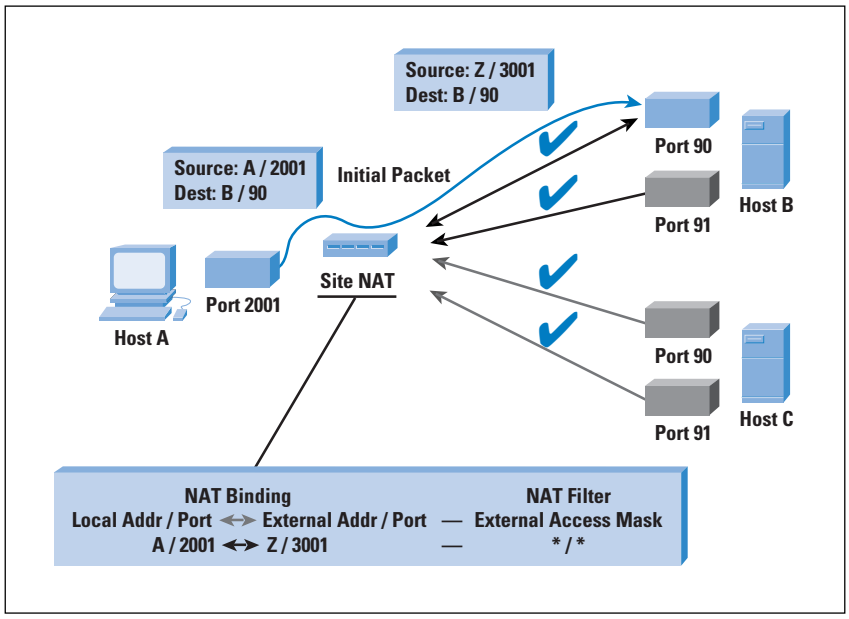
- *Symmetric:* We have already encountered the symmetric NAT, where the NAT mapping refers specifically to the connection between the local host address and port number and the destination address and port number and a binding of the local address and port to a public-side address and port. Any attempts to change any one of these fields requires a different NAT binding. This is the most restrictive form of NAT behavior under UDP, and it has been observed that this form of NAT behavior is becoming quite rare, because it prevents the operation of all forms of applications that undertake referral and handover.

Figure 5: Symmetric NAT



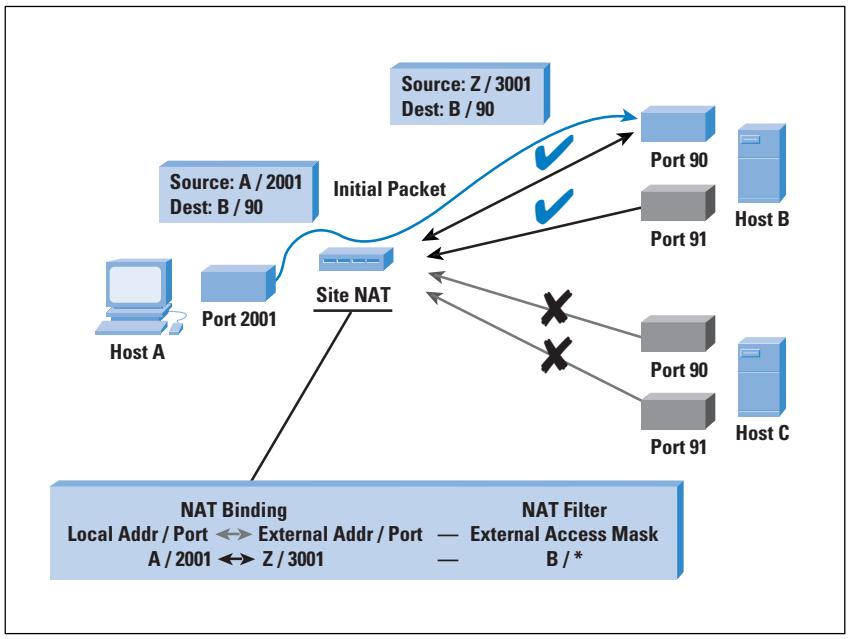
- *Full-cone:* A full-cone NAT is the least restrictive form of NAT behavior, where the binding of a local address and port to a public-side address and port, when established, can be used by any remote host on any remote port address. (Refer to Figure 6.)

Figure 6: Full Cone NAT



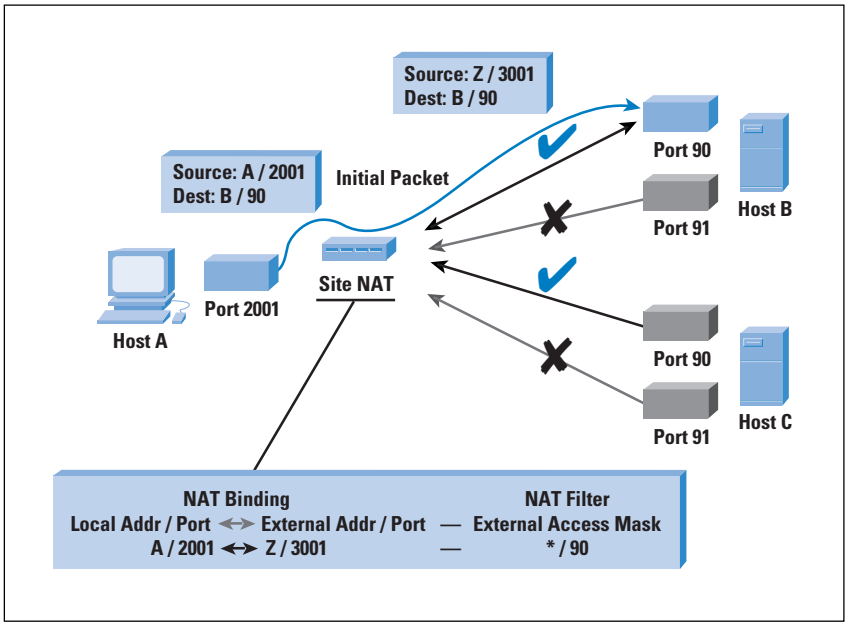
- *Restricted-cone:* A restricted-cone NAT is one where the NAT binding is accessible only by the destination host, although in this case the destination host can send packets from any port address after the binding is created. (Refer to Figure 7.)

Figure 7: Restricted-Cone NAT



- *Port-restricted-cone:* A port-restricted-cone NAT is one where the NAT binding is accessible by any remote host, although in this case the remote host must use the same source port address as the original port address that triggered the NAT binding. (Refer to Figure 8.)

Figure 8: Port-Restricted-Cone NAT



So can an application tell if one or more NATs are in the path, and, if so, what form of behavior the NAT is using? For this purpose the *Simple Traversal of UDP through NATs* (STUN) protocol has been developed[11]. STUN is a probe system that examines the interchange between a STUN client that may lie behind a NAT and a STUN server that is positioned on the public side of the NAT. The STUN-server host must be configured with two IP addresses, and the STUN itself should respond to queries on two UDP port numbers. The protocol is a simple UDP request-response protocol that uses embedded addresses in the data payload, and compares these addresses with header values in order to determine the type of NAT that may lie in the path between client and server.

The basic operation of STUN is a request-response protocol, using a common request of the form: "Please tell me what public address and port values were used to send this query to you."

STUN can be used to discover if a NAT is on the path between a client and server, and attempt to discover the type of NAT by a structured sequence of requests and responses. The client sends an initial request to the STUN server. If the public address and port in the returned response are the same as the local address, then the client can conclude that there is no NAT in the path between the client and the server. If the values differ, the client can conclude that there is a NAT on the path. STUN then uses subsequent requests to determine the type of NAT. One critical additional item of information returned by the STUN server in the initial response is an alternate IP address and port number that can also reach the same STUN server.

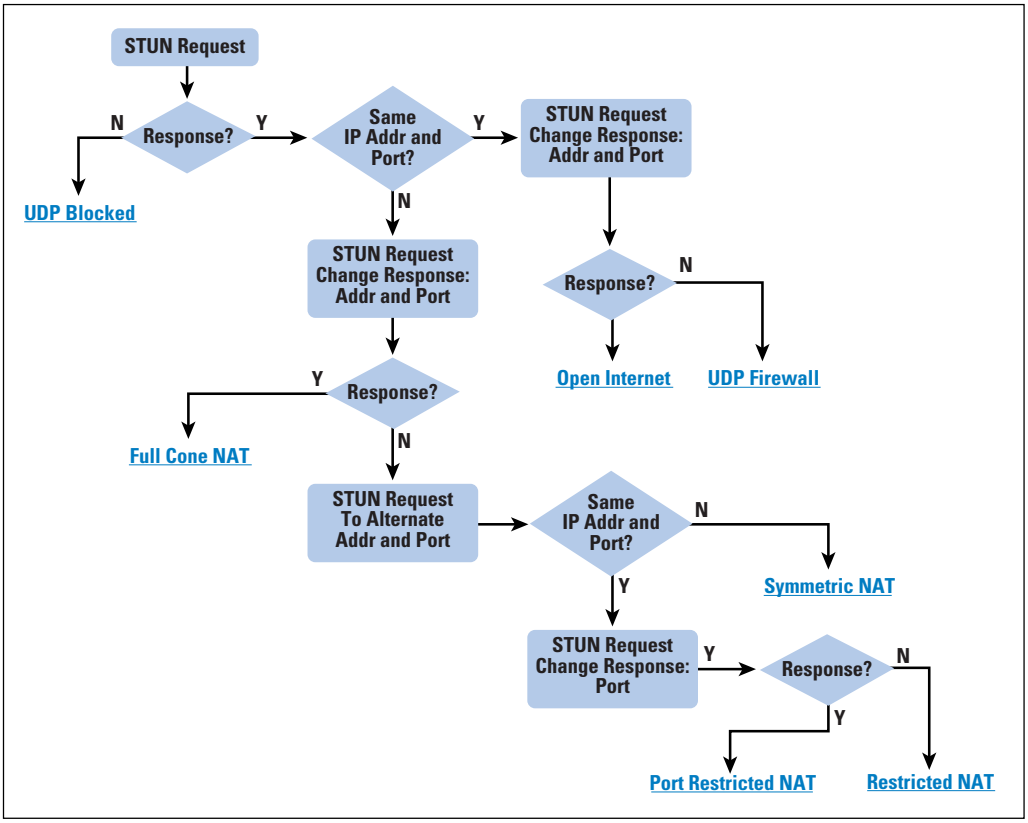
The second STUN request is directed to the same address and port as the initial request, but this time the request includes a control flag that requests the STUN server to respond using its alternate source address and port values. If the STUN client receives this alternate-sourced response, then it can conclude that it is behind a full-cone NAT. This is because the initial NAT binding of the local host address to the external presentation address can evidently be accessed by third-party external hosts.

If no response is received to the second request, then the STUN client sends the original probe request, but this time the request is addressed to the alternate destination address and port pair for the STUN client. If the returned address and port values relating to the new NAT binding are different from those of the first request, then the client can conclude that it is behind a symmetric NAT.

If the values are unaltered, then a further request can be made to determine the form of restricted-cone behavior. This fourth request includes a control flag to direct the STUN server to respond using the same IP address, but with the alternate port value. A received response indicates the presence of a port-restricted cone, and the lack of a response indicates the presence of a restricted cone.

Periodic exchanges between the STUN client and server can also discover the timer used by the NAT to maintain address bindings. Additional components of STUN are intended to provide some reasonable level of integrity in the packet exchange. A flowchart of a STUN-based NAT discovery process is shown in Figure 9.

Figure 9: NAT Discovery Process Using STUN



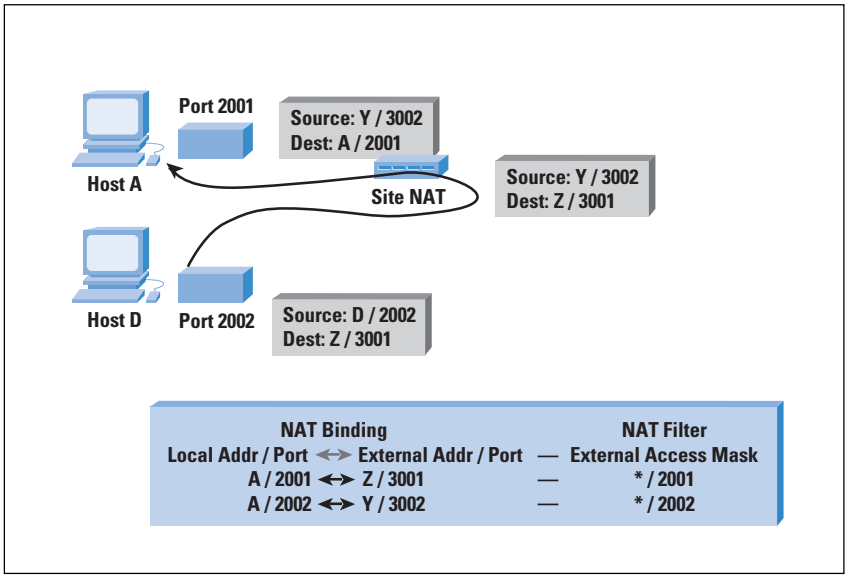
Further Behaviors: Hairpins and Determinism

It would be good if NAT behavior remained that simple. However, it does not, and some further tests on NATs reveal further differences in various NAT implementations[16].

The first area of difference is whether the NAT supports the so-called *hairpin* operation, where a local host directs a packet to the public address and port of an already mapped local host, or even to its own mapped address and port. If successful, then the NAT supports hairpin operation, where the NAT bindings, when created, are available to either side of the NAT. (Refer to Figure 10.)

Furthermore, the NAT may generate a binding for this operation—or not—thereby presenting the hairpin packet with an external address and port, indicating that an outbound binding has been performed in conjunction with the inbound binding, or with an internal address and port, indicating that only an inbound binding is being performed.

Figure 10: Hairpin NAT Operation



The second is in the general class of NAT determinism. Nondeterministic NATs change their binding behavior when a binding conflict of some sort occurs in the NAT. This is further based on the classification of whether "primary," "secondary," or even "tertiary" NAT behaviors differ. To explain primary, secondary, and tertiary behaviors, it is first noted that some NATs attempt to preserve the port address in the binding, so that the local source port and the externally bound port are the same whenever possible. This is the "primary" binding of the NAT. If another local host obtains a NAT binding using the same source port number, then the behavior of the NAT for this conflicting port binding may differ from that where the port number is preserved. The first conflict of port allocations in bindings is the "secondary" binding. In some cases the primary behavior is that of a full cone, or a restricted cone, while the NAT behaves in a symmetric fashion for the secondary instance where the port number has been mapped to a new value by the NAT.

A tertiary behavior occurs when a third binding is added to the NAT, because, again, the behavior of the NAT may be different for this binding.

It is also possible that the NAT may elect to preserve the binding in any case, and remove the current binding and replace it with a new binding that refers to the most recent packet that the NAT has processed.

All these behaviors can be classified as *nondeterministic,* in that the NAT behavior becomes one that is determined by the order of outbound traffic. The implication is that repetitions of the same STUN test at different times may produce different classifications of the type of NAT. The inference is that if an application uses STUN to determine the type of NAT in the path, and then selects a certain behavior based on this STUN-derived knowledge of the NAT type, nondeterministic NATs may behave differently between the STUN test and the application. The NAT response for a particular binding cannot be predicted in advance, and even when a binding state is established it may be disrupted or altered by subsequent traffic.

Another Approach to Classifying NATs

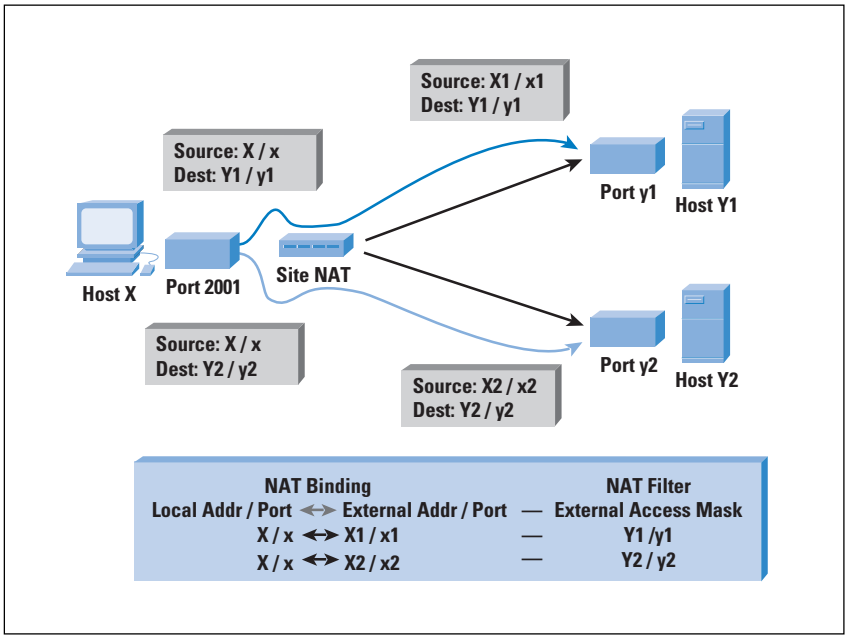
Further tests on NATs reveal that the various behaviors are yet more complex, and that different sequences of tests across a NAT will lead the test routine to come to different conclusions as to the type of NAT[13]. The key observation here is that NATs are the conjunction of two distinct behavior sets:

- *Binding,* or context-based packet translation: Detecting those packets that can be associated with a current binding and using that binding in a manner according to the logical direction of the packet to perform packet header transforms
- *Filtering,* or packet discard: Discarding those packets that cannot be associated with current bindings and discarding them

If a STUN-like test sequence was for a local host to send a packet to one destination and obtain a response of what NAT binding was used, and then to send a packet to a second destination and compare the results, the observation of the NAT using a different binding for each request may lead the tester to conclude that the NAT is a fully symmetric NAT. If the test sequence is for the NAT to send one packet to a destination and have the destination respond using a different source address, then the observation that the response packet is successfully delivered through the NAT back to the originating local host may lead the tester to the conclusion that the same tested NAT is some form of cone NAT.

The STUN approach classifies NAT behaviors on the basis of a single binding being established by the local host when contacting an external host, and then considers what constraints are placed on third-party external hosts as they attempt to access this initial binding. An adjunct to this approach is based on the local host establishing two bindings to two distinct external hosts, and looking for any relationship between these two bindings. (See Figure 11).

Figure 11: Outbound Connections from a Common Source



The behaviors of NATs under this condition can be classified under numerous behavioral aspects.

Binding

Binding behavior can be seen as the amalgam of three somewhat distinct design decisions, namely the manner in which a binding is generated, the behavior of the NAT in managing external ports used in bindings, and the manner in which expiration timers that govern the continued existence of the binding are refreshed.

NAT Binding Behavior:

- *Endpoint independent:* The NAT reuses the port binding for subsequent sessions initiated from the same internal IP address and port to any external IP address and port. This is analogous to a full-cone NAT.
- *Endpoint address dependent:* The NAT reuses the port binding for subsequent sessions initiated from the same internal IP address and port only for sessions to the same external IP address, regardless of the external port. This is a looser form of symmetric NAT, where the binding is created on the basis of the external address, rather than the external address and port.
- *Endpoint address and port dependent:* The NAT reuses the port binding for subsequent sessions initiated from the same internal IP address and port only for sessions to the same external IP address and port. This is a more precise form of UDP symmetry where the binding is available only to a single session, where a session is the 5-tuple of protocol, source address, source port, destination address, and destination port.

Port Binding Behavior:

- *Port preservation:* In addition to the differences in the binding between the two cases, the NAT may attempt to preserve the local port number, if possible. The terminology proposed here is port preservation to describe this NAT action.
- *Port overloading:* Some NATs attempt to undertake port preservation at all times, so that when a different local host establishes a binding using a port that is already being preserved, the new binding will usurp the existing binding. This behavior is proposed to be termed port overloading.
- *Port multiplexing:* The alternative to port overloading is use of the external entity to perform the demultiplexing of the port. In this case if two local systems use the same source port to send packets to two different external hosts, the NAT preserves the source port in the two bindings. If the NAT is using a single external address, the external view is two packets with the same source address and source port, sent to two different external addresses. The reverse packets have the same destination address and port, and the NAT determines the appropriate binding based on the source address and port in the reserve packets. This requires an endpoint address and port-dependant binding behavior. If two internal hosts are directing packets to the same external endpoint using the same source port addresses, then it is necessary for one of the sessions to use a binding with an altered port number. This could be considered as nondeterministic behavior.

Binding Timer Refresh:

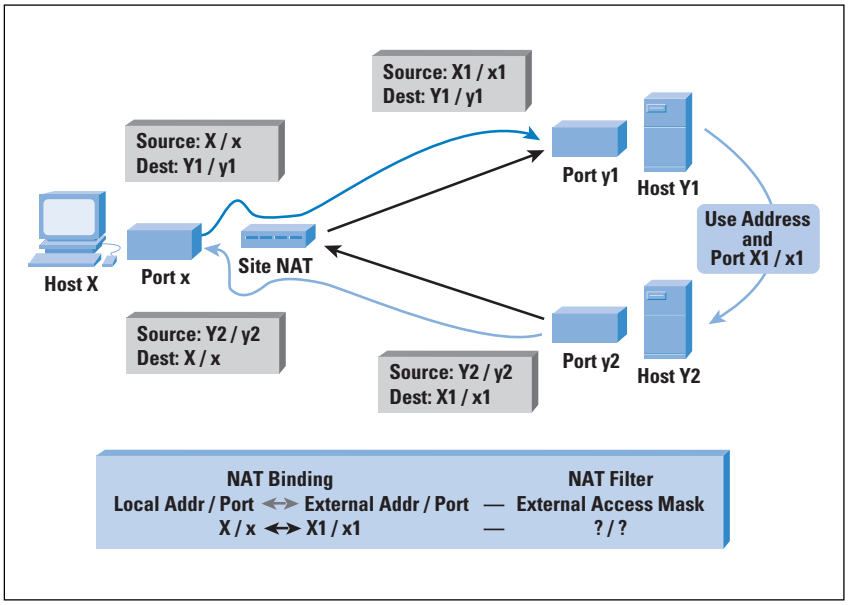
- *Bidirectional:* The NAT does not keep the binding active indefinitely, and normally removes the binding if there are no further packets that use the binding within a certain time period. However, there are variations in the classification of packets that the NAT considers as packets that reset the timer. In the case of bidirectional binding timer refresh, packets from either the local hosts or an external host that uses the NAT binding cause the NAT binding expiration time to be reset.
- *Outbound:* An outbound binding timer refresh NAT resets the expiration timer only when packets pass from the local host to the external host within the context of the binding. The implication is that a local host may have to use some form of keepalive operation to maintain a NAT binding in the face of an inbound UDP unidirectional traffic flow. Additionally, the expiration timer may be on a per-session basis, or may be on a per-binding basis if multiple sessions are associated to a single binding in the NAT.
- *Inbound:* As the name suggests, this is the opposite of the previous case, where only inbound packets cause the expiration timer of the binding to be refreshed.

- *Transport Protocol state:* Although these forms are useful in the case of UDP-based sessions, when the binding is based on a transport session (such as TCP), the NAT can base its binding timer refresh on the transport session state. For TCP this would infer a binding refresh time that is refreshed by any session packet in either direction (bidirectional), with the exception of packets with the TCP **`RST`** or **`FIN`** flags set. Although it would be an option to drop the NAT binding state when such packets are seen, this makes the NAT vulnerable to denial-of-service attacks by third-party injection of TCP **`RST`** packets, so there is some merit in using the binding timer for TCP sessions.

Filtering

The second phase of the test has two external hosts directing a probe to the same binding address, and classifying the behaviors based on what packets are filtered and discarded by the NAT (Figure 12).

Figure 12: Inbound Test



External Filtering:

- *Endpoint independent:* The NAT does not filter and discard packets that are addressed to the external part of the binding, irrespective of the source values in the packet. This is analogous to a full-cone NAT.
- *Endpoint address dependent:* The NAT filters and discards packets that are addressed to the external part of the binding, unless the source address of the packet matches the destination address used in the binding. This is analogous to a restricted-cone NAT.
- *Endpoint address and port dependent:* The NAT filters and discards packets that are addressed to the external part of the binding, unless the source address and port number of the packet matches the destination address used in the binding. This is analogous to a port-restricted-cone NAT or a symmetric NAT.

External Filtering Timer Refresh:
As with binding timers, these timers can be refreshed bidirectionally, inbound or outbound.

NAT Behaviors

The approach of carefully identifying the areas where NAT behaviors differ and classifying these behavioral differences in a methodical manner is one that has the potential to at least allow us to use the same sets of words when we talk about NAT behaviors, and hopefully also refer to the same set of actual behaviors when we use the same descriptions. The original approach with the STUN work used the terms *symmetric, full-cone,* and forms of *restricted-cone* to describe variations of NAT behaviors. Experience with this form of classification has exposed further variations in NAT behaviors, and this has led to a form of NAT classification that first uses a delineation of binding and filtering behaviors, and then classifies the various ways in which these bindings and filters are maintained within the NAT. Additional classification attributes include whether the NAT supports hairpin connections or not and whether it operates in a deterministic or nondeterministic manner.

This exercise is not another study in comparative taxonomies. A NAT has no standard way in which to advertise its presence, nor does it have any standard way in which to advise protocols or applications of the particular behaviors it applies to packets being passed through the NAT. In the absence of such explicit advertisements of the presence of a NAT, it is left to the application to make the necessary adjustments that allow it to function in the presence of NATs. The aim of behavioral classification is to associate test sequences that expose the presence of a NAT, and to determine its behavior. This allows applications to invoke a test procedure that exposes a particular choice of behaviors of a NAT implementation, and then allows the application to invoke a mode of operation that can operate across the particular NAT.

The choices available to application environments include the use of *agents* as session initiation intermediaries, where the endpoints make initial contact through agents, who then assist in passing binding information to the endpoints, allowing them to directly communicate. Other forms of application behavior need to be invoked when the NAT is endpoint address and port dependant for both binding and filtering. Different application responses are applicable when one endpoint is behind a NAT and when both endpoints are behind NATs. A typical application response in this latter case where both endpoints are behind highly restrictive NATs is for the endpoints to use agents as session intermediaries, so that the application payload is then passed through the intermediaries because an end-to-end pair of NAT bindings cannot be established.

Living in a NAT World

It would be a reasonable conclusion to draw from the previous sections that we are left in the somewhat unsatisfying position of observing that there is near-universal deployment in today's Internet of NAT devices that do not conform to any particular well-defined behavior set. NAT behavior varies across implementations, and NATs have no ability to disclose their particular behaviors to applications that are attempting to compensate for their presence in the path. It is extremely challenging for applications to reliably predict the behavior of the NATs that lie in the path, and more so in the face of multiparty applications, such as interactive game environments, where the application is attempting to understand the level to which this silent intermediary is capable of supporting a relatively promiscuous NAT binding state in terms of external entities that wish to send packets to the local host, and communicate between themselves about the local host as a single entity.

NATs, Client-Server, Peer-to-Peer, and Multiparty Applications

NATs, as a class of devices, have strong associations with a client-server model of communications. As long as all the servers have a consistent external visibility, with stable addresses in terms of an IP address and port number, and as long as clients initiate connections with servers in a fixed two-party communications model using TCP as a transport protocol, and refrain from turning on *IP Security* (IPSec), then NATs generally behave in a relatively stable and unobtrusive manner. Applications that operate conservatively in this limited mode can be unaware of the presence of NATs in their path. The relatively widespread deployment of NATs and the continued use of client-server-based applications on the Internet attests to the capability of the NAT to perform transparently and effectively within the strict confines of this particular mode of communication.

However, peer-to-peer applications are more problematic for NATs, because they have extended the model of a NAT beyond its original realm of capability. If the desire is to continue to support the NAT dynamic binding, but also allow external parties to initiate a communication to a local host, then the NAT ceases to be transparent and unobtrusive, and in this extended environment the NAT transforms itself into an application-visible network element. It is overly presumptuous to claim that NATs have led to the increasing deployment of multiparty applications on the Internet, but certainly multiparty applications have been seen to be useful in circumventing some of the more aggravating shortcomings of NATs in various peer-to-peer realms.

In this latter context, the local party is forced to advertise its willingness to participate in a peer-to-peer realm by communicating with an external agent. The local agent performs a NAT discovery test, and then selects a mode of operation that is consistent with the discovered behaviors of a NAT that may be on the path between the client and the agent. The agent then advertises itself as the local party's intermediary to other peers within the application realm. Attempts to initiate a connection with the local party are directed to the external agent, who then undertakes to perform a rendezvous function in order to establish a session.

Depending on the NATs that may exist between the two parties, the rendezvous function may need to perform a convoluted handshake process, or, in some instances, may not be able to set up a peer-to-peer session at all. This topic of establishing connectivity in the face of NATs in the path is sufficiently complex to warrant a separate examination, and the various techniques and approaches are not examined in this article other than providing some suggestions for further reading.

The salient general observation is that NATs have fueled a new generation of applications that use intermediaries and rendezvous protocols. This shift in application behavior has implied greater attention to security frameworks for applications, because intermediaries represent an additional active element in the trust model. This, in turn, has implied that the application level has to turn to other chains of derivation of trust, because the basic Internet model of some form of persistent identity as being an attribute of an IP address is no longer a workable proposition in the face of NATs. The position we are reaching here is that identity and trust need to be derived from other attributes of the end host and the application that it has invoked.

ICMP

If an *Internet Control Message Protocol* (ICMP) message is passed through NAT, there is not only the outer IP header to consider, but also the ICMP payload. Most ICMP messages contain part of the original IP packet in the body of the message, so for the NAT to behave as transparently as possible, the IP address of the IP header contained in the data part of the ICMP packet should be modified according to the NAT binding state, as well as the IP header Checksum field of this inner packet header.

NATs and IP Fragmentation

NATs that use bindings that include both address and port values do not have a clear and uniform response to fragments of an IP packet. The TCP or UDP header is resident only in the initial IP fragment, and subsequent IP packet fragments do not contain a copy of the transport layer packet header.

Some NATs attempt packet reassembly as if they were the end host, and they perform the NAT translation only when the original IP packet has been reassembled. Of course the reassembled packet may be too large to be forwarded onward, and the NAT may be forced to further fragment the packet. The interplay between this behavior and various forms of path *Maximum Transmission Unit* (MTU) discovery become a source of frustration.

Other NAT packet fragmentation behaviors do not attempt packet reassembly, but rely on a stored packet fragment translation state that directs the translation to be performed on subsequent packet fragments after the initial packet header translation has been performed on the initial IP packet fragment.

This form of behavior has weaknesses in terms of out-of-order fragments, when following fragments are received by the NAT prior to the initial IP packet fragment, and in such cases the NAT often has little choice but to silently discard the out-of-order fragment as untranslatable.

NATs and Application Level Gateways

This brings up one of the more vexing questions regarding NAT behavior, namely, should the NAT include knowledge of the payload of certain applications? Numerous applications, including FTP and the DNS resolution protocol, include IP addresses within the payload of the application. In an effort to achieve complete transparency of operation, some NATs have included *Application Level Gateway* (ALG) functionality for certain applications so that this use of IP addresses in the payload can be detected and altered according to the current NAT translation bindings.

The case of ICMP represents one of the simpler forms of gateway functionality, because it can be performed in the same manner as the basic NAT transform, on a per-packet basis while attempting to maintain retained session state. Payload transformations in the case of a TCP-based application have implications in terms of requiring subsequent alteration of TCP sequence numbers, length fields, and even the repacketization of the payload data stream, given that the data transform required by the address change may imply a change of payload length.

Some units attempt to combine the functionality of a NAT with that of an ALG, such that the NAT is an active intermediary in the transport session. This allows the NAT/ALG to perform "deep" inspection of the packets, and use both application protocol knowledge and per-application-session retained state in order to apply the NAT binding transforms to the application payload as well as to the outer IP packet header.

The most widely deployed application that can use IP addresses in the payload is FTP, where IP addresses are passed in the payload of the control channel in order to allow data sessions to be initiated on distinct transport sessions. The variability and reliability of FTP ALG support in NATs has led to the widespread use of the passive mode of FTP operation, where the data flow is passed within the control session.

A related question is that of the use of IPSec and NATs. IPSec with *Authenticated Header* protection attempts to protect what it believes is the fixed part of the IP packet header, including the source and destination addresses. The NAT changes to the IP packet invalidate the Authentication Header integrity check. Also the NAT changes the IP and UDP or TCP checksums, and this disrupts the *Encapsulating Security Payload* (ESP) function of IPSec. The implication is that IPSec needs to operate upon a TCP or UDP payload, as in the IPSec operating tunnel model, or IPSec carried as a payload within other types of tunnel operation.

It is also the case that NATs today are heavily enmeshed with the UDP and TCP transport protocols. Other transport protocols exist, including the *Streams Control Transport Protocol* (SCTP) and the *Datagram Congestion Control Protocol* (DCCP), and doubtless more transport protocol offerings will follow over time. In each case it is a matter of individual choice how NAT implementations define NAT responses to such additional transport protocols. Although it is tempting to propose that NATs should fall back to an address-only form of binding that was not address-and-port based, this does not appear to be practical guidance. Another aspect of today's NAT deployment is that the most common scenario appears to be that of a single external address and mapping each locally initiated session into a binding that uses this common external IP address and a variable external port number. This means that NATs need to be able to identify and transform port addresses from the Transport Protocol section of the IP header.

Another salient factor here is the common association of NATs and firewalls into a single unit, and the coupling of address utilization compression properties of the NAT with its associated packet-filtering actions. Deploying a NAT at the external interface of a site does lead to more restrictive site filtering outcomes and a more restrictive model of application interaction, where the model attempts to impose the constraint that applications are initiated from within the site, and that unknown or unidentifiable external traffic is considered hostile and should be subject to firewall-based inspection and filtering. From this perspective there is little desire to make more permissive NATs as an isolated exercise, and there is instead a codependence between NAT behaviors and popularly used applications. Applications that work across today's NATs appear to enjoy popular uptake, and applications that enjoy popular uptake appear to determine what forms of traffic pass across NATs.

Popular or not, there are a class of applications that simply cannot work in a "native mode" across NATs, nor can ALGs assist here. These are applications that attempt to impose some level of end-to-end protection on the IP header fields, or use the IP address of the endpoint in a context of some form of persistant identity token. When the NAT alters the IP address, an application that uses strong forms of header validation rejects such packets as corrupted. Within this class of applications and tools, one of the more commonly referenced tools is that of IPSec with Authentication Header. There is a certain sense of irony in the observation that NATs are often seen as part of an overall approach to site security, yet cannot support a "native mode" operation of some of the basic tools that applications could use to support secure end-to-end data transfer.

Views on NATs

It is certainly the case that NATs are very common in todays Internet, and it is worth understanding why NATs have enjoyed such widespread deployment while other technologies appear to be meeting some considerable resistance to widespread deployment. As the original NAT document points out:

"The huge advantage of this approach is that it can be installed incrementally, without changes to either hosts or routers. (A few unusual applications may require changes.) As such, this solution can be implemented and experimented with quickly. If nothing else, this solution can serve to provide temporarily relief while other, more complex and far-reaching solutions are worked out."

—Egevang and Fancis, "Network Address Translator," RFC 1631

More generally, the positive attributes of NATs include the following considerations:

- End hosts and local routers do not change. Whether there is a NAT in place between the local network and the Internet or not, local devices can use the same software and support the same applications. NATs do not require customized versions of operating systems or router images.
- As long as you accept the limitation that sessions must be initiated from the "inside," NATs can work in an entirely transparent fashion for a set of client-server classes of applications.
- If you accept the perspective that services and usage scenarios that are not supported by NATs are "unwelcome" or "unsafe," then NATs can be placed into a role as a component of a site's security architecture, providing protection from attacks launched from the outside toward the inside network.
- NAT conserves its use of public address space.
- NAT allows previously disconnected privately addressed networks to connect to the global Internet without any form of renumbering or host changes—and renumbering networks can be a very time-consuming, disruptive, and expensive operation, or, in other words, renumbering is difficult.
- NAT address space is an effective, provider-independent addressing solution with multihoming capabilities. NAT allows for rapid switching to a different upstream provider, by renumbering the NAT address pool to the new provider's address space. In essence, NATs provide the local network manager with the flexibility of using provider-independent space without having to meet certain size and use requirements that would normally be required for an allocation of public, provider-independent address space.
- NAT allows the network administrator to exercise some control over the form of network transactions that can occur between local hosts and the public network.
- NATs require no local device or application changes. This is perhaps one of the major "features" of NATs, in that the local network requires no changes in configuration to operate behind a NAT.

- NATs do not require a coordinated deployment. There is no transition, and no "flag day" across the Internet. Each local network manager can make an independent decision whether or not to use a NAT. This allows for incremental deployment without mutual dependencies.
- These days the common theme of the public address assignment policy stresses conservative use of address space with minimum waste. The standard benchmark is to be able to show that a target of 80 percent of assigned address space is assigned to a number of connected devices. Achieving such a very high usage rate is a challenging task in many network scenarios, and NATs represent an alternative approach where the local network can be configured using private addresses without reference to the use of public addresses.
- NATs are very widely available and bundled into a large variety of gateway and firewall units. In many units NATs are not an optional extra—they are configured in as a basic item of product functionality.

The market has taken NATs and embraced them wholeheartedly. And in a market-oriented business environment, what is wrong with that?

Unfortunately NATs represent a set of design compromises, and no delving into the world of NATs would be complete without exploring some of their shortcomings. So, after enumerating what are commonly seen as their benefits, it is now necessary to enumerate some of the broken aspects of the world of NATs.

"This solution has the disadvantage of taking away the end-to-end significance of an IP address, and making up for it with increased state in the network."

—Egevang and Francis,
"Network Address Translator," RFC 1631

"An opposing view of NAT is that of a malicious technology, a weed which is destined to choke out continued Internet development. While recognizing there are perceived address shortages, the opponents of NAT view it as operationally inadequate at best, bordering on a sham as an Internet access solution. Reality lies somewhere in between these extreme viewpoints."

—Tony Hain,
"Architectural Implications of NAT," RFC 2993

- First, NATs cannot support applications where the initiator lies on the "outside." The external device has no idea of the address of the local internal device, and, therefore, cannot direct any packets to that device in order to initiate a session. This implies that peer-to-peer services, such as voice, cannot work unaltered in a NAT environment.

- The workaround to this form of shortcoming is to force an altered deployment architecture, where service platforms used by external entities are placed "beside" the NAT, allowing command and control from the interior of the local network, and having a permanent (non-NAT) interface to the external network. Obviously this implies some further centralization of IT services within the NATed site.
- Even this approach does not work well for applications such as voice-over-IP, where the "server" now needs to operate as some form of proxy agent. The generic approach here for applications to traverse NATs in the "wrong" direction is for the inside device to forge a UDP connection to the outside agent, and for the inside device to then establish what NAT translated address has been used, and the nature of the NAT in the path, and then republish this address as the local entity's published service rendezvous point. Sounds fragile? Unfortunately, it is. The other approach is to shift the application to use a set of endpoint identifiers that are distinct from IP addresses, and use a distributed set of "agents" and "helpers" to dynamically translate the application level identifiers into transport IP addresses as required. This tends to create added complexity in application deployment, and also embarks on a path of interdependency that is less than desirable. In summary, workarounds to reestablish a peer-to-peer networking model with NATs tend to be limited, complex, and often fragile.
- The behavior of NATs varies dramatically from one implementation to another. Consequently, it is very difficult for applications to predict or expose the precise behavior of one or more NATs that may exist on the application data path.
- Robust security in IP environments typically operates on an end-to-end model, where both ends include additional information in the packet that can detect attempts to alter the packet in various ways. In IPSec the header part of the packet is protected by the Authentication Header, where an encrypted signature of certain packet header fields is included in the IPSec packet. If the packet header is changed in transit in unexpected ways, the signature check will fail. Obviously IPSec attempts to protect the packet address fields—the very same fields that NATs alter! This leads to the observation that robust security measures and NATs do not mix very well. NATs inhibit implementation of security at the IP level.
- NATs have no inherent failover. NATs are an active in-band mechanism that cannot fail into a safe operating fallback mode. When a NAT goes offline, all traffic through the NAT stops. NATs create a single point where fates are shared in the NAT device maintaining connection state and dynamic mapping information.

- NATs sit on the data path and attempt to process every packet. Obviously bandwidth scaling requires NAT scaling.
- NATs are not backed up by industry-standardized behavior. Although certain NAT-traversal applications make assumptions about the way NATs behave, it is not the case that all NATs necessarily behave in precisely the same way. Applications that work in one context may not necessarily operate in others.
- Multiple NATs can get very confusing with "inside" and "outside" concepts when NATs are configured in arbitrary ways. NATs are best deployed in a strict deployment model of an "inside" being a stub private network and an "outside" of the public Internet. Forms of multiple interconnects, potential loops, and other forms of network transit with intervening NATs lead to very strange failure modes that are at best highly frustrating.
- With NATs there is no clear, coherent, and stable concept of network identity. From the outside these NAT-filtered interior devices are visible only as transient entities.
- Policy-based mechanisms that are based on network identity (for example, *Policy Quality of Service* [QoS]) cannot work through NATs.
- Normal forms of IP mobility are broken when any element behind the NAT attempts to roam beyond its local private domain. Solutions are possible, generally involving specific NAT-related alterations to the behavior of the Home Agent and the mobile device.
- Applications that work with identified devices, or that actually identify devices (such as the *Simple Network Management Protocol* [SNMP] and DNS) require very careful configuration when operating an a NAT environment.
- NATs may drop IP packet fragments in either direction: without complete TCP/UDP headers, the NAT may not have sufficient stored state to undertake the correct header translation.
- NATs often contain ALGs that attempt to be context-sensitive, depending on the source or destination port number. The behavior of the ALGs can be difficult to anticipate, and these behaviors have not always been documented.
- Most NAT implementations with ALGs that attempt to translate TCP application protocols do not perform their functions correctly when the substrings they must translate span across multiple TCP segments; some of them are also known to fail on flows that use TCP option headers, for example timestamps.

From this perspective, NATs are a short-term expediency that is currently turning into a longer-term set of overriding constraints placed on the further evolution of the Internet. Not only do new applications need to include considerations of NAT traversal, but we appear to be entering into a situation where if an application cannot work across NATs, then the application itself fails to gain acceptance. We seem to be locking into a world that is almost the antithesis of the Internet concept. In this NAT-based world, servers reside within the network and are operated as part of the service provider's role, whereas end devices are seen as "dumb" clients, who can establish connections to servers but cannot establish connections between each other. The widespread use of NATs appears to be reinforcing a reemergence of the model of "smart network, dumb clients," whereas others would argue that the network is getting no smarter, it is just that the number of obstacles and amount of network debris is increasing while clients are getting worse at maintaining coherent end-to-end state in the face of such changes.

However, despite their shortcomings, despite the problems NATs create for numerous applications and their users, and despite the continued grappling over a common language to understand how NATs behave, numerous NATs are deployed, and, at least in the IPv4 realm, NATs appear to be a firmly fixed part of the future of the Internet. NATs continue to proliferate in today's Internet.

Moving on with NATs

One commonly held belief is that deployment of IPv6 will eliminate the problem of NATs within the Internet. Certainly it is reasonable to observe that if achieving high address utilization densities is no longer the objective, then there will be plentiful public IPv6 address space and that particular reason to deploy NATs is significantly discounted in an IPv6 realm.

That does not say that IPv6 NATs will not be implemented, nor used. Indeed IPv6 NATs are already available, and they are being used, albeit to some small extent. NATs are, rightly or wrongly, considered to be part of a security solution for a site because of their filtering properties that prevent incoming packets from entering the site unless the NAT already has a permitting binding initiated from the inside. In addition, NATs allow a site to use an internally persistent naming and addressing scheme based on some form of deployment of IPv6 unique *site local* address, and deploy NATs at the edge to create an external view of the site that fits within a provider-based address aggregated view of the IPv6 Internet.

So it would perhaps be too enthusiastic a level of conjecture to suppose that IPv6 will drive away all forms of NAT use in IPv6. It is reasonable to predict that some use of NAT will be seen in IPv6, although many would be highly disappointed if the level of IPv6 NAT use rose to anywhere approaching that of NAT in IPv4.

However, the Internet is still largely a network that uses IPv4 and NATs, and efforts continue along the lines of reducing the amount of friction and frustration in a world in which NATs are prolific. One of the ways to progress here is to treat NAT boxes as yet another instance of Internet middleware, and attempt to apply the same sets of processes to NATs that appear in other instances of middleware. The work of the IETF in the *Middlebox Communication Working Group* uses a model that attempts to expose NATs, as well as firewalls, performance-enhancing proxies, application proxies, and relay agents, to the application, and allows the application to specify the policy that the middlebox should apply. In the case of NATs, this could allow an application to communicate to a NAT that it does not require any form of third-party access, and that a fully symmetric behavior could be applied to the binding without any loss in application functionality. Equally, an application could indicate to the NAT that it expects third parties to be able to use the NAT binding, and that the binding that the NAT will set up for the application should be managed as a port-restricted cone. There is much that could be achieved here that would allow applications to function with some level of determinism, rather than attempting to equip an application with a large and complex toolset of all the relevant techniques of NAT traversal that may be required by the application when confronted by various NAT behaviors.

In the meantime the NAT-behavior guessing game continues. The generic class of techniques that support this function is termed *Unilateral Self-Address Fixing* (UNSAF). This is a process whereby the local entity attempts to determine the address and port by which the entity is known externally, and to determine the characteristics of this association to understand in what contexts the external address may be used as a service rendezvous point for externally initiated communication. Work in this area[10] has exposed many relevant considerations, including a set of deficiencies noted in the previous section.

So, what would a NAT implementation look like if there were standards relating to NAT behaviors and the implementation were to comply with these standards? Numerous efforts have been made to document various forms of network- and application-friendly ways in which NATs could behave, but it would appear that such an effort will require the imprimatur of a standard in order to attain a level of general acceptance from NAT implementations. However, it is possible to predict that any such effort at a "standardized" form of NAT behavior will include the following considerations. The following set of behaviors is based on that enumerated in[13]:

- NATs must show endpoint-independent behavior for UDP-based bindings. This is to ensure that the NAT can support application rendezvous without the need for various multiparty relays and agents.
- NAT should not use port preservation nor port overloading, and should operate in a deterministic manner. Port preservation exposes the NATs to nonstandard behaviors when port preservation cannot be enforced. In addition, NATs must have deterministic behavior.

- A dynamic NAT UDP binding timer should be 5 minutes, and should avoid expiration timers of 2 minutes or less. This is to ensure that the timeout is long enough to avoid excessively frequent timer refresh packets.
- The NAT UDP timeout binding must use a timer refresh based on outbound traffic, and all sessions that use a particular binding should use a common refresh timer. This requirement is a security consideration, in that letting inbound traffic refresh the timer allows an external party to keep a port open on the NAT.
- The NAT filtering function should be address dependant. This represents a balance between security and utility.
- The timeout behavior of the NAT UDP filter must be the same as that of the NAT UDP binding timeout. This is intended to reduce the complexity of applications that are reliant on long-held NAT state.
- The NAT should support hairpin connections, using the external address and port.
- If the NAT includes ALG support, the ALGs should be configurable in terms of being able to turn off the ALG function on a per-application basis.
- NATs should support fragmentation and forwarding of packet fragments.
- NATs must support ICMP *Destination Unreachable* messages, and the ICMP timeout should be greater than 2 seconds.

Learning from NATs

At this stage we can observe a few relevant lessons about NATs:

The first is that we need standards and we rely on standards. For many years the IETF has viewed standardization of NATs and their behavior as being an action that would encourage further deployment of a technology that was apparently considered undesirable. The result has been that NATs have been deployed for reasons entirely unconnected with the IETF and standardization, but because the original specification of NAT behavior was at such a general level each NAT implementor has been forced into making local decisions as to how the NAT should behave under specific circumstances. We now enjoy a network with widespread deployment of an active device that does not have consistent implementations and, in the worst cases, exhibits nondeterministic behaviors. This has made the task of deployment of certain applications on the Internet, including voice-based applications, incredibly difficult.

Whether NATs are good or bad, they would be less of a collective headache today if they shared a common standard core behavior. NATs for IPv6 may be considered to be unnecessary today, and it can be argued they represent no real value to an IPv6 site. But a collection of IPv6 NAT implantations with no common core behavior would constitute a far worse problem to application users. Standardization of technology at least eliminates some of the worst aspects of application level guesswork out of technology deployment.

Secondly, a little bit of security is often far worse than no security. NATs are very poor security devices, and in terms of their behavior with UDP, NATs afford only minor levels of protection. The task of securing a site from various forms of attack and disruption remains one of a careful exercise of assessment of acceptable risk coupled with detailed consideration of site-management functions. NATs are not a quick way out of this effort.

In considering NATs it seems that we are back to the very basics of networking. The basic requirements of any network are "who," "where," and "how," or "identity," "location," and "forwarding." In the case of IP, all these elements were included in the semantics of an IP address, and when addresses get translated dynamically we lose track of IP-level identity across the network. Maybe, just maybe, as we look at the longer-term developments of IP technology, one potential refinement may be the separation of endpoint identity to that of location, and as a potential outcome, NATs could readily manipulate location-based addresses while applications could look to a different token set as a means of establishing exactly who is the other party to the communications.

Of course, if we ever venture down such a path, I trust that such a move toward the use of explicit identities does not generate a complementary deployment of *Network Identity Translators,* or NITs, as an adjunct to the current set of NATs. Too many NITs and NATs will definitely send us all NUTs!

Further Reading

There is no shortage of material on NATs from a wide variety of sources. The following is a list of IETF-related documents, encompassing both published *Request for Comments* (RFCs) and works in progress, that have been circulated as *Internet Drafts.*

Letters to the Editor

Content Networks

Dear Editor,

Christophe Deleuze's article on Content Networks (*The Internet Protocol Journal,* Volume 7, Number 2, June 2004) made me realize that there are very different ways to look at this issue. I would like to use the term *Content Addressable Network* for a network that is used to retrieve information not by specifying its location but the identity of the content itself. The term points to similar concepts in electronics (*Content Addressable Memory*) and storage (*Content Addressable Storage*). One could argue that a Content Addressable Network is in fact a distributed Content Addressable Storage.

In a very real sense the Internet already is content addressable. Several of my non-IT friends use the "Search" field in the *Google* toolbar even for regular URLs, foregoing the Address field in their browsers. In doing so, they simply ignore the distinction between *content* and *location*. It usually gets them where they want to go.

Let's define content as a static binary object, for example, a document, picture, song, or movie. How can we identify content if not by location? We can create a hash of the object as a handle or placeholder. (A hash is the result of a calculation that takes the whole object as input. A good hashing algorithm ensures that if you change a bit in the object, at least one bit in its hash changes too.) If we know the placeholder, we can retrieve a copy of the original object, even if we don't know the location of any of the copies out there on the net. I could mail you the hash of a paper, song, or movie and you would be able to retrieve a copy, although not necessarily from the same place as where I got it. (You might have to pay to get it though!)

Suppose that the Google bot, while traversing the Internet to build its index, calculates the hash for each object it encounters. It can then build an index of all hash codes, relating them to the URLs where they were found. (This requires no change in Google: the hash is just one more word it found in the document). We can then google a hash code to find all occurrences of the object. (You can simulate this today by selecting a line of text from a document and launching a search for that sequence of words. Google will often find multiple copies. Just one line of text is an extremely poor hash, so you may get a few false hits, but in my experience not many.)

Simply by adding these hashes, we have turned the Internet into a Content Addressable Network. If our purpose is to make ourselves independent of any single copy on any particular server, this is all we need. For other applications, the objective is to optimize the network paths to the servers that hold a copy of our object (for example, a movie). We need a metric that tells us which of the listed locations is "closest" to our point of entry. This is complicated by the fact that the Internet is a weird space. The shortest route between Amsterdam and Brussels might well go via London or Paris.

Fortunately, there is a database that keeps track of all the available routes and their cost. It is the *Border Gateway Protocol* (BGP) routing table. BGP divides the Internet in chunks called *Autonomous Systems* or ASs and tracks the cost of the routes to each AS. If the Google bot would record the AS along with each URL, our client system could query our local BGP router (or a proxy holding a copy of its database) to find the AS and thus the copy that is closest in terms of network costs. Note that these costs also reflect policy rules such as peering arrangements between ISPs.

If our objective is to dynamically optimize the load on the servers, we cannot avoid querying (a local subset of) these servers for a bid. Distributing the load over servers in different time zones may sometimes be more important than keeping the transports local. Our client should select a server that is not too busy but no further away than necessary.

The Content Networks as discussed by Christophe Deleuze were created as a commercial offering that would require no cooperation from the clients—in every sense an operator's approach. It is restricted to the case where all copies of the object are published by a single entity. The way ahead is to create protocols for requesting network cost for a list of sites, and service costs from a list of servers, independent of the nature of the object and the servers that hold copies of it.

It may seem more efficient to let the publisher add the hash code to the objects. HTML files would be labeled with a **`<MD5=`** tag, obviating the need for bots and users (for "content bookmarks") to do the calculation. This would allow publishers to change content without changing the hash, to correct typos or remove scenes deemed unsuitable for local viewers. But it would no doubt result in fake objects, purporting to be copies of popular objects but peddling dubious commercial proposals. Creating fake objects is more difficult if the hash code is calculated by an independent and unrecognizable bot, although I'm sure the problem is not completely solved with that.

IPJ Article Identification

Hi,

I noticed that the IPJ page footer only says "The Internet Protocol Journal" but neither the Volume/Issue number, nor the issue date. That makes it a bit hard to correctly reference a given article when you only have a copy of that article and not the whole issue. I propose that you add something like (from the August issue of CACM):

Communications of the ACM August 2004/Vol. 47, No. 8

(I only checked the archived PDF files but I suppose the hardcopy has the same problem.)

—Örjan Petersson
orjan.petersson@logcode.com

We could certainly add the Volume/Issue identifier to the footer, but since this would have to be done retroactively for all 26 issues to date it is probably better to use our soon-to-be-deployed ASCII index. This will allow you to find any article with a simple search. A short sample of the index is shown below.

Fragments

IPv6 Address "Glue" added to the Root DNS Zone

The *Internet Corporation For Assigned Names and Numbers* (ICANN) recently announced that for the first time, an IPv6 nameserver address has been added to the Internet's root DNS zone. This next generation version of the Internet Protocol provides trillions more addresses than the IPv4 system that is in use by most networks today. By taking this significant step forward in the transition to IPv6, ICANN is supporting the innovations through which the Internet evolves to meet the growing needs of a global economy.

On 20 July 2004 at 18:33 UTC the IPv6 AAAA records for the Japan (**.jp**) and Korea (**.kr**) *country code Top Level Domain* (ccTLD) nameservers became visible in the root zone file with serial number 2004072000. It is expected that the IPv6 records for France (**.fr**) will be added shortly. Other requests are pending and will be added in accordance with documented procedure, which was developed through ICANN's unique multi-stakeholder consensus-based approach. See: **http://www.iana.org/procedures/delegation-data.html**

Recognizing the importance of IPv6 to the Internet community, ICANN has coordinated with its *Root Server System Advisory Committee, Top Level Domain* managers, *Security and Stability Advisory Committee,* and other interested parties in careful analysis of this issue. After a period of thorough examination, the decision was made to move forward with deployment of the IPv6 address records in the manner prescribed by the community.

ICANN is the global public-benefit non-profit organization responsible for coordinating the Internet's naming and numbering systems. For more information please visit: **http://www.icann.org**

Formation of Asia Pacific ENUM Engineering Team

China Network Information Center (CNNIC), *Japan Registry Service* (JPRS), *Korea Network Information Center* (KRNIC), *Singapore Network Information Center* (SGNIC) and *Taiwan Network Information Center* (TWNIC) recently announced the formation of the *Asia Pacific ENUM Engineering Team* (APEET), an informal technical project team formed to coordinate and synergize ENUM activities in the Asia Pacific region.

The proposal to form APEET was discussed during an ENUM BoF (Birds-of-a-Feather) session at the *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT) in February 2004. Founding member organizations of APEET shared a common vision that as a collective group, they will be able to achieve greater community awareness and better interoperability of ENUM-based trials.

"ENUM allows IP devices to be assigned a telephone number which is globally interoperable," said James Seng, Chairman of APEET. "It is a key enabling technology for seamless IP Telephony that will greatly benefit the end-users."

Before the formation of APEET, each member organization has been conducting its own ENUM trials, most of which are isolated trials conducted within each member organization's country/region. With the formation of APEET, member organizations will be able to implement technical solutions that facilitate ENUM trials across Asia Pacific.

"We are extremely excited about the formation of this much needed organization," said Hiro Hotta, Director JPRS. "We are ready to bring ENUM trials to the next level."

One of APEET's key project is to implement a live ENUM trial at APRICOT 2005, Kyoto, Japan. The live trial will allow hundreds of APRICOT participants to experience IP Telephony using wireless SIP Phones and calling each another with standard 10-key telephone interface via ENUM. The live trial, believed to be the first of its kind, will serve to demonstrate and educate the technical community on the power, capabilities and feasibility of ENUM together with SIP.

"This looks like one of the most exciting events of 2005 with a demonstration of technologies to rock Asia Pacific," said Richard Shockey, co-Chair of the ENUM Working Group of the IETF.

The formation of APEET has been well received by the Industry. The *Asia Pacific Network Information Centre* (APNIC) has extended its goodwill to host DNS records of **apenum.org**, the selected "golden root" of APEET technical trials. APEET is also fortunate to have individual experts member such as Richard Shockey.

APEET welcomes all Asia Pacific ccTLD administrators (or its designated representatives) to join and contribute towards the success of ENUM adoption in Asia Pacific. For more information, please visit **http://www.apenum.org**

Phill Gross Receives Postel Award

Phill Gross is this year's recipient of the prestigious *Jonathan B. Postel Service Award*. A co-founder of the *Internet Engineering Task Force* (IETF), Gross has been instrumental in defining and shaping the way in which the IETF standards process functions. He was awarded the Postel Service Award in recognition of his early leadership of the IETF and for firmly establishing the principles that are essential for its success. The Postel Award was presented on August 5th, during the 60th meeting of the IETF in San Diego, California.

"The Internet Society is pleased to recognize Phill's significant contribution to the area of Internet standardization by awarding him this year's Postel Award," said Internet Society President and CEO Lynn St.Amour. "The continued success of the IETF's consensus-based processes shows the importance of Phill's pioneering work in developing the IETF's foundations."

According to Steve Crocker, noted Internet authority and chair of this year's Postel award committee, "Many of the IETF's current structures, including Working Groups, Technical Areas, Proceedings and Internet Drafts came about thanks to Phill's dedication and passion for the Internet standards area. And we're delighted to be presenting the award to Phill in San Diego, the location of the first ever IETF meeting back in 1986."

Gross, who is currently Director of Academics and Technology for the Northern Virginia ECPI College of Technology, has worked with the Internet community for over 20 years. His career has taken him from working with government-funded research projects through to networking engineering responsibilities for large corporations and startups, including leading the development of MCI Corporation's first national network.

In 1986 Gross helped found the IETF. He became the first official chair in 1987—a position he held for seven years. During his chairmanship, the IETF evolved from a government-sponsored research group to an industry-wide Internet standards body. As well as contributing to developing the IETF standards process itself, Gross played an active role as co-chair of the IETF Routing and Addressing Working Group. This group led to solutions for growth-related Internet problems and was instrumental in specifying the initial direction for the next generation *Internet Protocol* (IPv6) in RFC 1719. He also served as a member of the *Internet Architecture Board* (IAB) from 1987 to 1996.

Expressing his appreciation for the award, Gross said "It was very gratifying to be there at the beginning and to work with such an incredible group of people. And, working with Jon over the years gives me a special appreciation for the honor that comes with this award."

The Jonathan B. Postel Service Award was established by the Internet Society to honor those who have made outstanding contributions in service to the data communications community. The award is focused on sustained and substantial technical contributions, service to the community, and leadership. With respect to leadership, the nominating committee places particular emphasis on candidates who have supported and enabled others in addition to their own specific actions. The award is named after Dr. Jonathan B. Postel, who embodied all of these qualities during his extraordinary stewardship over the course of a thirty-year career in networking. He served as the editor of the RFC series of notes from its inception in 1969, until 1998. He also served as the ARPANET "Numbers Czar" and the *Internet Assigned Numbers Authority* (IANA) over the same period of time. He was a founding member of the Internet Architecture Board and the first individual member of the Internet Society, where he also served as a trustee. Previous recipients of the Postel Award include Jon himself (posthumously and accepted by his mother), Scott Bradner, Daniel Karrenberg, Stephen Wolff and Peter Kirstein. Where did my copy of IPJ go?

Each time we mail out a new issue of IPJ, a certain number of copies are returned to us as undeliverable by the postal authorities around the globe. These so-called "Nixies" can take as much as a year to arrive back in San Jose, California, and almost all of them are returned without any updated delivery information. Obviously we cannot do much other than delete these records from our database. However, if you tell us when you move, we can make sure your address is up-to-date so that you will receive the next issue of IPJ. You can update your own record using the subscription tool at **`http://www.cisco.com/ipj`** or just send your updates via e-mail to: **`ipj@cisco.com`**

Where did you go?
Do let us know!

A Quarterly Technical Publication for Internet and Intranet Professionals

In This Issue

From The Editor

The electronics industry is full of examples of devices which contain one or two "special-purpose" chips. Your computer probably has a modem that is implemented with a single chip and a few analog components. It probably also contains a dedicated graphics processor responsible for driving your display. In networking, vendors have long since realized that in order to design highly efficient routers or switches, a custom-designed *network processor* is a good solution. We asked Doug Comer to give us an overview of network processors.

Attacks against individual computers on a network have become all too common. Usually these attacks take the form of a virus or worm which arrives via e-mail to the victim's machine. The industry has been relatively quick in responding to such attacks by means of antivirus software, as well as sophisticated filtering of content "on the way in." A more serious form of attack is the *Distributed Denial-of-Service* (DDoS) attack which may render an entire network unusable. Charalampos Patrikakis, Michalis Masikos, and Olga Zouraraki give an overview of the many variants of denial-of-service attacks and what can be done to prevent them.

Although we make every effort to provide you with an error-free journal, mistakes do happen occasionally. Sometimes it takes careful analysis by a reader to spot the mistake, and we are grateful for the correction provided in the "Letter to the Editor" on page 36. Other times, technology just gets in our way, such as when all the non-printing end-of-line and TAB characters became very much "printing"—see page 35 of the printed version of Volume 7, No. 3. At least it didn't show up in the PDF or HTML versions.

Take a moment to visit our Website: **http://www.cisco.com/ipj** and update your mailing address if necessary. You will also find all back issues and index files at the same address.

Network Processors: Programmable Technology for Building Network Systems

by Douglas Comer, Cisco Systems (on leave from Purdue University)

Chip vendors have defined a new technology that can be used to implement packet-processing systems such as routers, switches, and firewalls. The technology offers the advantages of being software-programmable and sufficiently high-speed to accommodate interfaces running at 10 Gbps.

This article provides an overview of the technology, describes the motivations, and presents a brief survey of hardware architectures. It also discusses the relationship between programming and the underlying hardware.

A wide variety of packet-processing systems are used in the Internet, including DSL modems, Ethernet switches, IP routers, *Network Address Translation* (NAT) boxes, *Intrusion Detection Systems* (IDS), Softswitches used for *Voice over IP* (VoIP), and security firewalls. Such systems are engineered to provide maximal functionality and performance (for example, operate at wire speed) while meeting constraints on size, cost, and time to market.

Engineers who design network systems face the additional challenges of keeping designs scalable, general, and flexible. In particular, because industry trends change rapidly, typical engineering efforts must accommodate changes in requirements during product construction and changes in the specification for a next-generation product.

Generations of Network Systems

During the past 20 years, engineering of network systems has changed dramatically. Architectures can be divided broadly into three generations:

- *First generation* (circa 1980s): Software running on a standard processor (for example, an IP router built by adding software to a standard minicomputer),
- *Second generation* (mid 1990s): Classification and a few other functions offloaded from the CPU with special-purpose hardware, and a higher-speed switching fabric replacing a shared bus.
- *Third generation* (late 1990s): Completely decentralized design with *Application-Specific Integrated Circuit* (ASIC) hardware plus a dedicated processor on each network interface offloading the CPU and handling the fast data path.

The change from a centralized to a completely distributed architecture has been fundamental because it introduces additional complexity. For example, in a third-generation IP router, where each network interface has a copy of the routing table, changing routes is difficult because all copies must be coordinated to ensure correctness and the router should not stop processing packets while changes are propagated.

Motivation for Network Processors

Although the demand for speed pushed engineers to use ASIC hardware in third-generation designs, the results were disappointing. First, building an ASIC costs approximately US$1 million. Second, it takes 18 to 22 months to generate a working ASIC chip. Third, although engineers can use software simulators to test ASIC designs before chips are manufactured, networking tasks are so complex that simulators cannot handle the thousands of packet sequences needed to verify the functionality. Fourth, and most important, ASICs are inflexible.

The inflexibility of ASICs impacts network systems design in two ways. First, changes during construction can cause substantial delay because a small change in requirements can require massive changes in the chip layout. Second, adapting an ASIC for use in another product or the next version of the current project can introduce high cost and long delays. Typically, a silicon respin takes an additional 18 to 20 months.

Network-Processor Technology

In the late 1990s as demand for rapid changes in network systems increased, chip manufacturers began to explore a new approach: programmable processors designed specifically for packet-processing tasks. The goal was clear: combine the advantage of software programmability, the hallmark of the first-generation network systems, with high speed, the hallmark of third-generation network systems.

Chip vendors named the new technology *network processors,* and predicted that in the future, most network systems would be constructed using network processors. Of course, before the prediction could come true, vendors faced a tough challenge: programming introduces an extra level of indirection, meaning that functionality implemented directly in hardware always performs faster than the same functionality implemented with software. Thus, to make a network processor fast enough, packet-processing tasks need to be identified and special-purpose hardware units constructed to handle the most intensive tasks.

Interestingly, vendors also face an economic challenge: although an ASIC costs a million dollars to produce, subsequent copies of the chip can be manufactured at very low cost. Thus, the initial development cost can be amortized over many copies. In contrast, purchasing conventional processors does not entail any initial development cost, but vendors typically charge at least an order of magnitude more per unit than for copies of an ASIC. So, vendors must consider a pricing strategy that entices systems builders to use network processors in systems that have many network interfaces with multiple processors per interface.

A Plethora of Architectures

As vendors began to create network processors, fundamental questions arose. What are the most important protocol-processing tasks to optimize? What hardware units should a network processor provide to increase performance? What I/O interfaces are needed? What sizes of instruction store and data store are needed? What memory technologies should be used (for example, *Static Random-Access Memory* [SRAM], *Dynamic Random-Access Memory* [DRAM], or others)? How should functional units on the network-processor chip be organized and interconnected (for example, what on-chip bus infrastructure should be used)?

Interestingly, although they realized that it was essential to identify the basic protocol-processing tasks before hardware could be built to handle those tasks efficiently, chip vendors had little help from the research community. Much effort had been expended considering how to implement specific protocols such as IP or TCP on conventional processors. However, researchers had not considered building blocks that worked across all types of network systems and all layers of the protocol stack. Consequently, in addition to designing network-processor chips, vendors needed to decide which protocol functions to embed in hardware, which to make programmable, and which (if any) to leave for special-purpose interface chips or coprocessors. Finally, chip vendors needed to choose software support including programming language(s), compilers, assemblers, linkers, loaders, libraries, and reference implementations.

Faced with a myriad of questions and possibilities about how to design network processors and the recognition that potential revenue was high if a design became successful, chip vendors reacted in the expected way: each vendor generated a design and presented it to the engineering community. By January 2003, more than 30 chip vendors sold products under the label "network processor."

Unfortunately, the euphoria did not last, and many designs did not receive wide acceptance. Thus, companies began to withdraw from the network-processor market, and by January 2004, fewer than 30 companies sold network processors.

Basic Architectural Approaches

Hardware engineers use three basic techniques to achieve high-speed processing: a single processor with a fast clock rate, parallel processors, and hardware pipelining. Figure 1 illustrates packet flow through a single processor, which is known as an *embedded processor architecture* or a *run-to-completion model*. In the figure, three functions must be performed on each packet.

Figure 1: Embedded Processor Architecture in Which a Single Processor Handles All Packets

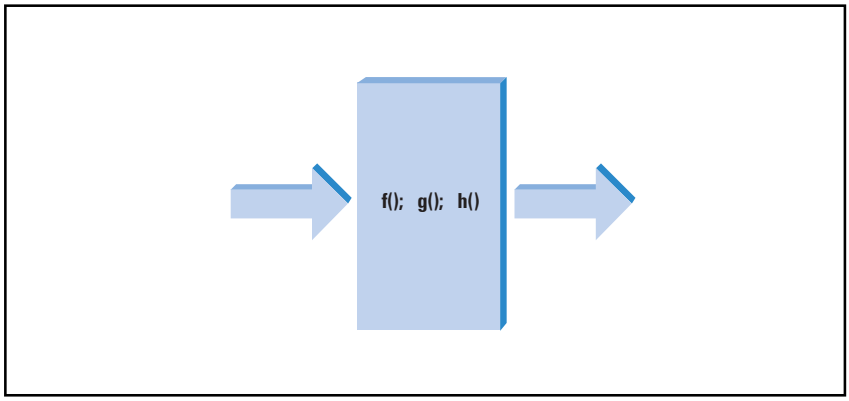

Figure 2 illustrates packet flow through an architecture that uses a parallel approach. A coordination mechanism on the ingress side chooses which packets are sent to which processor. Coordination hardware can use a simplistic round-robin approach in which a processor receives every *N*th packet, or a sophisticated approach in which a processor receives a packet whenever the processor becomes idle.

Figure 2: Parallel Architecture in Which the Incoming Packet Flow Is Divided Among Multiple Processors

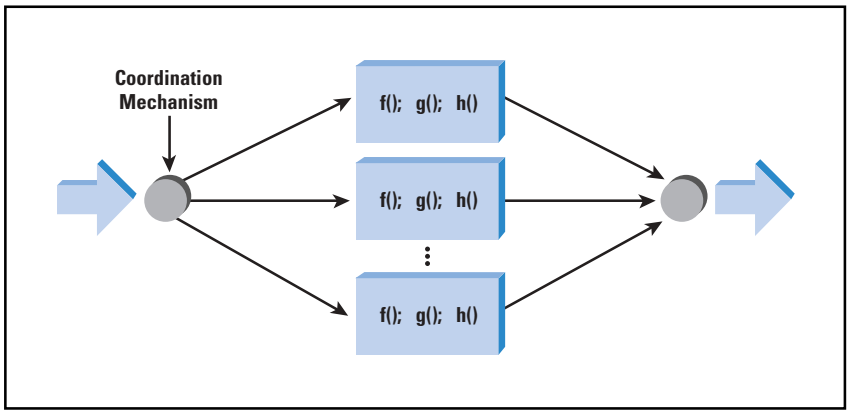

Figure 3 illustrates packet flow through a pipeline architecture. Each packet flows through the entire pipeline, and a given stage of the pipeline performs part of the required processing.

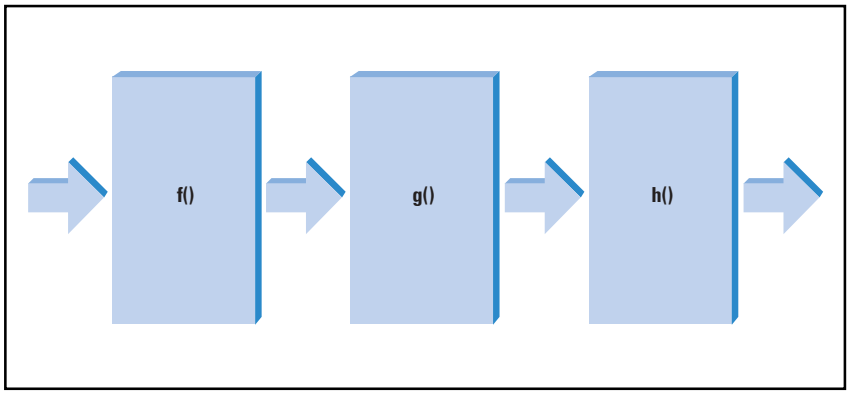
Figure 3: Pipeline Architecture in Which Each Incoming Packet Flows Through Multiple Stages of a Pipeline



As we will see, pipelining and parallelism can be combined to produce hybrid designs. For example, it is possible to have a pipeline in which each individual stage is implemented by parallel processors or a parallel architecture in which each parallel unit is implemented with a pipeline.

Examples of Commercial Architectures

To appreciate the broad range of network-processor architectures, we will examine a few commercial examples. Commercial network processors first emerged in the late 1990s, and were used in products as early as 2000. The examples contained in this article are chosen to illustrate concepts and show broad categories, not to endorse particular vendors or products. Thus, the examples are not necessarily the best, nor the most current.

Augmented RISC (Alchemy)

The first example, from Alchemy Semiconductor (now owned by Advanced Micro Devices), illustrates an embedded processor augmented with special instructions and I/O interfaces.

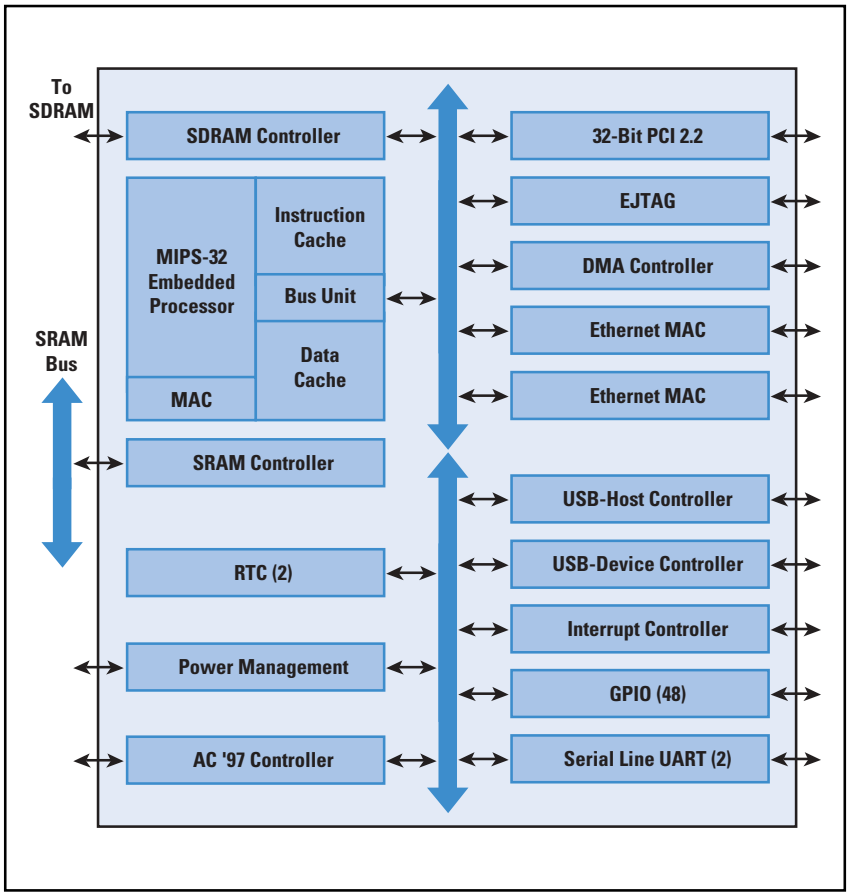


Figure 4: An Example Embedded Processor Architecture: The Processor Has Extra Instructions to Speed Packet Processing

Parallel Processors Plus Coprocessors (AMCC)

A network processor from AMCC uses an architecture with parallel processors plus coprocessors that handle packet-processing tasks. When a packet arrives, one of the parallel processors, called *cores*, handles the packet. The coprocessors are shared—any of the parallel processors can invoke a coprocessor, when needed.

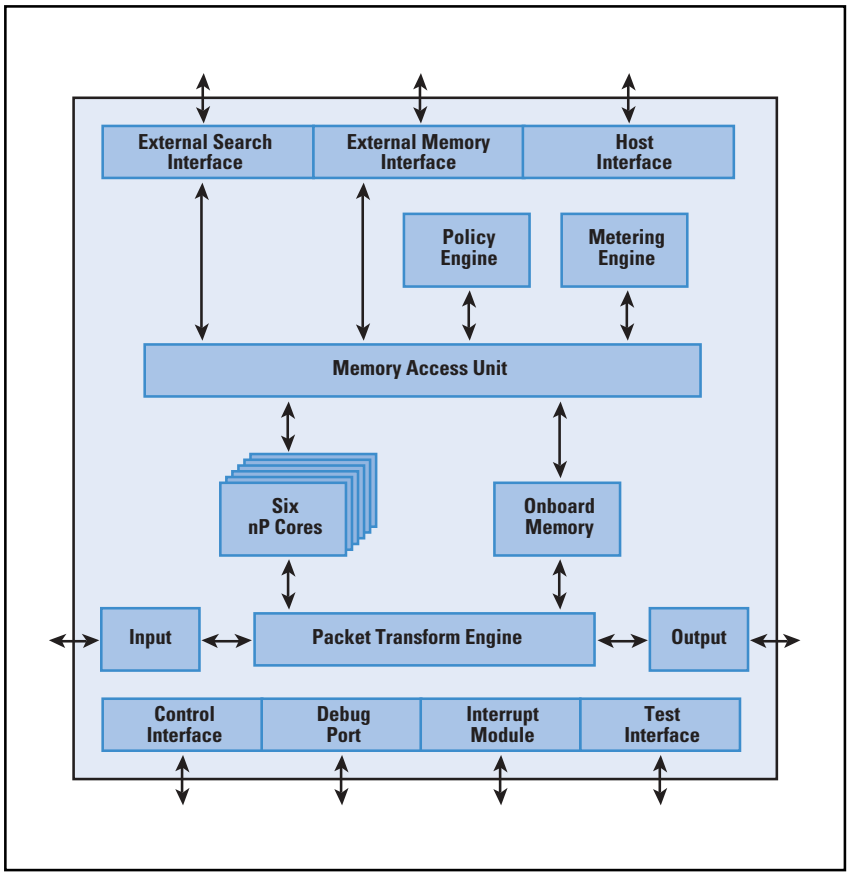

Figure 5: An Example Parallel Architecture that Uses Special-Purpose Coprocessors to Speed Execution

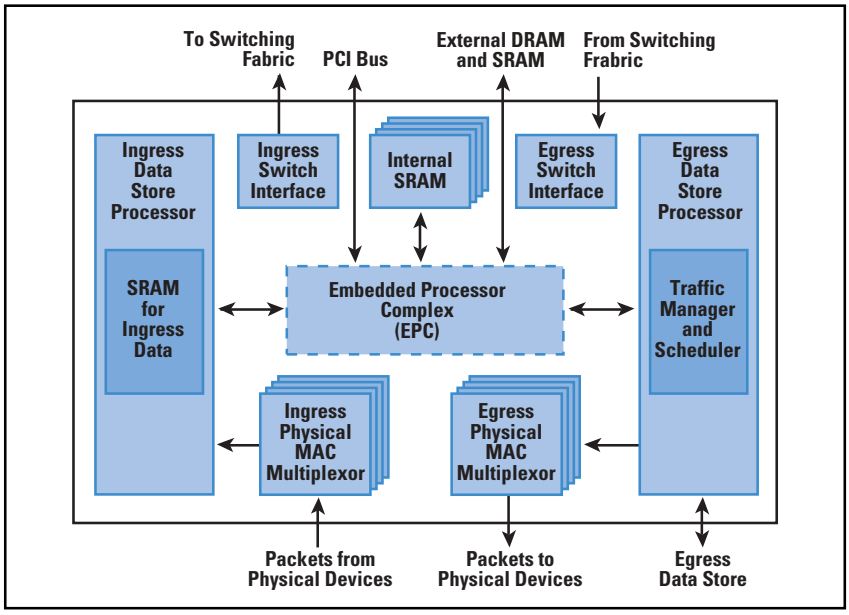
Extensive and Diverse Processors (Hifn)

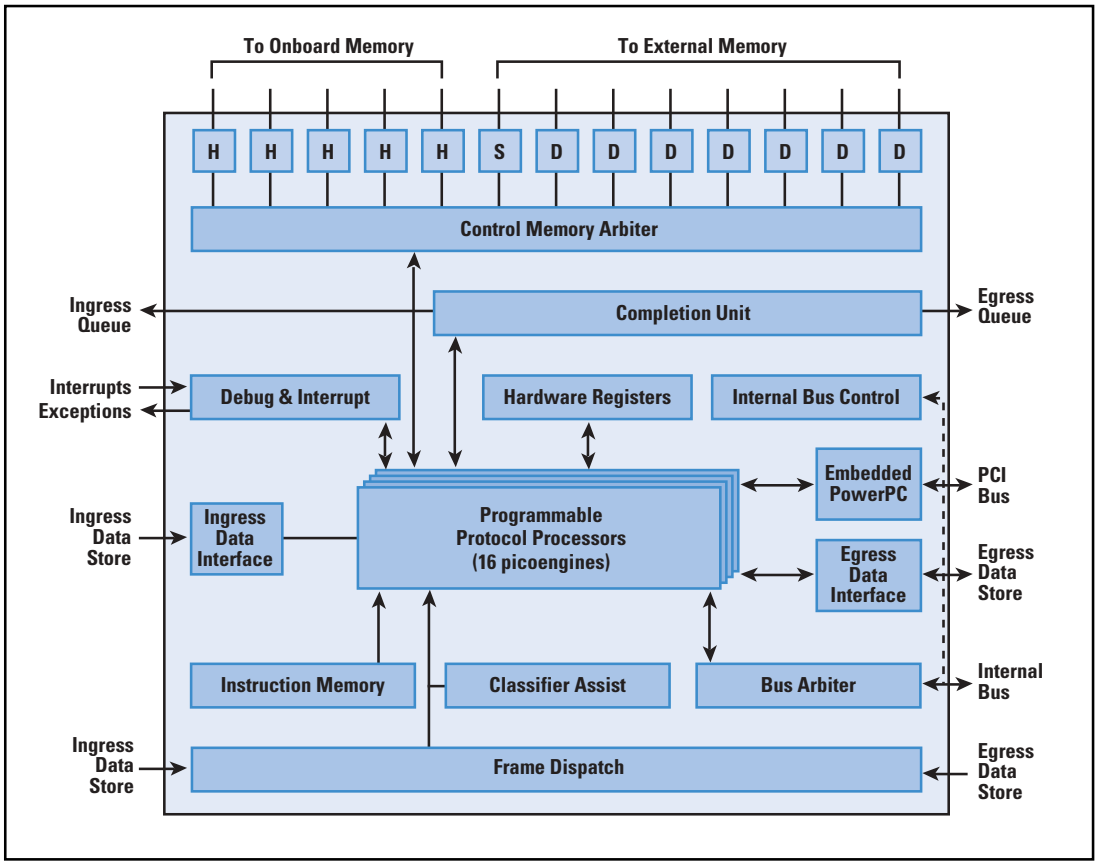
A network processor (named *Rainier*) originally developed by IBM and now owned by Hifn Corporation uses a parallel architecture, and includes a variety of special-purpose and general-purpose processors. For example, the chip provides parallel ingress and egress hardware to handle multiple high-speed network interfaces. It also has intelligent queue-management hardware that enqueues incoming packets in an ingress data store, a switching fabric interface built onto the chip, and an intelligent egress data store. Figure 6 illustrates the overall architecture of the Hifn chip.

Figure 6: An Example Parallel Architecture that Includes Hardware Support for Ingress and Egress Processing as well as Intelligent Queuing



The *Embedded Processor Complex* (EPC) on the Hifn chip contains 16 programmable packet processors, called *picoengines*, as well as various other coprocessors. In addition, the EPC contains an embedded PowerPC to handle control and management tasks. Figure 7 shows a few of the many processors in the EPC.

Figure 7: Structure of the Embedded Processor Complex on the Example Network Processor in Figure 6



Parallel Pipelines of Homogeneous Processors (Cisco)

Although it is not a chip vendor, Cisco Systems uses network processors in its products, and has developed network processors for internal use. One of the more interesting designs employs parallel pipelines of homogeneous processors. Figure 8 illustrates the architecture of the Cisco chip. When a packet enters, the hardware selects one of the pipelines, and the packet travels through the entire pipeline.

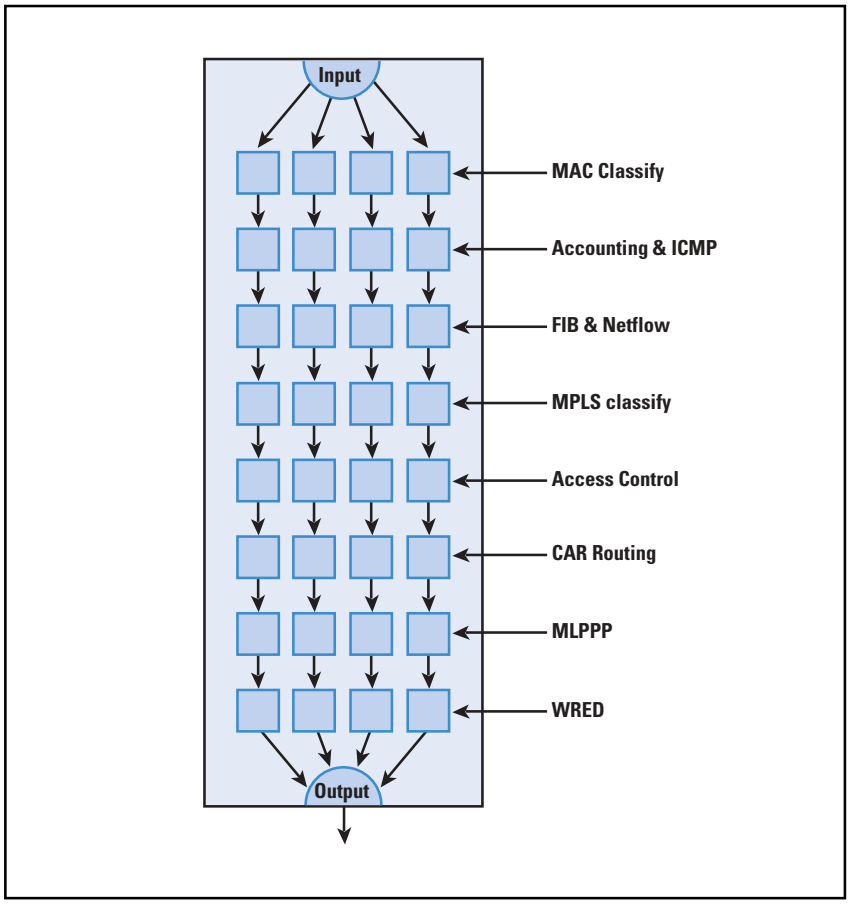


Figure 8: An Example Architecture that Uses Parallel Pipelines of Homogeneous Processors

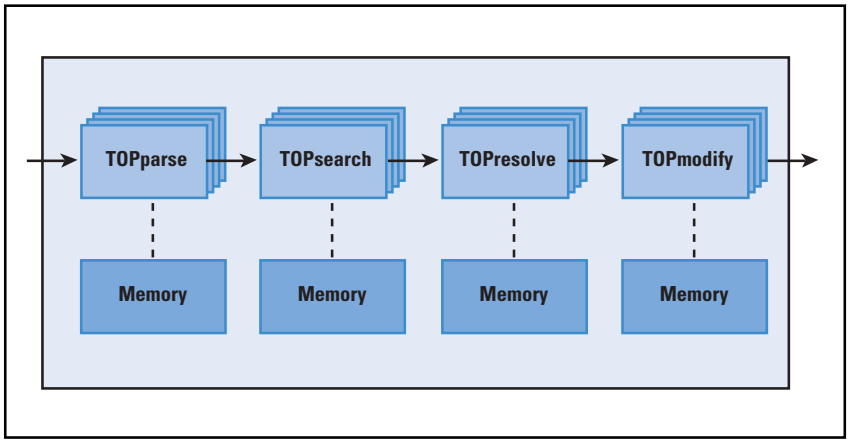
Pipeline of Parallel Heterogeneous Processors (EZchip)

EZchip Corporation sells a network processor that combines pipelining and parallelism by using a four-stage pipeline in which each stage is implemented by parallel processors. However, instead of using the same processor type at each stage, the EZchip architecture employs heterogeneous processors, with the processor type at each stage optimized for a certain task (for example, the processor that runs forwarding code is optimized for table lookup). Figure 9 illustrates the architecture.

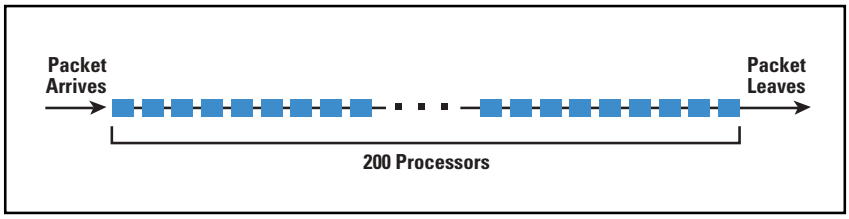
Figure 9: An Example Architecture that Uses a Pipeline of Parallel Stages with Heterogeneous Processors



Extremely Long Pipeline (Xelerated)

Xelerated Corporation sells an interesting network processor that uses a pipelining approach. Unlike other network processors, the Xelerated chip uses an extremely long pipeline of 200 stages. Figure 10 illustrates the overall architecture. To achieve high speed, each stage is limited to executing four instructions per packet.

Figure 10: An Example of an Extremely Long Pipeline with 200 Stages



In fact, the Xelerated architecture is more complex than the figure shows because the pipeline contains special hardware units after every 10 stages that allow external communication (for example, access to external memory or a call to a coprocessor).

More Details and Example Network-Processor Source Code

The previous survey is not meant to be complete. Two notable network processors have been omitted. Agere Systems and Intel each manufacture a network processor. Agere's design consists of a short pipeline that has two basic stages. Agere's architecture is both interesting and unusual because the two stages are composed of unconventional processors. For example, the processor used for classification performs high-speed pattern matching, but does not have conventional instructions for iteration or conditional testing. For details about the Agere network processor see[1], which includes the source code for an example *Differentiated Services* (DiffServ) network system.

Intel's chip uses a parallel approach in which a set of *microengines* are programmed to handle packets. The Intel hardware allows a programmer to pass packets between microengines, meaning a programmer can decide to arrange microengines in a software pipeline. For details about the Intel network processor see[2], which includes the source code for an example NAT implementation.

Programming Network Processors

Although the general idea of building programmable devices seems appealing, most network-processor designs make programming difficult. In particular, to achieve high speed, many designs use low-level hardware constructs and require a programmer to accommodate the hardware by writing low-level code. Many network processors are much closer to a microcontroller than a conventional processor, and are programmed in *microassembly* language. Programmers must be conscious of details such as register banks.

Programming is especially difficult in cases where the network-processor hardware uses explicit parallelism and requires a programmer to plan program execution in such a way that processors do not contend for resources simultaneously or otherwise stall. For example, on one vendor's chip, a packet processor can execute several hundred instructions while waiting for a single memory access to complete. Thus, to achieve high performance, a programmer must start a memory operation, go on with other calculations while the memory operation proceeds, and then check that the operation has completed.

In addition to considering processing, some network processors provide a set of memory technologies, and require a programmer to allocate each data item to a specific memory. A programmer must understand memory latency, the expected lifetime of a data object, and the expected frequency of access as well as properties of the hardware such as memory banks and interleaving.

A few pleasant exceptions exist. For example, Agere Systems provides special-purpose, high-level programming languages to program its network processors. Thus, it is easy to write classification code or traffic-management scripts for an Agere processor. More important, an Agere chip offers implicit parallelism: a programmer writes code as if a single processor is executing the program; the hardware automatically runs multiple copies on parallel hardware units and handles all details of coordination and synchronization.

Another pleasant exception comes from IP Fabrics, which has focused on building tools to simplify programming. Like Agere, IP Fabrics has developed a high-level language that allows a programmer to specify packet classification and the subsequent actions to be taken. The language from IP Fabrics is even more compact than the language from Agere.

Summary

To provide maximal flexibility, ease of change, and rapid development for network systems, chip vendors have defined a new technology known as network processors. The goal is to create chips for packet processing that combine the flexibility of programmable processors with the high speed of ASICs.

Because there is no consensus on which packet-processing functions are needed or which hardware architecture(s) are best, vendors have created many architectural experiments. The basic approaches comprise an embedded processor, parallelism, and hardware pipelining. Commercial chips often combine more than one approach (for example, a pipeline of parallel stages or parallel pipelines).

Programming network processors can be difficult because many network processors provide low-level hardware that requires a programmer to use a microassembly language and handle processor, memory, and parallelism details. A few exceptions exist where a vendor provides a high-level language.

Distributed Denial of Service Attacks

By Charalampos Patrikakis, Michalis Masikos, and Olga Zouraraki
National Technical University of Athens

The Internet consists of hundreds of millions of computers distributed all around the world. Millions of people use the Internet daily, taking full advantage of the available services at both personal and professional levels. The interconnectivity among computers on which the World Wide Web relies, however, renders its nodes an easy target for malicious users who attempt to exhaust their resources and launch *Denial-of-Service* (DoS) attacks against them.

A DoS attack is a malicious attempt by a single person or a group of people to cause the victim, site, or node to deny service to its customers. When this attempt derives from a single host of the network, it constitutes a DoS attack. On the other hand, it is also possible that a lot of malicious hosts coordinate to flood the victim with an abundance of attack packets, so that the attack takes place simultaneously from multiple points. This type of attack is called a *Distributed DoS,* or DDoS attack.

DDoS Attack Description

DoS attacks attempt to exhaust the victim's resources. These resources can be network bandwidth, computing power, or operating system data structures. To launch a DDoS attack, malicious users first build a network of computers that they will use to produce the volume of traffic needed to deny services to computer users. To create this attack network, attackers discover vulnerable sites or hosts on the network. Vulnerable hosts are usually those that are either running no antivirus software or out-of-date antivirus software, or those that have not been properly patched. Vulnerable hosts are then exploited by attackers who use their vulnerability to gain access to these hosts. The next step for the intruder is to install new programs (known as *attack tools*) on the compromised hosts of the attack network. The hosts that are running these attack tools are known as *zombies,* and they can carry out any attack under the control of the attacker. Many zombies together form what we call an *army.*

But how can attackers discover the hosts that will make up the attack network, and how can they install the attack tools on these hosts? Though this preparation stage of the attack is very crucial, discovering vulnerable hosts and installing attack tools on them has become a very easy process. There is no need for the intruder to spend time in creating the attack tools because there are already prepared programs that automatically find vulnerable systems, break into these systems, and then install the necessary programs for the attack. After that, the systems that have been infected by the malicious code look for other vulnerable computers and install on them the same malicious code. Because of that widespread scanning to identify victim systems, it is possible that large attack networks can be built very quickly.

The result of this automated process is the creation of a DDoS attack network that consists of handler (master) and agent (slave, daemon) machines. It can be inferred from this process that another DDos attack takes place while the attack network is being built, because the process itself creates a significant amount of traffic.

Recruiting the Vulnerable Machines

Attackers can use different kinds of techniques (referred to as *scanning techniques*) in order to find vulnerable machines[1][2][3]. The most important follow:

- *Random scanning:* In this technique, the machine that is infected by the malicious code (such a machine can be either the attacker's machine or the machine of a member of their army, such as a zombie) probes IP addresses randomly from the IP address space and checks their vulnerability. When it finds a vulnerable machine, it breaks into it and tries to infect it, installing on it the same malicious code that is installed on itself. This technique creates significant traffic, because the random scanning causes a large number of compromised hosts to probe and check the same addresses. An advantage (to attackers) of this scanning method is that the malicious code can be spread very quickly because the scans seem to come from everywhere. However, the fast rate at which the malicious code is dispersed cannot last forever. After a small period of time, the spreading rate reduces because the number of the new IP addresses that can be discovered is smaller as time passes. This becomes obvious if we consider the analysis of David Moore and Colleen Shannon[4] on the spread of the Code-Red (CRv2) Worm, which uses random scanning to spread itself.
- *Hit-list scanning:* Long before attackers start scanning, they collect a list of a large number of potentially vulnerable machines. In their effort to create their army, they begin scanning down the list in order to find vulnerable machines. When they find one, they install on it the malicious code and divide the list in half. Then they give one half to the newly compromised machine, keep the other half, and continue scanning the remaining list. The newly infected host begins scanning down its list, trying to find a vulnerable machine. When it finds one, it implements the same procedure as described previously, and in this way the hit-list scanning takes place simultaneously from an enduringly increasing number of compromised machines. This mechanism ensures that the malicious code is installed on all vulnerable machines contained in the hit list in a short period of time. In addition, the hit list possessed by a new compromised host is constantly reducing because of the partitioning of the list discussed previously.

  As has been mentioned, the construction of the list is carried out long before the attackers start scanning. For that reason, the attackers can create the list at a very slow rate and for a long period of time. If the attackers conduct a slow scan, it is possible that this activity would not be noticed because a scanning process in a network usually occurs at extremely high frequencies, so a slow scan could occur without anyone realizing that it is a malicious scan.

It should also be mentioned that there are public servers such as the Netcraft Survey[2] that can create such hit lists without scanning.

- *Topological scanning:* Topological scanning uses information contained on the victim machine in order to find new targets. In this technique, an already-compromised host looks for URLs in the disk of a machine that it wants to infect. Then it renders these URLs targets and checks their vulnerability. The fact that these URLs are valid Web servers means that the compromised host scans possible targets directly from the beginning of the scanning phase. For that reason, the accuracy of this technique is extremely good, and its performance seems to be similar to that of hit-list scanning. Hence, topological scanning can create a large army of attackers extremely quickly and in that way can accelerate the propagation of the malicious code.
- *Local subnet scanning:* This type of scanning acts behind a firewall in an area that is considered to be infected by the malicious scanning program. The compromised host looks for targets in its own local network, using the information that is hidden in "local" addresses. More specifically, a single copy of the scanning program is running behind a firewall and tries to break into all vulnerable machines that would otherwise be protected by the firewall. This mechanism can be used in conjunction with other scanning mechanisms: for example, a compromised host can start its scans with local subnet scanning, looking for vulnerable machines in its local network. As soon as it has probed all local machines, it can continue the probing process by switching to another scanning mechanism in order to scan off-local network machines. In that way, an army with numerous zombies can be constructed at an extremely high speed.
- *Permutation scanning:* In this type of scanning, all machines share a common pseudorandom permutation list of IP addresses. Such a permutation list can be constructed using any block cipher of 32 bits with a preselected key[3]. If a compromised host has been infected during either the hit-list scanning or local subnet scanning, it starts scanning just after its point in the permutation list and scans through this list in order to find new targets. Otherwise, if it has been infected during permutation scanning, it starts scanning at a random point. Whenever it encounters an already-infected machine, it chooses a new random start point in the permutation list and proceeds from there. A compromised host can recognize an already-infected machine among noninfected ones, because such machines respond differently than other machines. The process of scanning stops when the compromised host encounters sequentially a predefined number of already-infected machines without finding new targets during that period of time. Then, a new permutation key is produced and a new scanning phase begins. This mechanism serves two major purposes: first, it prevents unnecessary reinfections of the same target because when a compromised host recognizes an already-compromised machine, it changes the way it scans according to the process described previously.

Second, this mechanism maintains the advantages (to attackers) of random scanning, because the scanning of new targets takes place in a random way. Hence, permutation scanning can be characterized as a coordinated scanning with an extremely good performance, because the randomization mechanism allows high scanning speeds.

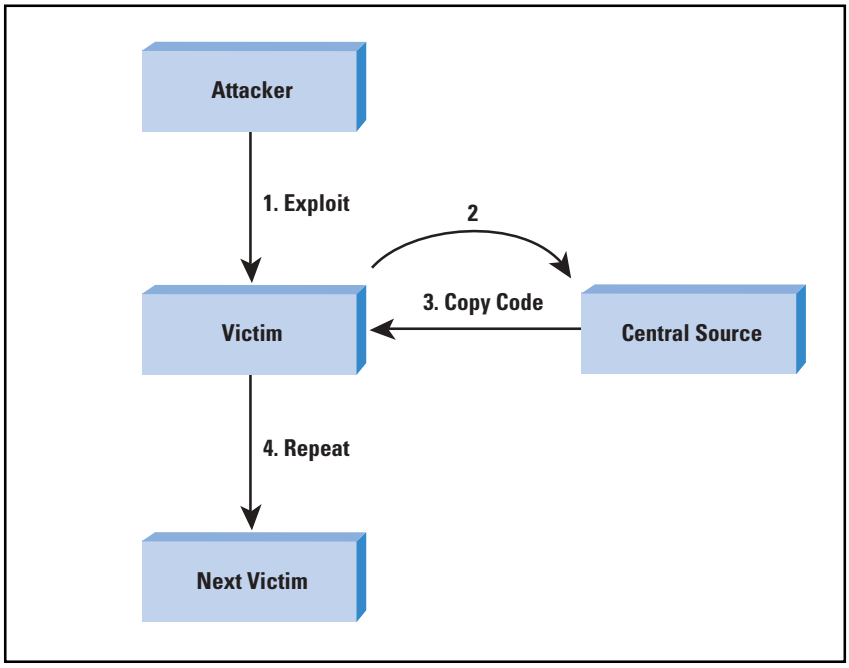
An improved version of permutation scanning is *partitioned permutation scanning*. This type of scanning is a combination of permutation and hit-list scanning. In this scenario, the compromised machine has a permutation list, which is cut in half when it finds a new target. Then it keeps one section of the list and gives the other section to the newly compromised machine. When the permutation list that an infected machine possesses reduces below a predefined level, the scanning scheme turns from partitioned permutation scanning into simple permutation scanning.

Propagating the Malicious Code

We can identify three groups of mechanisms for propagating malicious code and building attack networks[4]:

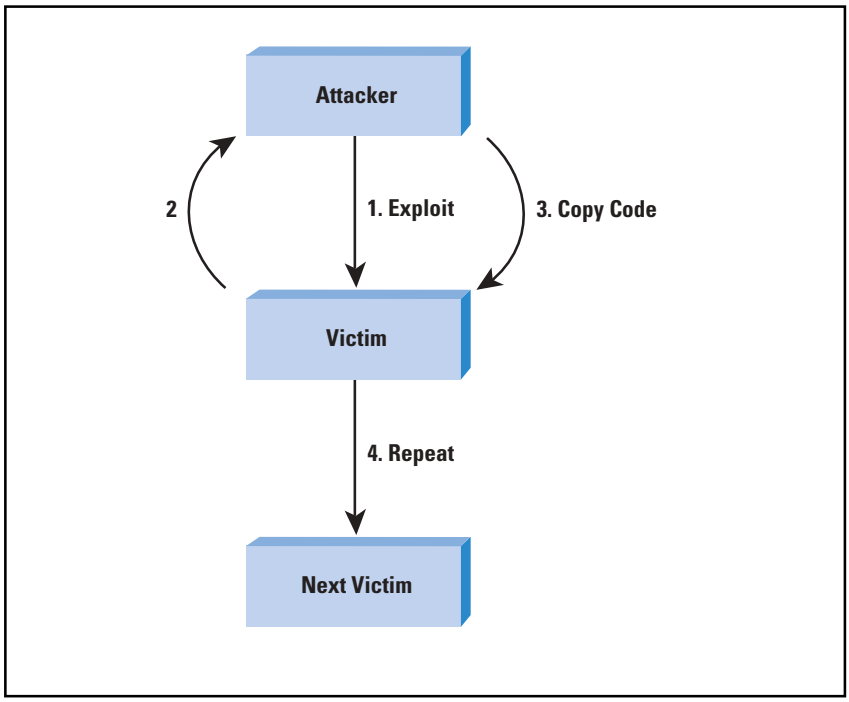
- *Central source propagation:* In this mechanism, after the discovery of the vulnerable system that will become one of the zombies, instructions are given to a central source so that a copy of the attack toolkit is transferred from a central location to the newly compromised system. After the toolkit is transferred, an automatic installation of the attack tools takes place on this system, controlled by a scripting mechanism. That initiates a new attack cycle, where the newly infected system looks for other vulnerable computers on which it can install the attack toolkit using the same process as the attacker. Like other file-transfer mechanisms, this mechanism commonly uses HTTP, FTP, and *remote-procedure call* (RPC) protocols. A graphical representation of this mechanism is shown in Figure 1.

Figure 1: Central Source Propagation



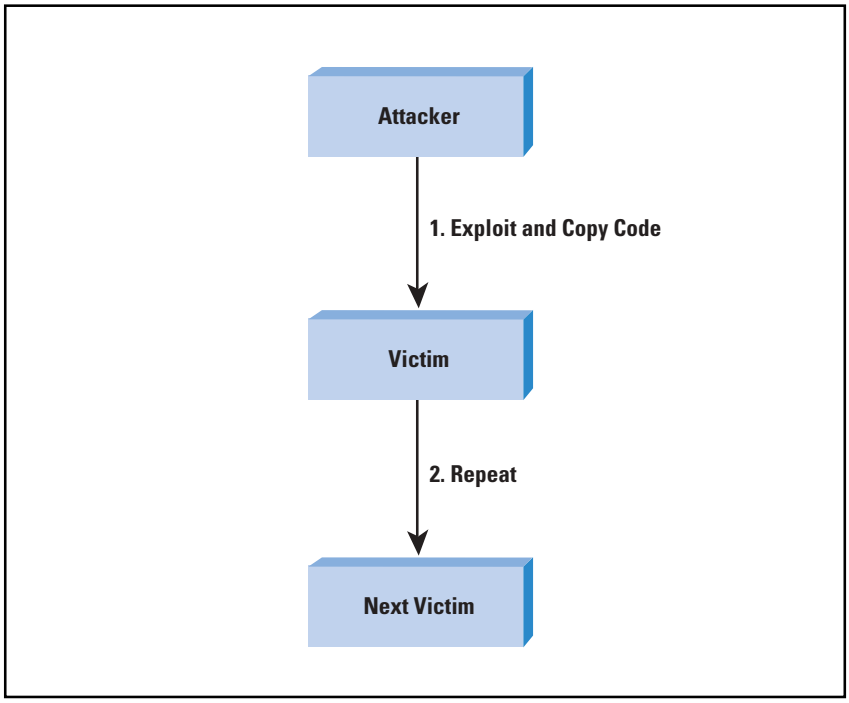
- *Back-chaining propagation:* In this mechanism, the attack toolkit is transferred to the newly compromised system from the attacker. More specifically, the attack tools that are installed on the attacker include special methods for accepting a connection from the compromised system and sending a file to it that contains the attack tools. This back-channel file copy can be supported by simple port listeners that copy file contents or by full intruder-installed Web servers, both of which use the *Trivial File Transfer Protocol* (TFTP). Figure 2 presents the this mechanism:

Figure 2: Back-Chaining Propagation



- *Autonomous propagation:* In this mechanism, the attacking host transfers the attack toolkit to the newly compromised system at the exact moment that it breaks into that system. This mechanism differs from the previously mentioned mechanisms in that the attack tools are planted into the compromised host by the attackers themselves and not by an external file source. Figure 3 shows the autonomous propagation.

Figure 3: Autonomous Propagation



After the construction of the attack network, the intruders use handler machines to specify the attack type and the victim's address and wait for the appropriate moment in order to mount the attack. Then, either they remotely command the launch of the chosen attack to agents or the daemons "wake up" simultaneously, as they had been programmed to do. The agent machines in turn begin to send a stream of packets to the victim, thereby flooding the victim's system with useless load and exhausting its resources. In this way, the attackers render the victim machine unavailable to legitimate clients and obtain unlimited access to it, so that they can inflict arbitrary damage. The volume of traffic may be so high that the networks that connect the attacking machines to the victim may also suffer from lower performance. Hence the provision of services over these networks is no longer possible, and in this way their clients are denied those services. Thus, the network that has been burdened by the attack load can be considered as one more victim of the DDos attack.

The whole procedure for carrying out a DDoS attack is mostly automated thanks to various attack tools. According to[5], the existence of the first controllable DDOS tool was reported by the *CERT Coordination Center* (CERT/CC) in early 1998 and it was called "Fapi." It is a tool that does not provide easy controls for setting up the DDoS network and does not handle networks with more than 10 hosts very well. In mid-1999 Trinoo arrived. Later that year the existence of *Tribe Flood Network* (TFN) and its upgraded version TFN2K (or TFN2000) was reported. Stacheldraht (German for "barbed wire") evolved out of the latter two tools (Trinoo and TFN). This tool is remarkable because it has full-control features and a Blowfish-encrypted control channel for the attacker. Moreover, in early 2000 it mutated into StacheldrahtV4, and later into Stacheldraht v1.666.

However, the development of attack tools did not stop, and many tools were later introduced, such as Mstream, Omega, Trinity, Derivatives, myServer, and Plague[6]. Dave Dittrich and his partners have provided the most comprehensive analyses of the Trinoo, Tribe Flood Network, Stacheldraht, shaft, and mstream DDoS attack tools[7]. Through this work, a lot of malicious code was captured, important observations were made about DDoS attack tools, and solutions were proposed toward detection and defense.

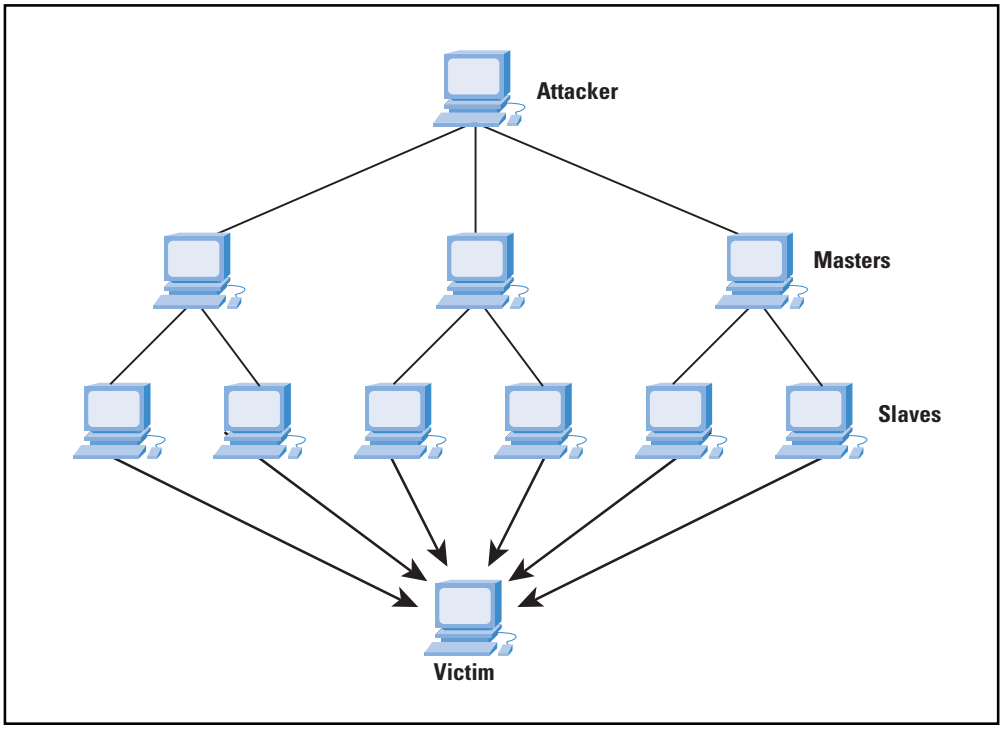
DDoS Attack Taxonomy

As has been already said, a DDoS attack takes place when many compromised machines infected by the malicious code act simultaneously and are coordinated under the control of a single attacker in order to break into the victim's system, exhaust its resources, and force it to deny service to its customers. There are mainly two kinds of DDoS attacks[10]: typical DDoS attacks and *distributed reflector DoS* (DRDoS) attacks. The following paragraphs describe these two kinds analytically.

Typical DDoS Attacks

In a typical DDoS attack, the army of the attacker consists of *master zombies* and *slave zombies*. The hosts of both categories are compromised machines that have arisen during the scanning process and are infected by malicious code. The attacker coordinates and orders master zombies and they, in turn, coordinate and trigger slave zombies. More specifically, the attacker sends an attack command to master zombies and activates all attack processes on those machines, which are in hibernation, waiting for the appropriate command to wake up and start attacking. Then, master zombies, through those processes, send attack commands to slave zombies, ordering them to mount a DDoS attack against the victim. In that way, the agent machines (slave zombies) begin to send a large volume of packets to the victim, flooding its system with useless load and exhausting its resources. Figure 4 shows this kind of DDoS attack.

Figure 4: A DDoS Attack



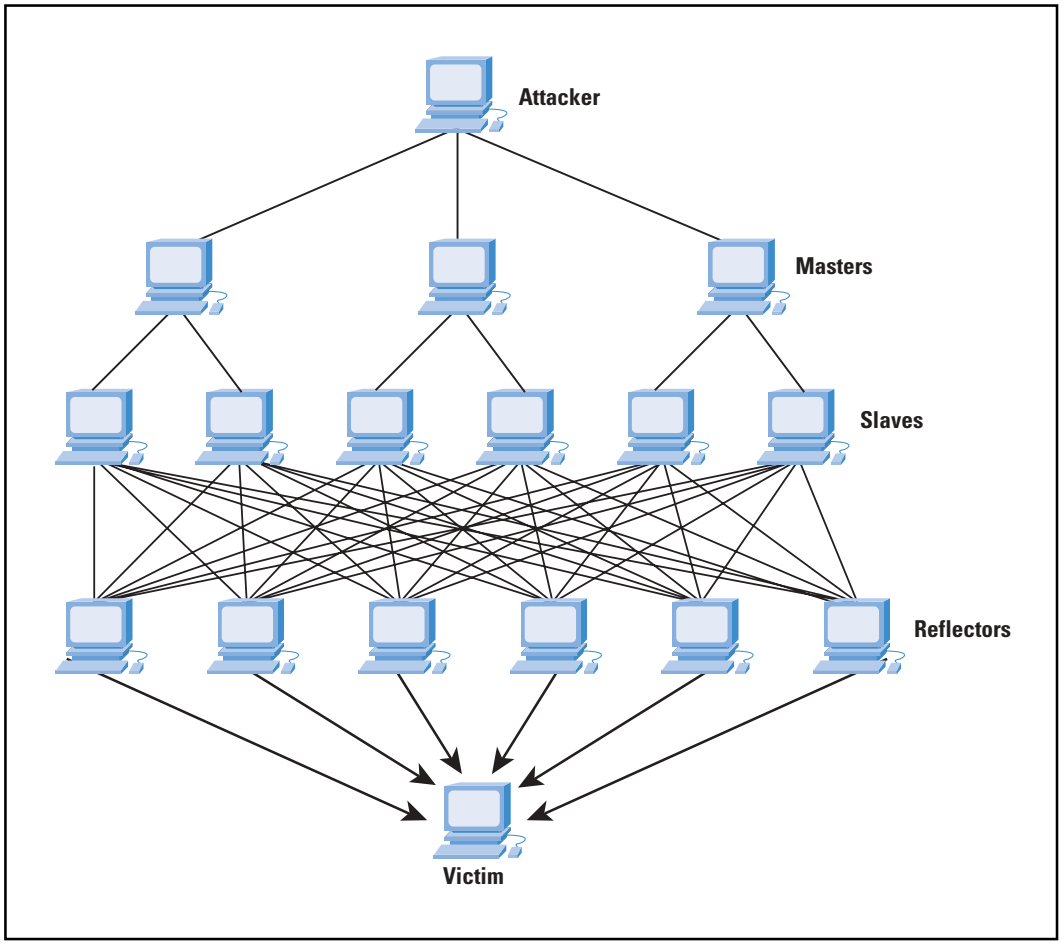
In cases of DDoS attacks, spoofed source IP addresses are used in the packets of the attack traffic. An attacker prefers to use such counterfeit source IP addresses for two major reasons: first, the attackers want to hide the identity of the zombies so that the victim cannot trace the attack back to them. The second reason concerns the performance of the attack. The attackers want to discourage any attempt of the victim to filter out the malicious traffic.

DRDoS Attacks

Unlike typical DDoS attacks, in DRDoS attacks the army of the attacker consists of master zombies, slave zombies, and reflectors[11]. The scenario of this type of attack is the same as that of typical DDoS attacks up to a specific stage. The attackers have control over master zombies, which, in turn, have control over slave zombies. The difference in this type of attack is that slave zombies are led by master zombies to send a stream of packets with the victim's IP address as the source IP address to other uninfected machines (known as *reflectors*), exhorting these machines to connect with the victim. Then the reflectors send the victim a greater volume of traffic, as a reply to its exhortation for the opening of a new connection, because they believe that the victim was the host that asked for it. Therefore, in DRDoS attacks, the attack is mounted by noncompromised machines, which mount the attack without being aware of the action.

Comparing the two scenarios of DDoS attacks, we should note that a DRDoS attack is more detrimental than a typical DDoS attack. This is because a DRDoS attack has more machines to share the attack, and hence the attack is more distributed. A second reason is that a DRDoS attack creates a greater volume of traffic because of its more distributed nature. Figure 5 graphically depicts a DRDoS attack.

Figure 5: A DRDoS Attack



Well-Known DDoS Attacks

This article would be incomplete without reference to some of the most well-known DDoS attacks. Some of the most famous documented DDoS attacks[12][13] are summarized in the following:

- *Apache2:* This attack is mounted against an Apache Web server where the client asks for a service by sending a request with many HTTP headers. However, when an Apache Web server receives many such requests, it cannot confront the load and it crashes.

- *ARP Poison: Address Resolution Protocol* (ARP) Poison attacks require the attacker to have access to the victim's LAN. The attacker deludes the hosts of a specific LAN by providing them with wrong MAC addresses for hosts with already-known IP addresses. This can be achieved by the attacker through the following process: The network is monitored for "arp who-has" requests. As soon as such a request is received, the malevolent attacker tries to respond as quickly as possible to the questioning host in order to mislead it for the requested address.
- *Back:* This attack is launched against an apache Web server, which is flooded with requests containing a large number of front-slash (/) characters in the URL description. As the server tries to process all these requests, it becomes unable to process other legitimate requests and hence it denies service to its customers.
- *CrashIIS:* The victim of a CrashIIS attack is commonly a Microsoft Windows NT IIS Web server. The attacker sends the victim a malformed GET request, which can crash the Web server.
- *DoSNuke:* In this kind of attack, the Microsoft Windows NT victim is inundated with "out-of-band" data (MSG_OOB). The packets being sent by the attacking machines are flagged "urg" because of the MSG_OOB flag. As a result, the target is weighed down, and the victim's machine could display a "blue screen of death."
- *Land:* In Land attacks, the attacker sends the victim a TCP SYN packet that contains the same IP address as the source and destination addresses. Such a packet completely locks the victim's system.
- *Mailbomb:* In a Mailbomb attack, the victim's mail queue is flooded by an abundance of messages, causing system failure.
- *SYN Flood:* A SYN flood attack occurs during the three-way handshake that marks the onset of a TCP connection. In the three-way handshake, a client requests a new connection by sending a TCP SYN packet to a server. After that, the server sends a SYN/ACK packet back to the client and places the connection request in a queue. Finally, the client acknowledges the SYN/ACK packet. If an attack occurs, however, the attacker sends an abundance of TCP SYN packets to the victim, obliging it both to open a lot of TCP connections and to respond to them. Then the attacker does not execute the third step of the three-way handshake that follows, rendering the victim unable to accept any new incoming connections, because its queue is full of half-open TCP connections.
- *Ping of Death:* In Ping of Death attacks, the attacker creates a packet that contains more than 65,536 bytes, which is the limit that the IP protocol defines. This packet can cause different kinds of damage to the machine that receives it, such as crashing and rebooting.

- *Process Table:* This attack exploits the feature of some network services to generate a new process each time a new TCP/IP connection is set up. The attacker tries to make as many uncompleted connections to the victim as possible in order to force the victim's system to generate an abundance of processes. Hence, because the number of processes that are running on the system cannot be boundlessly large, the attack renders the victim unable to serve any other request.
- *Smurf Attack:* In a "smurf" attack, the victim is flooded with *Internet Control Message Protocol* (ICMP) "echo-reply" packets. The attacker sends numerous ICMP "echo-request" packets to the broadcast address of many subnets. These packets contain the victim's address as the source IP address. Every machine that belongs to any of these subnets responds by sending ICMP "echo-reply" packets to the victim. Smurf attacks are very dangerous, because they are strongly distributed attacks.
- *SSH Process Table:* Like the Process Table attack, this attack makes hundreds of connections to the victim with the *Secure Shell* (SSH) Protocol without completing the login process. In this way, the daemon contacted by the SSH on the victim's system is obliged to start so many SSH processes that it is exhausted.
- *Syslogd:* The Syslogd attack crashes the *syslogd* program on a Solaris 2.5 server by sending it a message with an invalid source IP address.
- *TCP Reset:* In TCP Reset attacks, the network is monitored for "tcp-connection" requests to the victim. As soon as such a request is found, the malevolent attacker sends a spoofed TCP RESET packet to the victim and obliges it to terminate the TCP connection.
- *Teardrop:* While a packet is traveling from the source machine to the destination machine, it may be broken up into smaller fragments, through the process of fragmentation. A Teardrop attack creates a stream of IP fragments with their offset field overloaded. The destination host that tries to reassemble these malformed fragments eventually crashes or reboots.
- *UDP Storm:* In a *User Datagram Protocol* (UDP) connection, a character generation ("chargen") service generates a series of characters each time it receives a UDP packet, while an echo service echoes any character it receives. Exploiting these two services, the attacker sends a packet with the source spoofed to be that of the victim to another machine. Then, the echo service of the former machine echoes the data of that packet back to the victim's machine and the victim's machine, in turn, responds in the same way. Hence, a constant stream of useless load is created that burdens the network.

The first DoS attack occurred against Panix, the New York City area's oldest and largest *Internet Service Provider* (ISP), on September 6, 1996, at about 5:30 p.m.[14]. The attack was against different computers on the provider's network, including mail, news, and Web servers, user "login" machines, and name servers. The Panix attack was a SYN Flood attack deriving from random IP addresses and directed toward server *Simple Mail Transfer Protocol* (SMTP) ports. More specifically, Panix's computers were flooded by, on average, 150 SYN packets per second (50 per host), so Panix could not respond to legitimate requests[15]. Because the attackers used spoofed source IP addresses in their packets, the addresses could not be traced and malicious traffic could not be filtered. For that reason the attack was not immediately confronted. The solution was to use a special structure, instead of full *Transmission Control Block* (TCB), to hold half-open connections until the last ACK packet was received. In that way, the listen queue was large enough to keep all the SYN requests before the half-open connection timed out. The timeout, on the other hand, was adjusted to 94 seconds[16]. However, although Panix overcame this attack, the new threat (DoS attacks) made administrators worry.

Problems Caused and Countermeasures

The results of these attacks are disastrous. DDoS attacks have two characteristics: they are both distributed attacks and denial-of-service attacks. Distributed means that they are large-scale attacks having a great impact on the victims. Denial of service means that their goal is to deny the victim's access to a particular resource (service). This is not too difficult because the Internet was not designed with security in mind.

First, available *bandwidth* is one of the "goods" that attackers try to consume. Flooding the network with useless packets, for example, prevents legitimate ICMP echo packets from traveling over the network. Secondly, attackers try to consume *CPU power*. By generating several thousands of useless processes on the victim's system, attackers manage to fully occupy memory and process tables. In this way the victim's computer cannot execute any process and the system breaks down. Using this method, the attacker manages to prevent clients from accessing the victim's services and disrupts the current connections. Finally, attackers try to occupy victims' *services* so that no one else can access them. For example, by leaving TCP connections half open, attackers manage to consume the victim's data structures, and when they do so, no one else can establish a TCP connection with that victim.

The impact of these attacks is catastrophic, especially when victims are not individuals but companies. DDoS attacks prevent victims either from using the Internet, or from being reached by other people. Consequently, when the victim is an ISP, the results of such an attack are far more severe. ISPs' clients will not be served. E-business is also top on the "hit list." Being off line for a few hours could result in the loss of large sums of money for an ISP. Finally, the fact that companies use the Internet more and more for advertising or for providing goods and services increases the severity of such incidents.

Defense Mechanisms

From the beginning, all legitimate users have tried to respond against these threats. University communities and software corporations have proposed several methods against the DDoS threat. Despite the efforts, the solution remains a dream. The attackers manage to discover other weaknesses of the protocols and—what is worse—they exploit the defense mechanisms in order to develop attacks. They discover methods to overcome these mechanisms or they exploit them to generate false alarms and to cause catastrophic consequences.

Many experts have tried to classify the DDoS defense mechanisms in order to clarify them. This classification gives users an overall view of the situation and helps defense-mechanism developers cooperate against the threat. The basic discrimination is between *preventive* and *reactive* defense mechanisms.

Preventive Mechanisms

The preventive mechanisms try to eliminate the possibility of DDoS attacks altogether or to enable potential victims to endure the attack without denying services to legitimate clients. With regard to attack prevention, countermeasures can be taken on victims or on zombies. This means modification of the system configuration to eliminate the possibility of accepting a DDoS attack or participating unwillingly in a DDoS attack. Hosts should guard against illegitimate traffic from or toward the machine. By keeping protocols and software up-to-date, we can reduce the weaknesses of a computer. A regular scanning of the machine is also necessary in order to detect any "anomalous" behavior. Examples of system security mechanisms include monitoring access to the computer and applications, and installing security patches, firewall systems, virus scanners, and intrusion detection systems automatically. The modern trend is toward security companies that guard a client's network and inform the client in case of attack detection to take defending measures. Several sensors monitor the network traffic and send information to a server in order to determine the "health" of the network. Securing the computer reduces the possibility of being not only a victim, but also a zombie. Not being a zombie is very important because it wipes out the attacker's army. All these measures can never be 100-percent effective, but they certainly decrease the frequency and strength of DDoS attacks.

Many other measures can be taken in order to reduce the attacker's army or restrict its "power." Studying the attack methods can lead to recognizing loopholes in protocols. For example, administrators could adjust their network gateways in order to filter input and output traffic. The source IP address of output traffic should belong to the subnetwork, whereas the source IP address of input traffic should not. In this way, we can reduce traffic with spoofed IP addresses on the network[28].

Furthermore, over the last few years, several techniques have been proposed to test systems for possible drawbacks, before their shipment to the market. More precisely, by replacing the components of a system with malicious ones we can discover whether the system can survive an attack situation[38]. If the system breaks down, a drawback has been detected and developers must correct it.

On the other hand, DoS prevention mechanisms enable the victim to endure attack attempts without denying service to legitimate clients. Until now, two methods have been proposed for this scenario. The first one refers to policies that increase the privileges of users according to their behavior. When users' identities are verified, then no threat exists. Any illegitimate action from those users can lead to their legal prosecution. The second method is usually too expensive; it involves increasing the effective resources to such a degree that DDoS effects are limited. Most of the time application of such a measure is impossible.

Reactive Mechanisms

The reactive mechanisms (also referred to as *Early Warning Systems*) try to detect the attack and respond to it immediately. Hence, they restrict the impact of the attack on the victim. Again, there is the danger of characterizing a legitimate connection as an attack. For that reason it is necessary for researchers to be very careful.

The main detection strategies are *signature detection, anomaly detection,* and *hybrid systems*. Signature-based methods search for patterns (signatures) in observed network traffic that match known attack signatures from a database. The advantage of these methods is that they can easily and reliably detect known attacks, but they cannot recognize new attacks. Moreover, the signature database must always be kept up-to-date in order to retain the reliability of the system.

Anomaly-based methods compare the parameters of the observed network traffic with normal traffic. Hence it is possible for new attacks to be detected. However, in order to prevent a false alarm, the model of "normal traffic" must always be kept updated and the threshold of categorizing an anomaly must be properly adjusted.

Finally, hybrid systems combine both these methods. These systems update their signature database with attacks detected by anomaly detection. Again the danger is great because an attacker can fool the system by characterizing normal traffic as an attack. In that case an *Intrusion Detection System* (IDS) becomes an attack tool. Thus IDS designers must be very careful because their research can boomerang.

After detecting the attack, the reactive mechanisms respond to it. The relief of the impact of the attack is the primary concern. Some mechanisms react by limiting the accepted traffic rate. This means that legitimate traffic is also blocked. In this case the solution comes from traceback techniques that try to identify the attacker. If attackers are identified, despite their efforts to spoof their address, then it is easy to filter their traffic. Filtering is efficient only if attackers' detection is correct. In any other case filtering can become an attacker's tool.

The University of Washington provides an example of attack detection. Dave Dittrich and his team of 40 people discovered that more than 30 of their systems were zombies exploited by a single attacker[39]. By monitoring network traffic, Dittrich's team located directory and file names uncommon to the Windows operating systems the attacker ran on the network, as well as the port through which all these files were running communications.

Difficulties in Defending

Development of detection and defending tools is very complicated. Designers must think in advance of every possible situation because every weakness can be exploited. Difficulties involve:

- DDoS attacks flood victims with packets. This means that victims cannot contact anyone else in order to ask for help. So it is possible for a network neighbor to be attacked, but nobody would know it and nobody can help. Consequently, any action to react can be taken only if the attack is detected early. But can an attack be detected early? Usually traffic flow increases suddenly and without any warning[34][35][36]. For this reason defense mechanisms must react quickly.
- Any attempt of filtering the incoming flow means that legitimate traffic will also be rejected. And if legitimate traffic is rejected, how will applications that wait for information react? On the other hand, if zombies number in the thousands or millions, their traffic will flood the network and consume all the bandwidth. In that case filtering is useless because nothing can travel over the network.
- Attack packets usually have spoofed IP addresses. Hence it is more difficult to trace back to their source. Furthermore, it is possible that intermediate routers and ISPs may not cooperate in this attempt. Sometimes attackers, by spoofing source IP addresses, create counterfeit armies. Packets might derive from thousands of IP addresses, but zombies number only a few tens, for example.
- Defense mechanisms are applied in systems with differences in software and architecture. Also systems are managed by users with different levels of knowledge. Developers must design a platform independent of all these parameters.[37]

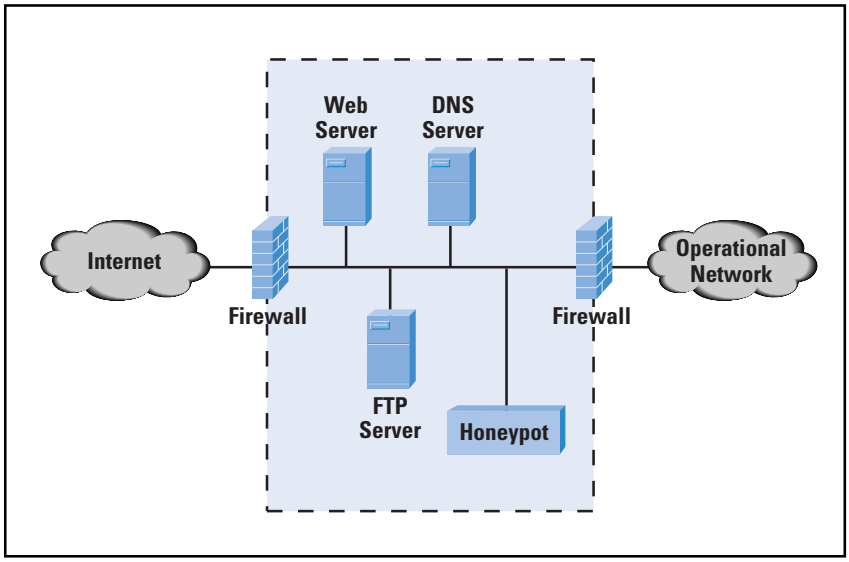
Modern Tendencies in Defending Against DDoS Attacks

Until now, developers have not managed to develop a 100-percent-effective defense mechanism. All mechanisms that have been presented either can confront only specific DDoS attacks or are being finally compromised by the attackers. Therefore, developers are currently working on DDoS diversion systems. *Honeypots* are the best representative of this category (See Figure 6).

Honeypots

There are two basic types of honeypots: *low-interaction honeypots* and *high-interaction honeypots*. The first ones refer to emulating services and operating systems. It is easy and safe to implement them. Attackers are not allowed to interact with the basic operating system, but only with specific services. For that reason, this type of honeypot cannot provide detailed informations for attackers' actions and they can easily be detected. However, they can detect communication attempts toward unused IP addresses. In that case an alarm is triggered, warning that someone is trying to compromise or attack the network. But what happens if the attack is not directed against the emulated service?

Figure 6: Honeypot



The answer comes from high-interaction honeypots. In [41], Honeynet is proposed. Honeynet is not a software solution that can be installed on a computer but a whole architecture, a network that is created to be attacked. Within this network, every activity is recorded and attackers are being trapped. Encrypted SSH sessions, e-mails, file uploads, and every possible attacker's action is captured. Moreover, a Honeywall gateway allows incoming traffic, but controls outgoing traffic using intrusion prevention technologies. This allows the attacker to interact with Honeynet systems, but prevents the attacker from harming other non-Honeynet systems. By studying the captured traffic, researchers can discover new methods and tools and they can fully understand attackers' tactics. However, Honeynet systems are more complex to install and deploy and the risk is increased as attackers interact with real operating systems and not with emulations. But what would happen if someone did compromise such a system? The consequences could be disastrous.

Route Filter Techniques

Different suggestions for defending against DDoS attacks derive from the *Border Gateway Protocol* (BGP) community. When routing protocols were designed, developers did not focus on security, but effective routing mechanisms and routing loop avoidance. Early on, attackers started directing their attention towards routers. By gaining access to a router, they could direct the traffic over bottlenecks, view critical data, and modify them. Cryptographic authentication mitigates these threats. Because of neighbor authentication, the routing update comes from a trusted source and there is no possibility that someone can give routers invalid routing information in order to compromise a network. On the other hand, routing filters are necessary for preventing critical routes and subnetworks from being advertised and suspicious routes from being incorporated in routing tables. In that way, attackers do not know the route toward critical servers and suspicious routes are not used.

Two other route filter techniques, *blackhole routing* and *sinkhole routing,* can be used when the network is under attack. These techniques try to temporarily mitigate the impact of the attack. The first one directs routing traffic to a null interface, where it is finally dropped. At first glance, it would be perfect to "blackhole" malicious traffic. But is it always possible to isolate malicious from legitimate traffic? If victims know the exact IP address being attacked, then they can ignore traffic originating from these sources. This way, the attack impact is restricted because the victims do not consume CPU time or memory as a consequence of the attack. Only network bandwidth is consumed. However, if the attackers' IP addresses cannot be distinguished and all traffic is blackholed, then legitimate traffic is dropped as well. In that case, this filter technique fails.

Sinkhole routing involves routing suspicious traffic to a valid IP address where it can be analyzed. There, traffic that is found to be malicious is rejected (routed to a null interface); otherwise it is routed to the next hop. A sniffer on the sinkhole router can capture traffic and analyze it. This technique is not as severe as the previous one. The effectiveness of each mechanism depends on the strength of the attack. Specifically, sinkholing cannot react to a severe attack as effectively as blackholing. However, it is a more sophisticated technique, because it is more selective in rejecting traffic.

Filtering malicious traffic seems to be an effective countermeasure against DDoS. The closer to the attacker the filtering is applied, the more effective it is. This is natural, because when traffic is filtered by victims, they "survive," but the ISP's network is already flooded. Consequently, the best solution would be to filter traffic on the source; in other words, filter zombies' traffic.

Until now, three filtering possibilities have been reported concerning criteria for filters. The first one is filtering on the *source address*. This one would be the best filtering method, if we knew each time who the attacker is. However, this is not always possible because attackers usually use spoofed IP addresses. Moreover, DDoS attacks usually derive from thousands of zombies and this makes it too difficult to discover all the IP addresses that carry out the attack. And even if all these IP addresses are discovered, the implementation of a filter that rejects thousands of IP addresses is practically impossible to deploy.

The second filtering possibility is filtering on the *service*. This tactic presupposes that we know the attack mechanism. In this case, we can filter traffic toward a specific UDP port or a TCP connection or ICMP messages. But what if the attack is directed toward a very common port or service? Then we must either reject every packet (even if it is legitimate) or suffer the attack.

Finally, there is the possibility of filtering on the *destination address*. DDoS attacks are usually addressed to a restricted number of victims, so it seems to be easy to reject all traffic toward them. But this means that legitimate traffic is also rejected. In case of a large-scale attack, this should not be a problem because the victims will soon break down and the ISP will not be able to serve anyone. So filtering prevents victims from breaking down by simply keeping them isolated.

Fred Baker and Paul Ferguson developed an technique called *Ingress Filtering* for mitigating DoS attacks (and, later, DDoS attacks too). After the Panix attack and a few other attacks, Paul Ferguson wrote RFC 2267[42], which became *Best Current Practices* (BCP) 38 in RFC 2827[43]. This RFC presents a method for using ingress traffic filtering against DoS attacks that use forged IP addresses and try to be propagated from "behind" an ISP's aggregation point. This method prevents the attack from forged source addresses, but nothing can be done against an attack from a valid source address. However, in that case, if the attack is detected, it is easy to trace the attacker. Finally, although this solution allows the network to protect itself from other attacks too (for example, spoofed management access to networking equipment), it can also create some problems, for example, with multihoming.

For that reason, RFC 2827 was recently (March 2004) updated by Fred Baker in BCP 84/ RFC 3704[44]. This RFC describes and evaluates the current ingress filtering mechanisms, examines some implementation matters related to ingress filtering, and presents some solutions to ingress filtering with multihoming. According to this RFC, ingress filtering should be implemented at multiple levels in order to prohibit the use of spoofed addresses and to make attackers more traceable, even if asymmetric/multihomed networks are presented. However, although Ferguson's work was published a long time ago, service providers in some cases ignore his suggestions.

Hybrid Methods and Guidelines

Currently researchers try to combine the advantages from all the methods stated previously in order to minimize their disadvantages. As a result, several mechanisms that implement two or more of these techniques are proposed for mitigation of the impact of DDoS attacks. The best solution to the DDoS problem seems to be the following: victims must detect that they are under attack as early as possible. Then they must trace back the IP addresses that caused the attack and warn zombies administrators about their actions. In that way, the attack can be confronted effectively.

However, as we saw previously, this is currently impossible. The lack of a 100-percent-effective defending tool imposes the necessity of private alerts. Users must care for their own security. Some basic suggestions follow:

- Prevent installation of distributed attack tools on our systems. This will help to restrict the zombies army. Several tasks also need to be performed. First, keep protocols and operating systems up-to-date. We can prevent system exploitation by eliminating the number of weaknesses of our system.
- Use firewalls in gateways to filter incoming and outgoing traffic. Incoming packets with source IP addresses belonging to the subnetwork and outgoing packets with source IP addresses not belonging to the subnetwork are not logical.
- Deploy IDS systems to detect patterns of attacks.
- Deploy antivirus programs to scan malicious code in our system.

Further Thoughts

The Internet is not stable—it reforms itself rapidly. This means that DDoS countermeasures quickly become obsolete. New services are offered through the Internet, and new attacks are deployed to prevent clients from accessing these services. However, the basic issue is whether DDoS attacks represent a network problem or an individual problem—or both. If attacks are mainly a network problem, a solution could derive from alterations in Internet protocols. Specifically, routers could filter malicious traffic, attackers could not spoof IP addresses, and there would be no drawback in routing protocols. If attacks are mostly the result of individual system weaknesses, the solution could derive from an effective IDS system, from an antivirus, or from an invulnerable firewall. Attackers then could not compromise systems in order to create a "zombies" army. Obviously, it appears that both network and individual hosts constitute the problem. Consequently, countermeasures should be taken from both sides. Because attackers cooperate in order to build the perfect attack methods, legitimate users and security developers should also cooperate against the threat. The solution will arise from combining both network and individual countermeasures.

Letter to the Editor

Ole,

I was reading your latest issue of IPJ (Volume 7, No. 3, September 2004) and I could be wrong but I think you mis-typed an explanation about the STUN protocol. On page 12, 3rd paragraph, last sentence, it reads: "A received response indicates the presence of a port-restricted cone, and the lack of a response indicates the presence of a restricted cone."

According to the definitions you gave about "restricted cone" and "port-restricted cone" on pages 10 and 11. Shouldn't this sentence instead read: "A received response indicates the presence of a restricted cone, and the lack of a response indicates the presence of a port-restricted cone."

—Ryan Liles
ryanliles@hotmail.com

The author responds:

Ryan is correct, there is an error here in the text.

The flow control of the sequence of STUN tests is detailed in Figure 9 of the article. The test referred to here is to determine if the NAT is a restricted cone NAT, or a port-restricted cone NAT.

The restricted cone NAT, in Figure 7, is one where the NAT binding is accessible using any source port number on the external host when responding to a UDP packet from the internal sending host.

The port-restricted cone NAT, in Figure 8, is one where the NAT binding is accessible using the same port number as originally used by the internal lost host, and this binding is accessible from any external IP address.

The test referenced in this section, as per Figure 9, is one where the local host requests the external agent to respond using the same port number, but an altered source address. The text should read "This fourth request includes a control flag to direct the STUN server to respond using the alternate IP address, but with the same port value," in which case the interpretation of the response—that a response indicates the presence of a port-restricted cone NAT and the lack of response indicates the presence of a restricted cone NAT—would be correct.

Ryan is also correct in that if the test is performed the other way, requesting the agent to use the same IP address, but with the alternate port value, then the opposite interpretation would hold, namely that a response indicates the presence of a restricted cone NAT, and the lack of a response would indicate the presence of a port-restricted cone NAT, as Ryan points out.

Thanks to Ryan for following through this rather complex explanation of the STUN algorithm and spotting this error.

Regards,

—Geoff Huston, APNIC

Book Review

The IP Multimedia Subsystem

The IP Multimedia Subsystem—Merging the Internet and the Cellular Worlds, by Gonzalo Camarillo and Miguel A. Garcia-Martin, John Wiley & Sons, 2004. ISBN 0470 87156 3.

The Internet and the cellular telephony system are the two most influential communication systems of the last half century. That the telecommunications industry would attempt to merge them into a single system was inevitable. The potential benefits are compelling—a single packet-based communication system with the capability to carry voice, video and data while providing ubiquitous wireless access and global mobility. The resulting system architecture is called the *Internet Multimedia Subsystem* (IMS) and is described comprehensively in this volume by Gonzalo Camarillo and Miguel A. Garcia Martin.

A "merging" of the two systems is only superficially what has happened. In practice, the IMS is an "embrace and extend" exercise which adapts the IP protocol suite to the existing architecture of the cellular telephony system. The cellular industry has taken a broad collection of IP protocols and mapped them onto their existing architecture, effecting a "protocol transplant" into an environment somewhat different from the Internet. Among the protocols imported are IPv6, SIP, DHCP, DNS, SDP, RTP, IPSec, and DIAMETER. Many are adopted unaltered; some are profiled by introducing new configuration data and rules; others are extended in various ways. The authors navigate their way through the various parts of the system with clarity and confidence. They can speak with authority on the subject—both were major contributors to the design through their key roles in the IETF and 3GPP (*Third Generation Partnership Project*—the standardization body for third generation cellular systems).

The book is clearly written and logically organized. The first part explains the reasoning behind adopting Internet-style packet networking for cellular mobile systems and describes the evolution of the standardization efforts. Although interesting, much of this material can be skimmed by those only interested in the meaty technical material which follows. The authors then explain the general principles behind the IMS architecture, including how various requirements of the cellular telephony industry drove the choices, and particularly the perceived need to extend and adapt the protocols rather than use them as deployed on the Internet. The majority of the book is devoted to ex-plaining in considerable technical depth how the protocols have been modified and how they are intended to work when IMS is successfully deployed. While not for the faint of heart, the writing is extremely clear and logical and hence should be understandable by anyone with a moderate background in the principles of protocol and system design. One aspect of the organization is particularly helpful to readers unfamiliar with some of the protocols in their native Internet instantiation. The authors divide the material into blocks where they first describe the native Internet flavor of the protocol, and then introduce the IMS-specific extensions and modifications.

Much of the volume is devoted to the *Session Initiation Protocol* (SIP) as the core signaling plane for IMS. All aspects of session establishment and management are covered. In addition, the ancillary parts of the control system are covered, including *Authentication, Authorization, and Accounting* (AAA), Security, Session Policies, and Quality of Service. For completeness, the data plane is also covered briefly through a discussion of the 3GPP audio, video, and text encoders, plus material on the media transport protocols.

The book concludes with a substantial section on how services are build on top of the core IMS protocols. Two of the most important, *Presence* and *Instant Messaging*, get comprehensive treatment, with a briefer discussion of the push-to-talk application.

As an old time "IP-head," it is hard to come away from this deep exploration of IMS without a bit of trepidation. The hallmark of IP and the Internet are simplicity and generality. IMS arguably succeeds at the latter, but at the expense of almost numbing complexity. This was perhaps inevitable given that the goal was to adapt Internet packet technology to the cellular system, which is itself quite complex. IMS will be quite a challenge to deploy. It remains to be seen if transplanting IP into a cellular telephony architectural model will result in economically sustainable services for the service providers or if a more native peer-to-peer Internet approach will simply bypass all the fancy IMS elements and just use basic packet transport. Such a market experiment is currently playing out in the broadband access arena with the broadband pipe suppliers offering telephony-oriented services themselves via customized standards like PacketCable, while third parties like Vonage and Skype simply piggyback on basic IP packet transport.

The next few years will be interesting. Whatever the outcome, anyone needing to be technically conversant with the architecture and protocols of IMS will find *The IP Multimedia Subsystem* indispensable.

Read Any Good Books Lately?

Then why not share your thoughts with the readers of IPJ? We accept reviews of new titles, as well as some of the "networking classics." In some cases, we may be able to get a publisher to send you a book for review if you don't have access to it. Contact us at **ipj@cisco.com** for more information.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

From The Editor

Internet Protocol Version 6 (IPv6) continues to be the focus of much work within the IETF as well as throughout the world in numerous deployment projects. The success of IPv6 depends not only on the protocol itself but also on its interaction with existing services such as the *Domain Name System* (DNS). In our first article, David Malone looks at some issues with DNS servers and IPv6. If you are interested in following the progress of IPv6 deployment, you might want to visit The IPv6 Forum's Website at: **http://www.ipv6forum.org**

A couple of years ago I signed up for GSM cellphone service and later added GPRS data service to my account. With my Bluetooth-enabled phone and laptop, I can access the Internet from almost anywhere in the world. The service is neither particularly fast nor inexpensive, but for occasional use it works very well, and has "saved the day" for me numerous times. However, GPRS is not the only wide-area wireless data network technology. Kostas Pentikousis gives an overview of the many alternatives.

The term "Internet Governance" is not well-defined, but it is being used more frequently when speaking about such organizations as the *Internet Corporation for Assigned Names and Numbers* (ICANN). The formation of the *World Summit on the Information Society* (WSIS) and its *Working Group on Internet Governance* (WGIG) has certainly brought the term into sharper focus. Although governance is certainly not a technical protocol issue, we still believe that it is important for our readers to follow both the debate about and the actual evolution of Internet Governance issues. However, we fully appreciate that this is an area where opinions differ—and that is why the article by Geoff Huston on this topic is labeled "Opinion."

We remind you to visit our Website, **http://www.cisco.com/ipj**, where you can find back issues of this journal, search the index files, or make changes to your subscription information. Your feedback is also very much appreciated, so drop us a line at **ipj@cisco.com**

Misbehaving Name Servers and What They're Missing

by David Malone, Hamilton Institute, NUI Maynooth, Ireland

IPv6-capable hosts abound, and the number is growing. Evidence[1] shows that more than 2 million Windows XP machines are probing for 6to4[2] connectivity. When combined with deployments of Linux and BSD that have been shipping with IPv6 support enabled by default for some time, that is a sizable platform on which to build IPv6 applications. Most Web browsers (Internet Explorer, Mozilla, Opera) now support IPv6 if the underlying platform does, so that is a significant number of applications ready to start making IPv6 queries.

In fact, many of these applications are already looking for IPv6 addresses in the *Domain Name System* (DNS), even if IPv6 connectivity is not actually available. This usually does not result in a problem—the name server says there are no IPv6 records and the application falls back to IPv4. In a small number of cases, name servers running outdated or errant software are misbehaving when faced with a request for an IPv6 address.

The Problem

So, what problem are these name servers having with the request for IPv6 addresses? Well, the DNS stores different types of information, such as host names and addresses. Different types of data are stored using different record types. For example, IPv4 addresses are stored using a type "A" record and host names are stored using a type "PTR" record. Some new record types have been introduced for IPv6. The most important one is "AAAA," which is for storing IPv6 addresses. (Another type called "A6" was also introduced, but it is now consigned to experimental status because it proved too complicated in certain situations.)

When you issue a request to the DNS, you indicate the domain and type of record that you are interested in. If the server has records of that type for that domain, it replies, including those records. If the server has no records of that type, it should respond saying "there are no records of this type." If the domain does not exist, then the server should return a "no such domain" error.

However, the problems arise when the DNS server does something different, and some name servers behave badly when faced with a query for a type they do not explicitly know about. For the sake of simplicity, we will highlight three wrong reactions to an unknown query that have been observed. A more complete technical analysis of the problem can be found in[3].

The first reaction that people notice is that some name servers do not reply when faced with a query for an unknown type. In this case, the person who made the request waits a while before the request is reissued. Eventually the application falls back to IPv4. "Eventually" means anything from 10 seconds to 100 seconds, depending on the operating system and application—enough to irk the casual Web user.

The second reaction is more subtle. Here the name server returns a "no such domain" response. At first glance this may seem harmless enough—the query for an IPv4 address is issued quickly. However, DNS specifications say that the "no such domain" response may be cached. This means that the "A" query is never issued, and the system acts as if the domain does not exist.

The third reaction is that the server issues some other sort of incorrect response. Usually this is less serious than the two previous reactions, because other responses at worst result in a particular name server being considered "bad" and being avoided for future queries. This means that some better-behaved name server can answer the query.

The Extent of the Problem

Although sites with these problems are sometimes discussed on mailing lists, the extent of a problem is not always proportional to the coverage it receives. Historically, numerous online advertising companies have had load-balancing DNS servers that exhibit these symptoms. Because the content of an ad server is embedded in the Web pages of many organizations, this means a single errant DNS server can give the end user the impression that this problem is more widespread than it is.

To give some idea of the scale of the problem, Table 1 shows the results of querying the name servers for the names mentioned in a month's worth of Web proxy logs. The number of servers responding in each of the three ways mentioned (no reply, no such domain, or other error) is shown, along with a total. Also shown is the number of name servers that actually returned IPv6 addresses.

These results show that actually only a small number of name servers have this problem. Unfortunately, it also looks as if the number of name servers distributing IPv6 addresses is actually comparable. However, it does look like the proportion of problem name servers is decreasing over time.

Table 1: Responses to Name Queries

Nameservers that:	January 2004	April 2004	*August 2004*
Responded to type A	*16838*	*20631*	*17934*
Did not reply to type A	*64 (0.38%)*	*49 (0.24%)*	*36 (0.20%)*
Returned no such domain	*11 (0.07%)*	*19 (0.09%)*	*11 (0.06%)*
Returned other error	*22 (0.13%)*	*39 (0.19%)*	*11 (0.06%)*
Had any issue with AAAA	*97 (0.58%)*	*107 (0.52%)*	*58 (0.32%)*
Returned AAAA records	*105 (0.62%)*	*123 (0.60%)*	*18 (0.66%)*

Looking at Web logs to determine the size of the problem gives us a feeling for the number of name servers that need attention. Another interesting parameter to consider is the proportion of requests that might be subject to this problem. The answer would tell us how many queries might be mishandled if your name server cannot deal with new query types.

Looking at the queries for addresses at one authoritative name server shows that 65 percent of queries are for A records, 21 percent are for AAAA records, and 14 percent are for A6 records. Although this server is IPv6-capable and might attract more queries for AAAA records, even the root servers run by RIPE show that 10 percent of address queries are for IPv6 addresses.

The Solution

Some of the name servers that exhibit this problem are simply running old versions of DNS server software. If this is the case, then the fix is simple: *upgrade!*

A significant number of the remaining problem servers are running unusual name server software, and the only way to fix the problem is to have that software fixed. Where the name server software is maintained in house, there should be enough DNS expertise to resolve the issue when it is identified. Where DNS systems have been bought in, it can be difficult to get the relevant information to the developers who can make the necessary changes. Thus increasing awareness of the issue among DNS vendors and troubleshooters is important.

In some cases[5,6], discussions on Internet mailing lists has alerted those responsible for the server to the problem and the issue has been resolved. In other cases, feedback provided by users and customers has marked IPv6 conformance as an issue for future upgrades of a site's DNS infrastructure. Unfortunately, on some occasions, feedback has been ignored and the problem has persisted. This is maybe not so surprising because it is a subtle problem. The fact that it is IPv6-related means it is sometimes dismissed because the organization thinks "we have not begun IPv6 deployment yet, so it cannot affect us."

Where problems have persisted, people have resorted to various practical solutions (hacks?) to avoid the issue. Some people, who do not need IPv6 at this time, have just suppressed the AAAA queries. Others, when they discover a name server that times out, add it to a blacklist. This avoids any delays, but may make a site unavailable. Mozilla includes a more forgiving style of blacklisting, in the form of a "ipv4OnlyDomains" setting, that can be set to a list of domains known to have problems[7].

The long-term solution seems straightforward. As we have seen, the number of name servers exhibiting this problem is relatively small, though some do serve some often-queried domains. If we can ensure that no more servers with these problems get deployed, then as the existing servers are updated or retired the problem will be resolved.

To this end, it is worth testing new DNS deployments to make sure that they correctly respond to unusual query types[8]. This will smooth the path not just for IPv6, but also for other new technology such the *Domain Name System Security Extension* (DNSSEC)[9].

Wireless Data Networks

by Kostas Pentikousis, VTT

Most IPJ readers are familiar with *Wireless Local-Area Networks* (WLANs; see, for example, IPJ Volume 5, No. 1). Some may even be familiar with recent developments in *Wireless Metropolitan-Area Networks* (WMANs), such as WiMAX. Although nonproprietary WMAN technologies are still in the standardization phase, the IEEE 802.11 family of protocols has reached maturity and rendered inexpensive (and often free) WLAN access increasingly popular. Both WLANs and WMANs provide high-speed connectivity (in the order of tens of Mbps), but user mobility is restricted. In fact, it is probably more appropriate to talk about "portability" rather than "mobility"[1] when referring to WLANs and WMANs.

Wireless wide-area networks (WWANs), on the other hand, allow full user mobility but at data rates typically in the order of tens of kbps. This will change to some extent when *third-generation* (3G) cellular networks are fully deployed. Still, 3G deployment is slower than originally anticipated, a development often attributed to the combination of high spectrum license costs, the recent economic downturn, and high equipment costs. As a result, both population and geographical coverage tend to be uneven. For example, in Finland, a forerunner in wireless communications, population coverage is well below the 35-percent level, and geographical coverage is even smaller

This article introduces several wireless network technologies, perhaps not so widely known, which deserve attention when considering how to provide mobile connectivity to field personnel, introduce *machine-to-machine* (M2M) communication, or deploy applications that require always-on connectivity. The approach taken in this article is a bit different from the one typically followed in the literature: We focus more on higher-level issues, the information that is essential for application developers, instead of modulation, channel coding, and other low-level details. Unlike WLANs and WMANs, none of the networks surveyed provide data rates in the order of tens of Mbps. Nevertheless, successful applications can be built even with stringent bandwidth limitations. For example, online gambling and several gaming applications can be served by really "thin" networks (and possibly "thick" clients).

Cellular Networks

The *Global System for Mobile Communications* (GSM) specifies a cellular, wide-area, circuit-switched, digital mobile phone network architecture[2]. Circuit-switched networks such as GSM and IS-95, commonly referred to as *Code Division Multiple Access* (CDMA) in the United States, can provide wireless data connectivity, cover a large area, and handle mobile host handovers efficiently[3]. Users can transfer data over, say, GSM, by establishing a "dialup" connection[4]. Mobile hosts can roam, even at high speeds, and remain connected throughout.

Communication is full-duplex at a radio data rate of 9.6 kbps or 14.4 kbps in GSM Phase 2+[5]. User throughput is always smaller than the nominal radio data rate.

While the user is connected using a wireless circuit-switched network, phone calls cannot be initiated or received whether data is being transferred or not. This is not much different from wire-line dialups over basic telephone service. The difference is that a dialup over a *Public Switched Telephone Network* (PSTN) takes up a resource, namely the wire-line local loop, which is dedicated to a single user, whereas a dialup over a cellular network such as GSM consumes a resource, the radio channel, which is shared among many users. Because of the *burstiness* that data traffic usually exhibits, circuit switching may lead to inefficient use of the network capacity. Establishing a GSM dialup connection usually takes several seconds, meaning that if the user has a small amount of data to send, a small e-mail message, for example, the overall experience is poor. Moreover, after the connection is established, the channel remains idle between traffic bursts and the allocated bandwidth is wasted. Packet switching is more efficient for bursty data transmission over a shared medium[6].

Another variable that favors packet-switching over circuit-switching, especially over slow wireless networks, is *billing*. Users of circuit-switched networks are usually charged based on the duration of a connection regardless of the amount of traffic transmitted or received. On the other hand, users of packet-switched networks can be charged based solely on the amount of data transferred—not how long they remain attached to the network. In short, introducing packet switching to wireless networks can lead to better use of network resources and attract more users as data transfers become more economical.

Two-way, packet-switched WWANs permit users to roam freely indoors and outdoors, even at relatively high speeds[7]. Most WWANs employ a cellular architecture to take advantage of frequency reuse and increase capacity while covering a larger area. Furthermore, because the coverage area of a single cell is generally large (cell diameters are typically in the order of dozens of kilometers), mobile hosts do not have to go through frequent and lengthy handovers. Hosts remain connected throughout after they attach to the network, permitting users to receive and transmit data on demand without having to dial up. The following sections survey some of the most widely deployed packet-switched wireless data networks.

Mobitex

Mobitex is the first digital data-only WWAN developed by Ericsson and Swedish Telecom. Not based on IP, Mobitex was introduced in Sweden in 1986 for emergency communications[8]. It uses a cellular architecture with cell diameters of up to 30 km. Each service area can operate 10–30 channels[9] and each base station is usually allocated 1 to 4 channels. Each channel is composed of a frequency pair: different frequencies are used for the uplink and the downlink.

Communication between the base station and a single mobile host is, nevertheless, effectively half-duplex. Although base stations can transmit and receive simultaneously, mobile nodes are unable to do so[10]. The Mobitex *Maximum Transmission Unit* (MTU) is 545 bytes, with up to 512 bytes of user data. Although the system has undergone several revisions, the raw transfer rate remains only 8 kbps. Effective user throughputs range from 4 kbps (for 125-byte packets) to 4.6 kbps (for 512-byte packets)[11], and round-trip times can be up to 10 seconds.

Mobitex deals with network lapses using a store-and-forward procedure: Packets destined for a mobile node outside the network coverage area are stored while awaiting delivery. When the mobile node reconnects, the stored packets are delivered. Mobitex uses a hierarchical routing architecture that prevents local traffic from being injected into the backbone network. In other words, packets destined for a node in the range of the same base station are switched locally[8]. Besides supporting unicast addressing, Mobitex allows hosts to send one packet to several recipients[10]. According to the *Mobitex Association* (**`www.mobitex.org`**), the technology features "true push functionality," whereby data can be pushed to both a single mobile node and a predefined group of nodes, a feature that can be very useful when trying to send an urgent message to field personnel. And, because the mobile host does not have to keep querying for pending data, network traffic can be kept to a minimum. All these features can also significantly boost battery life.

According to the Yankee Group, despite the limited data rates, a variety of applications have been developed based on Mobitex, including: burglar and fire alarm systems; paging, interactive messaging, e-mail, form-based applications, and access to databases; telemetry; credit card authorizations; field service; and fleet management. Virtually all of them require small and bursty transfers. Mobitex does not lend itself to large file transfers, e-mail with large attachments, or video transmission. In fact, file transfers of more than 20 KB used to be discouraged[8]. On the other hand, by using a slotted ALOHA[12] variation for channel access, Mobitex can provide message delivery delay guarantees and support hundreds of users within the same cell. Parsa[13] calculated that Mobitex can accommodate 2,000 users per channel, assuming two uplink and two downlink messages per hour. Other networks simply cannot provide tight delay bounds for such a large number of users. For example, the *Mobile Data Magazine* (No. 1, 2002) reported that a Korean operator launched real-time stock trading and horse gambling mobile applications with great commercial success, by guaranteeing delay bounds notwithstanding the low data rates.

DataTAC

DataTAC (also known as ARDIS in the United States) was developed by Motorola in the mid-1980s. DataTAC is also a non-IP based, wide-area, data-only message-oriented network. A single base station can cover an area exceeding 20 km in diameter[14]. Like Mobitex, communication between the base station and a single DataTAC mobile node is half-duplex, and mobile hosts have to compete to get access to transmit and receive data.

Unlike Mobitex, DataTAC was designed to provide optimal in-building coverage, and it uses a cellular architecture that does not take advantage of frequency reuse. Instead, a single frequency is used, increasing the probability that a packet transmission is successful (because the same transmission can be picked up by more than one base station), but at the expense of network capacity[8]. Bodsky notes that the U.S. DataTAC operator formerly recommended refraining from transferring files larger than 10 KB.

Although neither Mobitex nor DataTAC provides native IP support, middleware can take care of protocol translation and allow unmodified, off-the-shelf applications to communicate. The maximum Data-TAC message size is 2048 bytes[15], but the maximum over-the-air packet size depends on the link layer. For rural areas the maximum radio data rate is 4.8 kbps, and the maximum over-the-air packet size is 256 bytes. In metropolitan areas, the radio data rate is 19.2 kbps and the maximum packet size is 512 bytes[16]; end-user throughput does not exceed 10 kbps on average. Traditionally, DataTAC was used for dispatching and law enforcement applications. The *Worldwide Wireless Data Network Operators Group* (**www.datatac.com**) reports that DataTAC networks are also used for two-way messaging, wireless e-mail, telemetry, access to corporate databases, and package tracking by courier carriers.

CDPD

Cellular Digital Packet Data (CDPD) was designed by IBM and McCaw Cellular Communications in the early 1990s to take advantage of channels that do not carry voice traffic in the *Advanced Mobile Phone Service* (AMPS), the first-generation analog cellular network[17]. Data channels are allocated dynamically, sharing the network capacity with AMPS voice traffic, which is quite different from Mobitex and DataTAC. This, for example, might mean that data can be transmitted and received only when phone calls do not consume all available capacity. One could argue that CDPD considers data traffic less important than voice. However, the standard allows network operators to specifically assign channels to data traffic only. In theory, deployment can be more economical than it is for other WWANs because CDPD takes advantage of existing AMPS infrastructure and does not require licensing new spectrum. Original projections anticipated that as CDPD gained popularity—and AMPS became obsolete—more CDPD dedicated channels would be allocated. With time, CDPD would have taken over the existing AMPS bandwidth, effectively becoming a data-only WWAN.

CDPD is based on a *Carrier Sense Multiple Access* (CSMA) variant called *Digital Sense Multiple Access*[14] and transparently provides IP services, constituting a great advantage. CDPD allows for an MTU of 2048 bytes. However, one has to account for the TCP/*User Datagram Protocol* (UDP) and IP headers that are used to encapsulate the application payload before sending it over the CDPD network and also for the fact that CDPD user data is transmitted in much smaller blocks. Although the CDPD raw data rate is 19.2 kbps, the effective throughput is in the order of 10 kbps and response times have been reported to be in the order of 4 seconds[18].

GPRS

The *General Packet Radio Service* (GPRS) is overlaid on a GSM network in a fashion similar to the way CDPD is embedded in AMPS: Voice and data traffic share the same bandwidth and network infrastructure[14]. In other words, GPRS is an add-on to GSM networks, and it requires certain hardware and software upgrades and introduces packet switching to a circuit-switched architecture. GSM voice traffic is oblivious to the presence of GPRS data traffic. Similar to CDPD, GPRS is designed to appear as a regular IP subnetwork both to hosts attached over the air interface and to hosts outside the GPRS network.

The GPRS standard was finalized by the *European Telecommunications Standards Institute* (ETSI) in late 1997 as part of GSM Phase 2+[5]. It is regarded as a transitional technology toward 3G networks[19], and is commonly referred to as 2.5G. One of its main advantages is that the same device can be used to transmit and receive data, and initiate and accept phone calls. GPRS defines three classes with respect to simultaneous usage of voice and data. Class A mobile hosts can transmit and receive voice and data at the same time. Class B hosts can transmit and receive either voice or data but not both simultaneously. Finally, class C hosts have the user manually select if the host should be attached to the GSM (voice) or GPRS (data) network. When compared to Mobitex, DataTAC, and CDPD, GRPS class A devices can have simultaneous access to a packet-switched and circuit-switched network. Of course, GSM-only devices do not have this capability either, as mentioned earlier.

GSM uses a combination of *Frequency Division Multiple Access* (FDMA) and *Time Division Multiple Access* (TDMA) for channel allocation, as explained in detail in[5]. In short, each frequency channel carries eight TDMA channels. Each of these channels is essentially a time slot in a TDMA frame. Thus, any GSM frequency channel can carry up to eight circuit-switched connections with each slot reserved for a single connection (read *voice call*). In GPRS, each slot is treated as a shared resource and any mobile host can use it to transmit or receive data. In addition, a mobile host can be allocated more than one of the eight available slots in the same TDMA frame. In other words, GPRS can multiplex different traffic sources in one channel and allocate several channels to the same traffic source.

GPRS defines four different channel coding schemes[20], namely CS1, CS2, CS3, and CS4, with radio data rates 8.8 kbps, 13.3 kbps, 15.6 kbps, and 21.4 kbps, respectively. CS1 is the most "conservative" (includes more error correction bits) and is used for signaling packets and when poor channel conditions prevail. CS4 is the most "optimistic" (includes minimal error correction bits), and, assuming excellent channel conditions, allows operators to advertise a maximum radio data rate of 171.2 kbps per 200-kHz frequency channel (or TDMA frame).

In practice, CS4 is rarely used because it can lead to frequent retransmissions of lost packets and overall network underperformance. CS3 is commonly used, providing 124.8 kbps per frequency channel. Because a mobile host can be allocated multiple slots, user throughputs can range between 40 and 60 kbps. Mobile hosts typically use an MTU of 1500 bytes.

Communication between the base station and any given mobile host is full-duplex but can be *asymmetric;* that is, the downlink and uplink capacities need not be the same. The *GSM Association* has defined 12 multislot classes for GPRS. Each class is associated with a maximum number of uplink and downlink slots that can be allocated to a single mobile host. The slot allocation is usually written as *M* + *N*, where *M* is the maximum number of downlink slots and *N* is the maximum number of uplink slots. For example, class 1 is "1 + 1" (one downlink slot plus one uplink slot); class 2 is "2 + 1"; . . . ; and class 12 is "4 + 4" (four downlink and four uplink slots). In addition, each multislot class has an active slot constraint: A mobile host cannot use more than *K* active slots simultaneously. Given the number of slots and the channel coding scheme, one can calculate the peak rate. For example, for a class 12 device the sum of the physical downlink and uplink rates cannot exceed 124.8 kbps, if CS3 is used. However, the active slot constraint limits this rate even further. In the case of a class 12 mobile node, *K* = 5, that is, only "4 + 1", "3 + 2", "2 + 3", or "1 + 4" slots can be used simultaneously. See **www.gsmworld.com**

EDGE and Beyond

Enhanced Data for GSM Evolution (EDGE), also known as Enhanced GPRS, builds on the changes introduced by GPRS to GSM. EDGE essentially increases the radio data rates by using a more efficient modulation scheme[21], namely *8-Phase Shift Keying* (8-PSK) instead of the *Gaussian Minimum Shift Keying* (GMSK) used by both GSM and GPRS. EDGE defines nine modulation coding schemes named MCS1 to MCS9. MCS1 to MCS4 use GMSK with radio data rates similar to the four GPRS coding schemes. The real throughput improvements come from MCS6 (29.6 kbps per slot) through MCS9 (59.2 kbps per slot). The data rate usually associated with EDGE is a (shared) 384 kbps. This corresponds to using MCS7 for all 8 TDMA slots. Higher data rates are theoretically possible (up to 473 kbps using MCS9) but are not commonly deployed.

EDGE improves not only on the high end of data rates but also on the low end[22]. First, the greater diversity of coding schemes permits an EDGE network to choose the most appropriate one depending on channel conditions. Changing coding schemes is dynamic. Second, EDGE supports *packet resegmentation:* Packets that failed to be transmitted successfully can be resegmented and retransmitted using a more "conservative" coding scheme.

Table 1 summarizes the main high-level features for the WWANs surveyed.

Table 1: WWAN Characteristics

	Transmit/ Receive	Radio Data Rate	User Throughput	MTU
Mobitex	*Half duplex*	*8.0 kbps*	*<4.6 kbps*	*512 B*
DataTAC	*Half duplex*	*19.2 kbps*	*<10 kbps*	*2048 B**
CDPD	*Full duplex*	*19.2 kbps*	*<10 kbps*	*2048 B*
GPRS	*Full duplex*	*<171 kbps*	*40–60 kbps*	*1500 B*
EDGE	*Full duplex*	*<473 kbps*	*50–60 kbps*	*1500 B*

* Typically 512 B

Discussion and Trends

Among the WWANs presented, Mobitex and GPRS can be singled out as the most widely deployed; they also have enjoyed significant gains in the number of users and traffic volume in recent years. The popularity of enterprise wireless e-mail (due in part to the success of the Research in Motion BlackBerry devices) allowed Mobitex and DataTAC operators to revive their business models briefly. Worldwide, however, GSM dwarfs all other technologies: There are more than 1 billion GSM subscribers compared to the 1 million Mobitex users. DataTAC enjoys an even smaller user base. Even if a small percentage of GSM subscribers use GPRS and EDGE, the potential market for wireless applications is tremendous. On the other hand, subscribers who do not take advantage of GPRS or EDGE do use the inexpensive, (two-way) *Short Message Service* (SMS), which is built in GSM. Two-way messaging was available for many years but was certainly popularized by less-affluent and younger GSM users in the late 1990s. SMS is now commonplace, and in many countries it is more popular than e-mail. Dedicated data-only networks such as Mobitex have to look elsewhere for their niche.

For some, Mobitex, let alone DataTAC and CDPD, is virtually moribund. In the United States, for example, Cingular sold its Mobitex network and is investing heavily on GRPS and EDGE. DataTAC and CDPD are phased out by service providers in the United States in favor of newer technologies. Low-speed packet radio is considered lackluster and is not popular with younger crowds. After all, narrowband WWANs had their chance and failed to attract large numbers of subscribers. Recent pricing trends, too, reveal a heavy operator push in favor of GRPS and EDGE. In Finland, for example, 100 MB over GPRS costs less than 18 euros (approximately $24). Compare that to the $30–50 that 1 MB of traffic costs over Mobitex. Service and product popularity create economies of scale that cannot be ignored.

Nonetheless, open standards, an explicit focus on business applications with *Quality-of-Service* (QoS) guarantees in service response times, and narrowband M2M communication may well keep Mobitex going for years to come. Besides, bundling Mobitex with a wireless network that features fast and inexpensive connectivity, for example, WLAN or Bluetooth, might be promising: Large downloads and software updates can be done over the high-speed wireless network and critical messages can always reach the user through the WWAN.

Bundling several functions in a single handheld device is, after all, a major trend in the industry. Vendors scramble to integrate *Personal Information Managers* (PIMs), voice and data communications, as well as entertainment features (digital camera, games, or digital music players) in a single product. This is quite different from earlier mobile devices, which tended to be either single-purpose or tied to a particular set of applications. Even the BlackBerry devices still work, to some extent, in a closed architecture. Enterprise e-mail systems need to be supported by and integrated with BlackBerry servers in order to be accessible over the WWAN. Yet, one of the main objectives in 2.5G and 3G is to allow mobile users to use standard Internet protocols on a mobile radio network at significantly higher bit rates than other systems. In particular, GPRS was designed with certain office applications in mind and can support consumer and enterprise mobile communications alike, without being tied to any given platform or application servers. I expect that functionality bundling and 2.5G and 3G WWANs will allow for more open systems and will expedite the transformation of WWAN operators from integrated application providers to wireless ISPs.

Opinion: ICANN, the ITU, WSIS, and Internet Governance

by Geoff Huston, APNIC

This is an opinion piece, intended primarily to provoke thought and comment. The author does not claim to personally hold any of the opinions expressed in this article.

It may have taken some three decades to get here, but there is no doubt that the Internet is now a major public communications utility. That is hardly the most important piece of news you are likely to read today, but the implication of this public role is that there are legitimate issues of public policy to consider when looking at the broad topic of coordination of various aspects of Internet infrastructure. In other words, "Internet Governance" is a matter of significant concern to many.

This opinion piece looks at the various range of views about the *Internet Corporation for Assigned Names and Numbers* (ICANN)[1] and its rationale and role over its brief history. Of course, no look at Internet Governance would be complete without also looking at the role of the *International Telecommunications Union* (ITU), as well as the broader background to this topic. It is a large topic and it has already been the catalyst for numerous articles.

Data Networking and Public Networks

Whether it was because of its antecedents in the research community, or simply because it was not originally envisaged that the Internet would become a global communications platform in its own right, or for whatever reasons, the administration of the Internet infrastructure was not originally crafted with conventional public network coordination in mind. The retrofitting of a model that incorporates considerations of a public utility role is proving to be a rather complicated process.

For example, the original hierarchical name space for the Internet used a set of generic top-level root zone names of "**edu**," "**net**," "**com**," "**gov**," and "**mil**." Adding country codes to the root of the name space was a later modification. Even then the original country code delegations were undertaken to individuals or entities who appeared to have some form of link to the national Internet community, rather than specifically seeking out an appropriate office of the national administration of communications services as the point of delegation. Similarly, IP addresses were structured without any form of national prefix, nor were IP addresses distributed along any national lines. In these respects the Internet was really no different from any other computing networking protocols of the 1980s, such as *DECnet,* the *Xerox Network System* (XNS), *AppleTalk,* or IBM's *Systems Network Architecture* (SNA), where names and addresses were defined in a limited context of the scope of the network, rather than within some broader public name framework.

There were two notable exceptions to this characterization of computer network protocols, and both were designed with a public communications utility as their primary objective, namely *X.25* and the *Open Systems Interconnection* (OSI) model. They can be regarded as offerings from the data services sector of the established telephone industry. X.25, the earlier of these two protocols, had a very obvious relationship to telephony, complete with the notion of a "call" as the means of establishing a data connection and as the unit of a transaction. The addressing scheme used a structured space that drew heavily on the telephone number structure. Like telephony, there was no associated name scheme and endpoints were identified by their numeric X.25 protocol address. OSI represented a later effort to design a packet-switched network architecture that was intended to reflect an increasing level of experience with this technology, but nevertheless continued to draw heavily on telephony design. Much was written about OSI at the time, and it would be a diversion to explore it in depth here. However, the salient observation here is that despite the extensive effort invested into its promotion, OSI was a market failure, and whatever its technical merits it was simply not accepted by the communications industry.

OSI was heavily supported by the ITU, and by virtue of this very active sponsorship of this technology, the implication of the aftermath of OSI was that the ITU was seen as being simply out of touch with data networking. It was often portrayed that the ITU was coming from a mindset that was incapable of engaging with either the data communications industry or the broader consumer market for data services. From the perspective of data networking, the failure of OSI was seen as a failure of the ITU itself.

The ITU and the Internet

The ITU is certainly one of the more venerable institutions in the communications sector. It can trace its origins to May 1865, when the first *International Telegraph Convention* was signed by 20 founding national members, and the *International Telegraph Union* was established to facilitate subsequent amendments to this initial agreement. Two decades later, in 1885, the ITU drafted international legislation governing telephony. With the invention in 1896 of wireless telegraphy, similar coordinating measures were adopted by the *International Radiotelegraph Convention*. In 1932 the Union combined the International Telegraph Convention of 1865 and the International Radiotelegraph Convention of 1906 to form the *International Telecommunication Convention*. The name of the body was changed to *International Telecommunication Union* to properly reflect the full scope of the Union's responsibilities, which by this time covered all forms of wireline and wireless communication.

In 1947 the ITU, under an agreement with the newly created United Nations, became an agency of the United Nations, with responsibilities in international telephony, telegraphy, and radio communications. Over the next four decades the ITU oversaw a system of international interconnection of telephony and data systems that became an industry in and of itself.

The ITU assumed a role of facilitating what was asserted to be a balanced international environment where the costs of running the international system were fairly apportioned between national service providers. In practice these lofty goals were not achieved very efficiently, and international facilities were priced at levels that were considerably higher than the associated costs of actual service provision. When attempts were made to redress the imbalances between large and small national carriers, the outcomes included collective action on the part of the national carriers that operated in ways not dissimilar to a cartel.

In 1992 the ITU was restructured into three sectors, corresponding to its three main areas of activity, namely the standardization of telecommunications technologies in the ITU-T, the coordination of radiocommunications in the ITU-R, and telecommunication development in the ITU-D. In 1994 the ITU established the *World Telecommunication Policy Forum* (WTPF), a group that encouraged the exchange of ideas and information about emerging policy issues arising from the changing telecommunication environment. The first WTPF was held in 1996 on the theme of global mobile personal communications by satellite, and the second in 1998, on trade in telecommunication services.

The ITU was heavily criticized over the ponderous amount of time taken to generate telecommunications standards, the nature of the process used in developing these standards in a closed set of forums, the marginal relevance of these standards, and the final indignity, that the ITU charged for paper and electronic copies of these standards. As some critics pointed out, perhaps harshly, this was not just a case of paperware about vapourware, it was a case of very expensive paperware about vapourware!

More recently, the ITU has focused on attempting to strengthen the participation of the private sector in the work of the Union, as well as streamlining the ITU's processes to reduce the level of delay and amount of process overhead in standardization of technology and operational practices. The ITU has sponsored the establishment of the *World Summit on the Information Society* (WSIS)[2], and has been attempting to position itself more centrally in the process of further evolution of the Internet as part of its overall charter.

The Internet has posed a severe challenge to the ITU. Not only was the ITU often perceived as being out of touch with the data communications sector, more critically it had been perceived as being incapable of making the necessary reforms to its mode of operation and policy setting to bring it back into relevance for the rapidly changing communications industry. The inference was being drawn that the ITU was apparently in a state of denial over progressive deregulation of national communications sectors. In many cases the national position had already moved to a position of lightweight regulation, relying on strong competitive pressures in the private sector to enforce regimes of efficiency and effectiveness in the supply of communications services to consumers. The ITU, as an intergovernmental organization, was being seen in some quarters as an anachronistic recalcitrant relic of an earlier era of communications service provision.

It was also evident that this critical view of the ITU was most strongly held within the United States, and in particular those parts of the U.S. administration and industry that were involved with the growth of the Internet. It was perhaps no coincidence that in these growth industries of personal computer technologies and the related Internet industry it was U.S. enterprises that were the "poster children" of this new model of industry-led deregulated communications services. Their consequent rapid expansion into a massive global undertaking of the global Internet was perhaps the most eloquent form of statement about the effectiveness of deregulation, and the degree to which the previous regulatory model had simply not managed to encompass the burgeoning demand for data services in a timely fashion.

From this perspective it should be no surprise to observe that when the transition of the *Internet Assigned Numbers Authority* (IANA) function from a fully federally funded research activity to some form of new foundational base was being considered by the U.S. administration, it appears that the ITU was never seriously contemplated as a viable home for this function. If the Internet was a child of deregulation and industry initiative taking on the outcomes of research activity, then the appropriate progression of the IANA function was also from a research context into an enterprise context. IANA should be responsive to industry needs, and to best achieve this the IANA function itself should be undertaken as a task housed within the deregulated private enterprise sector, rather than establishing yet another public bureaucracy, or using existing bureaucracies for the role. ICANN was the embodiment of this aspiration on the part of the U.S. administration, and to pass the effective levers of control of the Internet to the ITU was seen as denying the Internet any form of a productive, innovative, and successful future.

The Formation of ICANN

Whatever the original motivation in creating ICANN to administer the IANA responsibilities, it is now apparent that ICANN was deliberately structured to provide the industry with an alternative structure of coordination and regulation within national and international communications sectors to that of the ITU. The critical difference is that ICANN had not placed governments at the forefront of visible activity, but instead placed industry needs and the operation of a competitive deregulated international communications sector as being the major thrust of coordination activities.

As with any novel model of public policy determination, ICANN's acceptance ranged from cautious approval to advanced skepticism. Even within the U.S. administration ICANN has yet to be "unleashed," and it currently operates under the terms of a Cooperative Agreement with the *National Telecommunications and Information Administration* of the U.S. Department of Commerce under a sole source cooperative agreement. In this light ICANN appears to be a cautious step in a bold direction.

ICANN undertakes activities of management of Internet Protocol infrastructure in the areas of the content of the root of the *Domain Name System* (DNS) and the identification of parties to whom are delegated administrative and operational control of the top-level domains and the associated specification of terms and conditions of this delegation. ICANN, through IANA, also manages the pool of unallocated IP addresses (IPv4 and IPv6 addresses and Autonomous System numbers), and also manages the protocol parameter registries as defined by IETF Standards Actions.

ICANN Mkl

The initial structure of ICANN had three "supporting organizations," focusing on:

- Coordination of the DNS with the *Names Supporting Organization* (NSO)
- Coordination of address policies with the *Address Supporting Organization* (ASO)
- Operation of Internet Protocol parameter registries with the assistance of the *Protocol Supporting Organization* (PSO)

The intended role of these supporting organizations was to provide a venue where interested parties could develop and consider policy proposals, leaving the task of ultimate identification of broad support for particular policy initiatives to the ICANN Board.

As has been evident to any observer of the ICANN process, things did not proceed within the parameters of that plan. The NSO met problems due to the diversity of interests that were encompassed with the DNS domain, including emerging national and regional interests in the country code top-level domains, the operators of the generic top-level domains, the trademark and intellectual property collection of interests, the emerging industry of registrars, and a continual interest of individuals who maintained that they had legitimacy of inclusion by virtue of their representation of interests of end users and consumers, or, to use an emerging ICANN lexicon, the "at large" constituency.

The ASO was formed within the parameters of a different model. The *Regional Internet Registries* (RIRs) had already developed a considerable history of working within their communities, and being widely accepted by these communities as an appropriate means of coordination of activity in the role of number resource administration and distribution. The ASO was formed with membership of the associated council based on processes determined by each RIR. Even then it was unclear as to the relationship between the RIRs' already well-established open policy development process and the ASO and ICANN. The RIRs were unwilling to pass all regionally developed policies to ICANN for a second round of consideration and potential alteration. They insisted that only those policies that were considered to be "global," in that they were common to all the RIRs, would be passed into this ICANN sphere.

The PSO was placed under strong pressure to include the ITU-T and the *European Telecommunications Standards Institute* (ETSI), and the *World Wide Web Consortium* (W3C) was also enlisted, in addition to the IETF. If the objective of the PSO was oversight and policy formulation concerning the role of protocol parameter registration of IETF protocols, then this enlarged membership of the PSO was unwarranted. Even within the terms of consideration of the PSO as a source of standards-based technical advice to the ICANN Board, the presence of these additional organizations was somewhat puzzling in terms of the match of resultant structure of the PSO to its intended role. The PSO, however, had a role in seating individuals onto the board of ICANN, and it was likely that this aspect of the PSO had been part of the reason for the interest in broader institutional membership. Uncertainty about the extent of the role of ICANN saw many groups attempting to gain access to board seats.

Missing from this mosaic of diverse interests was the inclusion of various national public communications sector entities who also felt that they had clear legitimacy to undertake an active role within the ICANN policy development process, and, in response, the *Government Advisory Committee* (GAC) was formed.

ICANN Evolution and Reform

If a camel is a horse designed by a committee, then it is unclear whether ICANN was a three-humped camel or a three- and three-quarter-humped camel as a result of all this, but camel it undoubtedly was.

The PSO was dysfunctional and missing any tangible agenda of activity. A fracture was apparent in the relationship between ICANN and the IETF. Attempts to create an agreement between ICANN and the IETF over the IANA function were not recognized by the U.S. administration, who continued to insist that, formally, the IANA function for the IETF was undertaken at the behest of the U.S. Department of Commerce rather than the IETF. This view was not shared by the IETF.

The ASO was criticized by ICANN itself of being insufficiently "representative" of the addressing community, and the ICANN Board established its own temporary advisory committee on addresses, and in so doing alienated the RIR community from the entire ICANN framework.

The NSO was hopelessly wedged into factional-based politics.

The GAC decided at the outset that it would operate behind closed doors, in contrast to ICANN's continuing efforts to operate in an open and transparent manner.

The "At Large" election process undertaken by ICANN appeared to be of dubious validity because of problems in establishing a reliable constituency of individuals who had an interest in ICANN, and a direct election process was attempted only once.

Not surprisingly, ICANN fell into some disarray under these pressures, and by early 2002 the CEO of ICANN at the time, Stuart Lynn[3], was warning all who cared to listen that ICANN was paralyzed, dysfunctional, and in danger of an imminent demise. Whether this was a message directed to the ICANN Board or to a fractious set of communities that had some intersection with ICANN, or to the U.S. administration who had been influential in determining the original ICANN structure was not entirely clear to any observer of the process.

However, given that ICANN had been set up as an example of a new form of international coordination of communication infrastructure support activities that was based on private-sector activity rather than governmental fiat, this message of imminent failure was widely interpreted both as a potential failure of ICANN and a sign of failure of this new model of coordination of international activity. ICANN was seen as a point of vulnerability with respect to the U.S. administration's diplomatic efforts to reform this international activity sector. The ITU-T's activities in this same area was reinvigorated, with considerable support from national sectors who saw their national interests being potentially advantaged in a ITU-led international environment.

ICANN MkII

Although still firmly positioned as a private-sector activity, and although still making no concessions in the direction of the ITU, ICANN has managed to reorganize its structure through a protracted evolution and reform process.

With respect to the ASO, The Regional Internet Registries formed its own coordination entity, the *Number Resource Organization* (NRO)[4], and has proposed this entity to ICANN as the means of interfacing between the addressing community and ICANN's policy-development activities.

The PSO was abolished, to be replaced by a *Technical Liaison Group* that, apart from its function of seating an individual on the ICANN Board, is a group without an obvious role or agenda.

The NSO was forced to recognize the fundamental difference between the generic top-level domains, which fall under a more direct relationship with ICANN and its processes, and the country code domains (ccTLDs), which have from the outset been quite wary of ICANN. From the ICANN reform process emerged the *Country Code Name Supporting Organization* (CCNSO) and the *Generic Names Supporting Organization* (GNSO), as a recognition that these two groupings are so dissimilar that they have almost nothing in common.

In addition, an *At Large Advisory Committee* was formed.

The reform process has had some more tangible outcomes, in that formal open meetings of the ICANN Board of Directors have managed to be progressively refined from efforts at direct dialogue and open debate into highly structured events with many formalisms and appropriate quantities of ceremony.

ICANN Today

Despite the effort to encompass coordination activities in the areas of names, addresses, and protocol parameters, ICANN has been largely captured by the names industry, and ICANN's agenda, activity focus, and outcomes are concentrated mostly in the name domain.

In this activity domain, the track record of ICANN is very mixed. To its credit, it has managed to dismantle the most objectionable parts of the monopoly hold over the *generic Top-Level Domains* (gTLDs), create an operational model that makes a clear distinction between registry operators and registrars, impose price and business controls on the registry operation as a means of controlling the natural tendency for the registry operation to reflect its unique position in the form of monopoly rentals, and assist in the creation of a global network of competitive enterprises, with the expectation that competition will instill operational and price efficiency in the registrar business.

In addition, ICANN has been successful in not only introducing new gTLDs to complete with the established brands of **.com**, **.net**, and **.org**, but also in moving **.org** and **.net** to new registry operations (**.net** is under way at the time of writing of this article). Despite these positive achievements, it is not clear that this new regime has been entirely successful.

True competition in the name space is still some way off, and the recently introduced gTLD brands have failed to gain any leverage within the market. The name market itself remains one where the role of name speculators continues to play a significant role in terms of proportion of registered names. The overarching dominance of **.com** as a brand has continued, and the advantaged position of the U.S.-based registrar of this zone continues.

The obscure nature of the relationships between the IETF, ICANN, and the U.S. administration over the protocol parameter registries remains unresolved. The IETF is clearly not in control of its own protocol parameters, and has abrogated this role to ICANN. Standards making entirely divorced from any effective engagement with deployment tends to result in a standards body of dubious long-term validity, and despite its impressive track record in the past, the IETF is clearly already well-distanced from current technology directions in the industry—and the gap continues to widen.

The DNS *Root Server Operators* continue to operate as an independent group. The recent moves to dramatically increase the number of DNS root servers and improve the overall robustness of DNS resolution through anycasting root servers and distributing anycast instances across the globe has been a well-received initiative. The fact this has occurred without any form of ICANN involvement is an interesting commentary on the ability of ICANN to engage with the operational parts of the infrastructure of the Internet. Comparable activities to improve the DNS in terms of resolution services within the ICANN sphere have become protracted exercises that impose a very heavy burden on the patience of the players.

The moves to introduce IPv6 AAAA records into the DNS root have been anticipated for many years, and the response to the recent ICANN announcement is, in general, of the tenor "why didn't this happen some years ago?" The continuing frustration to get the DNS root to include *Secure DNS* (DNSSEC)[5] important information continues to illustrate a perspective that the ICANN process appears to be unresponsive to technical needs and end-user imperatives.

The situation today is that ICANN appears to enjoy a mixed level of success. It has managed to establish itself as a means of administering the infrastructure elements of the Internet Protocol in a manner that is reflective of the deregulated nature of the Internet industry. It has managed to reform parts of the landscape and generate an industry structure that uses open competition as the major control mechanism. ICANN has managed to bring much of the discussion about the administration of Internet infrastructure out into the open. All these are major milestones, and it is to the credit of many dedicated individuals that ICANN has managed these impressive outcomes. However, it has been able to achieve all this with the continued sponsorship of the U.S. administration, and the question of whether it can firmly establish itself in its own right in the coming years remains today perhaps a matter of hope rather than absolute certainty.

There are still the lingering concerns that if ICANN, as a private-sector entity, were to once more explore positioning itself on the brink of imminent demise, the collective task of picking up the pieces and continuing to support the operation of the Internet is one that appears to have a very uncomfortable level of uncertainty. In addition, the perception of ICANN as an entity whose single purpose is to maintain an entrenched advantaged position of the United States and of U.S.-based enterprises in the global Internet has been widely promulgated. It is often portrayed that ICANN offers no viable mechanisms for other national or regional interests at a governmental level to alter this somewhat disturbing picture of international imbalance. Although other aspects of international activity fall under various political or trading frameworks, and national and regional interests and positions can be collectively considered and negotiated, critics of ICANN point out that the message ICANN sends to the rest of the world is that the United States is withholding the Internet from conventional international governance processes. Skeptical commentators interpret the U.S. administration's use of ICANN as at best a delaying technique to gain time to further strengthen the position of U.S.-based enterprises across a lucrative global Internet market, aided and abetted by a compliant industry body that masquerades as an international standards organization.

Such a critical perspective also points to ICANN's tenuous lines of authority, its lack of performance in many aspects of the domain name enterprise, its seeming obsession with the registrar sector to the apparent exclusion of any other activity, its burgeoning costs, and its lack of acceptance, particularly as it relates to the acceptance of ICANN by the various country code DNS administrators, to name but a few factors.

Accompanying this strident criticism is the line of argument that the Internet does not actually represent a viable challenge to existing mechanisms for coordination of international activity. At both a national and international level, the Internet should not require novel and untested regulatory mechanisms as a means of expressing public interest and public policies. The line of argument from this perspective is that there is neither the demonstrated need, nor any appropriate level of international support at a governmental level to sustain the argument that a private-sector, nonprofit corporation is the best, or even the only viable model of coordination of Internet activity. If "Internet Governance" is the question, then, the line of argument goes, the model upon which ICANN is based is definitely not the best answer we can devise. This very critical line of reasoning has become particularly prominent in the WSIS process, and lies behind much of the continual fascination of the topic of "Internet Governance" in WSIS meetings.

WSIS and Internet Governance

The WSIS has been a long time coming, and it represents a move on the part of the ITU to formulate a revised role for the ITU to engage with a world richly populated by all manner of information services layered upon a highly diverse and capable communications environment. This summit was planned in two phases. The first summit was held in Geneva December 10–12, 2003, where the foundations were laid by reaching agreement on a *Declaration of Principles* and a *Plan of Action*. The second phase will be held in Tunis, November 16–18, 2005, to implement the agenda leading up to achievable targets by 2015, and to agree on unfinished business, most importantly on the question of Internet governance and of financing mechanisms.

Irrespective of any particular political perspective here, the universal observation is that the Internet has heralded a revolutionary change to the global communications enterprise. Markets for communications services are changing, the technology base is changing, the economic models of communication are changing, and the models of interaction at the provider level are changing. The challenge from the public-policy perspective at a world level is to create a framework that ensures that the benefits of this change, in both social and economic terms, are accessible to all, rather than to a subset of the world's population. It is within this broad framework that WSIS has been positioned.

These are lofty and ambitious goals, and the task before WSIS is certainly as challenging as any in this environment. The hope is that the myriad of participants in this process includes sufficient resources to engage in the agenda in a meaningful way.

However, the underlying issue is that of the progressive change in the role of communications infrastructure from a predominately public-sector activity to a very diverse spectrum of public- and private-sector activity. We appear to have become increasingly reliant on private-sector investment and private enterprise to support the public communications enterprise. But is this necessarily the appropriate model for the entire world, or even any part of the world?

As many recently privatized industries could attest, private-sector activity has entirely different investment motivations and entirely different service objectives. If the nature of the activity is one that requires long-term investment in infrastructure with low returns, then private-sector activity tends to use the existing infrastructure base without necessarily making adequate longer-term replenishment investments. Private activity also tends to concentrate service delivery to the most lucrative sectors of the market, and, if possible, will deliberately avoid establishing services in areas that are less financially attractive. The task of structural cross-subsidization that makes ubiquitous equity of access possible is not seen as a private enterprise outcome, and aspects of communications such as universal service obligations and equity of access are seen as public regulatory functions rather than natural market outcomes of a deregulated industry.

The Internet today is anything but a level and balanced environment. There are concentrations of investment capability, concentrations of technical knowledge and logistical capability, concentrations of intellectual wealth, and concentrations of power and influence. How to create from this current diverse environment some form of structural cross-subsidization that extends the basic means of access to all is the appropriately lofty goal of the WSIS endeavor. There is also the more focused investigation of "Internet Governance" and the agenda of establishing to what extent the perception of the advantaged position of a small number of national entities in all this can be balanced by measures that allow other national economies to invest in this space on terms and conditions that do not involve a continuing flow of money and a ceding of power to these existing advantaged national interests.

As the WSIS documentation points out, "... building the foundations for an Information Society is a complex task. The digital revolution is already impacting the world in deeply intrinsic ways, perhaps more profoundly than even the industrial revolution itself. Yet, while the digital revolution has extended the frontiers of the global village, the vast majority of the world remains unhooked from this unfolding phenomenon."

The Secretary General of the UN chartered a smaller group to examine Internet Governance, in particular, the *Working Group on Internet Governance,* or WGIG. Its nine-month brief is to glean these issues of public policy in an environment that has very significant private-sector interest. Indeed from an international perspective, where regulatory powers, even of a reserve nature, are in a very real sense ephemeral, the work in WGIG to date with its discussion papers has done little. The discussion papers have illustrated the broad nature of the topics raised in the context of Internet Governance, but their poor depth, visibly poor levels of research, and lack of any real analysis of the selected topics only highlights the complexity of the underlying interplay of public- and private-sector interests within a domain that is also bounded by technical considerations.

At the same time the poor quality of these reports highlights the inability of WGIG to engage directly into the heart of this exercise, given their obvious constraints of time and resources. It is not surprising to observe that, following its February meeting WGIG has decided to abandon this set of discussion papers. If a fresh start is being contemplated for WGIG, then perhaps it is time to note that only half of the group's allocated time remains, and the topic is getting no easier with the passing of the days.

For those interests who wanted the ITU to become engaged in the Internet, hope has now been passed to the WSIS process and the related WGIG study into Internet Governance issues. This is seen as being a means of opening up the control of the Internet into a more conventional international process that dismantles what they see as the current position of global taxation that U.S. national interests have imposed on the rest of the world's population in the adoption of Internet-based services. For those who think the ITU remains an unreformed vehicle for the imposition of anachronistic, inappropriate regulatory measures that stultify any form of innovation and progress in telecommunications, the WSIS process is yet another venue to parade the stark contrast between the rather impressive track record of a deregulated market-driven approach to coordination of telecommunications services, as seen with the Internet, and the ineffectual outcomes from the international public regulatory sector.

Looking Forward

One view of this process is that this is a negotiation of national roles of influence and power over the coming century or more, and that this process requires some considerable care and attention at an international level.

This topic is one that places a model of deregulated private sector-led activity, with its market-based disciplines, into direct contrast with a more traditional model of the balancing of various national interests through common regulatory measures undertaken within each national regime as a regulated public-sector process. The proponents of a deregulated approach argue that the Internet is a child of the progressive position of deregulation of communications markets in many national environments, and it is the dynamic and creative impetus of highly competitive markets that has led to the rapid spread of the Internet and the consequent improvements in the efficiency and effectiveness of national and international communications systems. None of these outcomes would have been achievable, they argue, in a regulated regime where innovation and competition for the consumer were completely stifled by the deadening weight of regressive regulation.

Like many bold innovative experiments in international coordination and the establishment of new world orders, ICANN stands a strong risk of falling foul of an inherent conservatism in international politics, where the careful balancing of national interests is seen as being far more critical an objective than any actual outcomes that may be achieved from the process.

From this perspective, ICANN is critically reliant on its acceptance by all players of its legitimacy to operate in this space, and also critically reliant on acceptance of the proposition that these issues are best addressed in open forums of debate. This task is difficult, and the limited set of outcomes that ICANN can point to as being products of this process do not install a high degree of confidence that this process is stable, scalable, well-founded, and sustaining. Currently the proposition is not that ICANN represents the most appropriate enduring framework here, but that the track record of the alternative has failed in the past and nothing has changed to prevent the historical alternative framework making similar flawed decisions in the future.

The opposite end of the spectrum of views argues that nothing has really changed with the introduction of the Internet, and the international regime remains one where various national interests need to be resolved in a coordinated and equitable fashion. Without some form of common regulatory constraint, there are inevitable market distortions where the expression of vigorous national aspirations results in an advantaged position in the international domain. Public communications is a public-sector activity, they argue, and, ultimately, the only points of control rest within national regulatory regimes, and internationally it is a case where national interests must be balanced through a process that recognizes political realities of coordination and compromise. From this perspective it is asserted that the ITU is the intergovernmental venue for this activity as it relates to the communications sector, and it is to the ITU that national interests must look to redress distortions where one national entity or one region holds a contrived privileged position with respect to international communications.

In looking at these two extremes of perspective, an obvious question is what then is the role of international public policy setting? In this form of market-mediated service supply functions, are international issues being progressively transformed into aspects of international trade? Does such an environment provide adequate protection for developing economies? Are common social priorities being adequately considered in such a framework?

This leads to a more basic question of whether the existing international institutions, such as the ITU, are appropriately positioned to meet these public policy challenges, or should we be considering changes here in order to bring the international institutional framework into better alignment with the emerging information society?

These are certainly difficult positions to attempt to reconcile, and perhaps it is being impatient to expect clear outcomes in the near future, and certainly very difficult to expect that in a few short months WGIG and WSIS will be able to deliver a balanced, considered, and generally acceptable outcome in this space. It is also a natural concern in looking at these rather aggressive schedules for WSIS that short-term political expediency will obstruct genuine attempts to truly understand the fundamental nature of the changes that are happening with the differing model of communications that are heralded by the Internet model.

Book Review

Unix Network Programming

Unix Network Programming, 3rd Edition, by W. Richard Stevens, Bill Fenner, Andrew M. Rudoff, ISBN 0131411551, Addison-Wesley Professional, 2003.

It would be difficult to put value on a book that has been a classic text and a reference in academia and in the real world in the context of network programming for over a decade. Richard Stevens published the ever-popular *Unix Network Programming* [UNP] back in 1990, and the second edition followed in 1998. With a dedication to the memory of R. Stevens, the UNP book found itself two new authors, Bill Fenner and Andrew M. Rudoff, who would write the third edition of this book. The third edition has many updates, a new look and feel and many of new chapters that cover the topics more applicable these days. In my opinion, it is still the most valuable and profound text in the context of network programming.

Changes and Updates

For those of us who have the first two editions of this book, the third edition has the following changes:

- IPv6 updates. In the second version of the book, IPv6 was merely a draft, and the sections covering IPv6 have been updated to reflect these changes.
- POSIX updates. The functions/APIs and examples have been updated to reflect the changes to the latest version of the POSIX specification (1003.1-2001).
- SCTP coverage. Three new chapters that cover this new reliable, message-based transport protocol have been added.
- Key Management Sockets coverage. Network security and its applicability and use with IPsec are covered.
- The Operating Systems and machines that are used for the examples have been updated.
- Some topics such as Transaction TCP and X/Open Transport Interface have been dropped.

Many topics and sections have been updated with the authors' comments. These comments even though simple for someone new to the profession, are extremely useful because they are like hints and tips from one developer to the next to help you in your next programming assignment.

Unix Focus

If this is the only edition of the book that you will read, you are in for a treat. Topics in Network Programming are covered in detail, using concrete programming examples that all of us can relate to—all Unix, but what else is there?!

All kidding aside, the topics are covered well enough that they are useful information under any operating system. The concepts don't change; sockets are sockets under any operating system. The function call is different, but one needs to go through the same steps under any environment.

Being the most popular networking protocol, TCP/IP is covered in Part I of the book. You need to have prior understanding of the TCP/IP protocol and the OSI model, however. If this is the first time you are looking at the programming aspects of networking protocols, Part I of this book covers the basics. It begins with a couple of simple examples such as such as daytime client and a daytime server and it builds on that. TCP, UDP, and SCTP (*Stream Control Transmission Protocol*) are covered in brief in Part I, and basic concepts such as the three-way handshake of TCP and the four-way handshake of SCTP are depicted.

Part II of the book covers *sockets* and socket programming. Topics such as the socket Address Structure in IPv4 and IPv6 for TCP, UDP and SCTP are covered and examples (the same daytime client/server) are given to convey the point. It is important to mention here that all the topics and concepts are depicted for the three transport protocols: TCP, UDP and SCTP. Every socket API under the Unix programming environment is covered and examples are given for each function call to show the reader how the function can be utilized. Much attention is dedicated to Socket Options and how they are used or can be used for best results. Hints are given throughout the chapter about the pitfalls and best practices of each option.

After the basics are been covered, various I/O models are depicted in detail and examples are shown to convey the advantages and disadvantages of each I/O model. The five I/O models used through the book (and available under the Unix environment) follow:

- Blocking I/O
- Non-blocking I/O
- I/O Multiplexing (using select and poll)
- Signal driven I/O
- Asynchronous I/O

The *Stream Control Transmission Protocol* (SCTP), a new IETF standard is also covered in detail—from the basics to the advanced. The two interface models of SCTP (one-to-one and one-to-many) are covered in detail, and their differences with TCP are also explained in full. The client/server example used throughout the book is ported to use the new SCTP protocol. The authors then explain in detail the problems that SCTP solves over TCP and where and how it would be useful to use SCTP.

Advanced topics such as IPv4 and IPv6 portability, Unix Domain Protocols, Multicasting and advanced Socket programming for UDP, TCP and SCTP cover the rest of the chapters in this book.

Various options for interoperability between IPv4 and IPv6 are discussed in the last section of the book. Advanced I/O functions bring us a new perspective of how complicated Network Programming can become. Benefits and examples of nonblocking I/O are covered in detail—the authors give examples to show us how, with very few modifications, the performance of a socket application can improve dramatically. Various methods on how to control socket operations are discussed including the use of an alarm along with SIGALRM, the use of select and various timeout options that are available in the API.

The chapters that discuss Multicasting and adding reliability to UDP are my favorite chapters in this book. The Time Server used throughout the book is re-coded to become a multicast application. Some issues that arise when designing multicast applications such as multicast on a WAN are also discussed.

As Good as Ever

The third edition of *Unix Network Programming* is as good as ever. The updates truly reflect solutions to today's challenges in network programming. Bill Fenner and Andrew Rudoff did an amazing job continuing the work of a true legend in the field of Computer Science.

Read Any Good Books Lately?

Then why not share your thoughts with the readers of IPJ? We accept reviews of new titles, as well as some of the "networking classics." In some cases, we may be able to get a publisher to send you a book for review if you don't have access to it. Contact us at **ipj@cisco.com** for more information.

Fragments

Internet Pioneers Cerf and Kahn to Receive ACM Turing Award

The *Association for Computing Machinery* (ACM), has named Vinton G. Cerf and Robert E. Kahn the winners of the 2004 *A.M. Turing Award,* considered the "Nobel Prize of Computing," for pioneering work on the design and implementation of the Internet's basic communications protocols. The Turing Award, first awarded in 1966, carries a $100,000 prize, with financial support provided by Intel Corporation. Cerf and Kahn developed TCP/IP, a format and procedure for transmitting data that enables computers in diverse environments to communicate with each other. This computer networking protocol, widely used in information technology for a variety of applications, allows networks to be joined into a network of networks now known as the Internet.

ACM President David Patterson said the collaboration of Cerf and Kahn in defining the Internet architecture and its associated protocols represents a cornerstone of the information technology field. "Their work has enabled the many rapid and accessible applications on the Internet that we rely on today, including e-mail, the World Wide Web, Instant Messaging, Peer-to-Peer transfers, and a wide range of collaboration and conferencing tools. These developments have helped make IT a critical component across the industrial world," he said.

"The Turing Award is widely acknowledged as our industry's highest recognition of the scientists and engineers whose innovations have fueled the digital revolution," said Intel's David Tennenhouse, Vice President in the Corporate Technology Group and Director of Research. "This award also serves to encourage the next generation of technology pioneers to deliver the ideas and inventions that will continue to drive our industry forward. As part of its long-standing support for innovation and incubation, Intel is proud to sponsor this year's Turing Award. As a fellow DARPA alumnus, I am especially pleased to congratulate this year's winners, who are outstanding role models, mentors and research collaborators to myself and many others within the network research community."

In 1973, Cerf joined Kahn in a *Defense Advanced Research Projects Agency* (ARPA, now called DARPA) project to link three independent networks into an integrated "network of networks." They sought to develop an open-architecture network model for heterogeneous networks to communicate with each other independent of individual hardware and software configuration, with sufficient flexibility and end-to-end reliability to overcome transmission failures and disparity among the participating networks. Their collaboration led to the realization that a "gateway" (now known as a *router*) was needed between each network to accommodate different interfaces and route packets of data. This meant designating host computers on a global Internet, for which they introduced the notion of an *Internet Protocol* (IP) address.

As a graduate student at the University of California at Los Angeles, Cerf had contributed to a host-to-host protocol for ARPA's fledgling packet-switching network known as ARPANET. Kahn, prior to his arrival at ARPA, led the architectural development of the ARPANET packet switches while at Bolt Beranek and Newman (BBN), and had showcased the ARPANET in 1972, at the first International Conference on Computer Communications. ARPANET had already connected some 40 different computers and demonstrated the world's first networked e-mail application.

In May 1974, they published a paper describing a new method of communication called *Transmission Control Protocol* (TCP) to route messages or packets of data. Like an envelope containing a letter, TCP broke serial streams of information into pieces, enclosed these pieces in envelopes called "datagrams" marked with standardized "to and from" addresses, and passed them through the underlying network to deliver them to host computers. Only the host computers would "open" the envelope and read the contents.

This networking arrangement allowed for a three-way "handshake" that introduced distant and different computers to each other and confirmed their readiness to communicate in a virtual space. In 1978, Cerf and several colleagues split the original protocol into two parts, with TCP responsible for controlling and tracking the flow of data packets ("letters"), and IP responsible for addressing and forwarding individual packets ("envelopes"). The new protocol, TCP/IP, has since become the standard for all Internet communications.

Vinton Cerf and Robert Kahn share a number of awards, including the 1991 ACM Software System Award, the 2001 Charles Stark Draper Prize from the National Academy of Engineering, the 2002 Prince of Asturias Award, and the 1997 National Medal of Technology from President Bill Clinton. They are both the recipients of numerous honorary degrees. ACM will present the Turing Award at the annual ACM Awards Banquet on June 11, 2005, in San Francisco, CA.

The A.M. Turing Award was named for Alan M. Turing, the British mathematician who articulated the mathematical foundation and limits of computing, and who was a key contributor to the Allied cryptanalysis of the German Enigma cipher during World War II. Since its inception, the Turing Award has honored the computer scientists and engineers who created the systems and underlying theoretical foundations that have propelled the information technology industry.

New Administrative Structure for the IETF

The *Internet Engineering Task Force* (IETF) is well advanced in the process of making a significant change to the administrative structure that supports the world's leading Internet standards development group. The creation of an *IETF Administrative Support Activity* (IASA) is an important move designed to help the IETF maintain and expand the unique open processes that have enabled the development of Internet standards since 1986.

The new structure will allow the IETF to take full responsibility for managing the resources required to accomplish its work—giving the IETF a solid foundation on which future operations will be based.

This is the first time that all the IETF's administrative and support functions will be managed directly by the IETF as one fully integrated entity. Until now, administration of the IETF has been carried out exclusively by helper organizations and volunteers. The new IASA will be formally structured as an activity within the *Internet Society* (ISOC)—the organizational home of the IETF—and an *IASA Administrative Director* (IAD) will be appointed to provide central management of IETF administration.

The decision to move forward with the new structure was taken after extensive consultations with the Internet community. A number of key prerequisites for efficient administrative operations were identified, including the need for the IETF to have budgetary autonomy. The IETF is currently supported by funding from multiple sources, including meeting fees, donations from interested corporate and non-corporate entities, and donations in kind of equipment or manpower. The IASA will allow the IETF to be able to consider all sources of income, and all expenses involved in running the IETF, as pieces of one budget.

The IASA will also be responsible for defining clear contractual relationships with other organizations that will continue to provide basic services, including meeting organization, secretarial services, IT services, etc. The new structure also gives the IETF flexibility in how it chooses to fund and develop any additional services that may be required.

The IETF is a large open international community of network designers, operators, vendors, and researchers concerned with the evolution of the Internet architecture and the smooth operation of the Internet. It is open to any interested individual. See: **`http://www.ietf.org`**

ISOC is a non-governmental international organization for global cooperation and coordination for the Internet and its internetworking technologies and applications. Members comprise commercial companies, governmental agencies, foundations, and individuals. ISOC has 82 Chapters in over 60 countries around the world. For more information see: **`http://www.isoc.org`**

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

From The Editor

The Internet is a constantly evolving environment which puts pressures on existing and evolving protocols. Any protocol changes must be carefully designed and even more carefully deployed to avoid any disruption to the running system. It is no longer possible to orchestrate a simple overnight switch, so engineers are considering various transition and evolution strategies. In this issue we bring you two examples of this kind of evolutionary protocol development.

Our first example relates to *IP Version 6* (IPv6). A great deal of effort is going into the deployment of IPv6, and good transition strategies can help. Tejas Suthar explains how *Multiprotocol Label Switching* (MPLS) can be used for a transition from IPv4 to IPv6.

Our second example looks at a possible enhancement to the *Border Gateway Protocol* (BGP). BGP in its current form is already nearly ten years old, and calls for its replacement can be heard from network operators. Russ White discusses some possible changes that would not require a wholesale protocol replacement.

It is not every day that a book on punctuation becomes an international best seller, and it is certainly not common for IPJ to review such a non-computer related book. But I think it is appropriate for several reasons. First, accurate punctuation is important not just for computer parsers, it is important for all professionals whether we are sending quick e-mails or writing project reports. Second, this is a really *fun* as well as informative book. And last, but not least, it gives me an opportunity to introduce you to Bonnie Hupton, who provides copy-editing services for this journal. Without her help, IPJ would be far less readable.

Our Website at **www.cisco.com/ipj** has a new look, but still contains links to our back issues, index files and the IPJ subscription system. Please take a moment to renew or update your subscription. If you have questions or comments, please send them to **ipj@cisco.com**.

IPv6—A Service Provider View in Advancing MPLS Networks

by Tejas Suthar, TELUS Communications Inc.

We are all aware of the evolution of the *Internet Protocol* (IP) and its dominance on all aspects of our lives, either directly or indirectly. Currently IP Version 4 delivers critical business application traffic in a so-called new world of the Internet. As the evolution goes on, *IP Version 6* (IPv6)[5] is becoming a necessary element of the network. IPv6 will enable businesses to expand their capabilities exponentially without having any limitations or restrictions. As technologies evolve and the adoption of IP-enabled devices accelerates, IP will enter a new era as the protocol of choice for communications. Using globally unique IPv6 addresses increases the opportunity for service providers to create new business models and add revenue, and it increases the portfolio of services. However, the major demand for support of IPv6 will be mobile applications; the IT world will also tie in all the systems for transparent operation. The days are not far when permanent IPv6 addresses will be assigned to individuals for their communication purposes—either *Voice over IP* (VoIP), video over IP, video on demand, wireless Internet access, unified messaging, etc. Also, IP smart appliances are becoming more and more popular, and the result will be explosive usage and adoption of IPv6 addresses. Articles outlining the importance of IPv6 and limitations of IPv4 abound. This article is mainly geared toward highlighting the service provider networks that are built or currently being built to support IPv6 in a VPN fashion.

Multiprotocol Label Switching (MPLS)[4] is widely accepted as a core technology for the Next-Generation Internet that provides speed and functions in packet forwarding. Service providers that offer MPLS/VPN services to their customers are looking forward to adding IPv6 VPN services to their portfolio. Service providers that want to support IPv6 in traditional ways have few options, such as tunneling methods (for example, manual, *Tunnel Broker, Generic Routing Encapsulation* [GRE], or *Intrasite Automatic Tunnel Addressing Protocol* [ISATAP], which has scalability problems); or Native IPv6 with dual-stacked MPLS core. However, consider the following:

- For MPLS VPN services, service providers made a significant investment in building the IPv4/MPLS backbone. The return on investment thresholds are probably yet to be achieved.
- Backbone stability is another critical factor; service providers must offer reliable services, especially with regard to voice over MPLS. Most service providers have recently managed to stabilize their IPv4 infrastructure, and they are hesitant to make another significant move when it comes to supporting IPv6 unless the integration is smooth.

Standards bodies with help from vendors and leading service providers are addressing these concerns. Currently service providers have two approaches that they can deploy to support IPv6 without making any changes to the current IP (v4) MPLS backbones, namely *6PE*[1] and *6VPE*[2], originally defined in RFC 2547.

The 6PE approach lets IPv6 domains communicate with each other over an IPv4 cloud without explicit tunnel setup, requiring only one IPv4 address per IPv6 domain. The 6PE technique allows service providers to provide global IPv6 reachability over IPv4 MPLS. It allows one shared routing table for all other devices. Typical applications are IP toll voice traffic and Internet transit services over a common MPLS infrastructure. The 6PE technique does not provide any logical separation because it is for MPLS VPN.

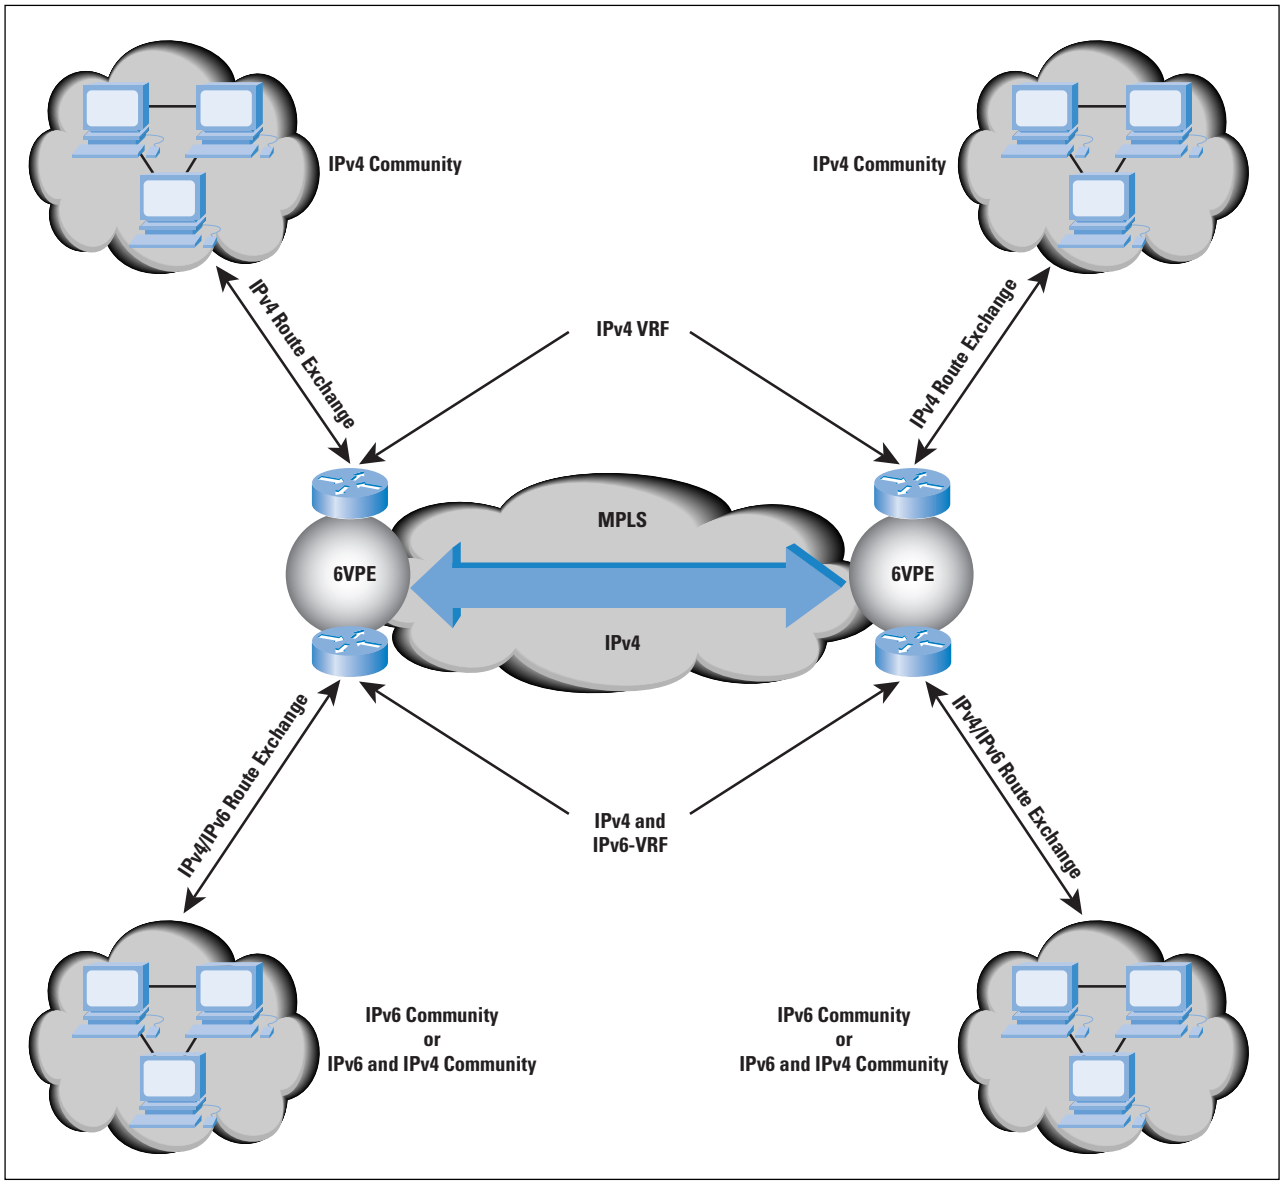
The newest feature to facilitate the RFC 2547bis-like VPN model for IPv6 networks is called 6VPE. It will save service providers from enabling a separate signaling plane, and it takes advantage of operational IPv4 MPLS backbones. Thus there is no need for dual-stacking within the MPLS core. This represents a huge cost savings from the operating expenses perspective and addresses the security limitations of the 6PE approach. 6VPE is more like a regular IPv4 MPLS-VPN provider edge, with an addition of IPv6 support within *Virtual Routing and Forwarding* (VRF). It provides logically separate routing table entries for VPN member devices. This article reviews this approach in more detail because it is the likely approach to succeed in the service provider network.

Under the Hood of 6VPE

Before we look into the 6VPE, it is important to clarify the definition of "dual stack," a technique that allows IPv4 and IPv6 to coexist on the same interfaces. Today, IPv4 has roots in most of the hosts that run applications. Moreover, stability as well as reliability of new applications over IPv6 is maturing. Therefore, coexistence of IPv4 and IPv6 is a requirement for initial deployment. With regard to supporting IPv6 on a MPLS network, two important aspects of the network should be examined:

- *Core:* The 6VPE technique allows carrying IPv6 in a VPN fashion over a non-IPv6-aware MPLS core. It also allows IPv4 or IPv6 communities to communicate with each other over an IPv4 MPLS backbone without modifying the core infrastructure. By avoiding dual-stacking on the core routers, the resources can be dedicated to their primary function to avoid any complexity on the operational side. The transition and integration with respect to the current state of networks is also transparent.
- *Access:* In order to support native IPv6, the access that connects to IPv4/IPv6 domains need to be IPv6-aware. Service provider edge elements (provider edge routers) can exchange routing information with end users. Hence dual stacking is a mandatory requirement on the access layer as shown in Figure 1.

Figure 1: 6VPE Overview



The IPv6 VPN solution defined in this article offers many benefits. Especially where a coexistence of IPv4 and IPv6 is concerned, the same MPLS infrastructure can be used without putting additional stress on the provider router. Also the same set of *Multiprotocol Border Gateway Protocol* (MPBGP) peering relationships can be used. Because it is independent of whether the core runs IPv4 or IPv6, the IPv6 VPN service supported before and after a migration of the core to IPv6 can be done independent of the customer VPN.

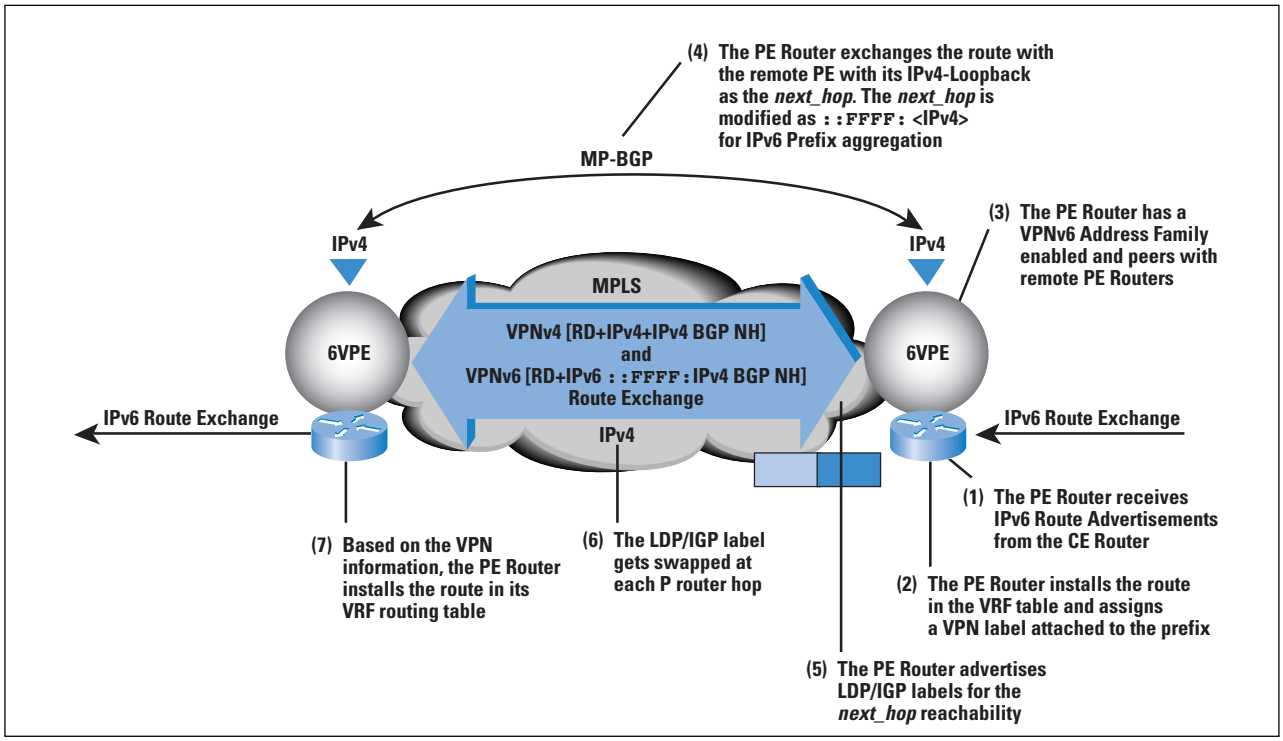
Within the MPLS core, the backbone *Interior Gateway Protocol* (IGP) (*Intermediate System-to-Intermediate System* [IS-IS] or *Open Shortest Path First* [OSPF]) populates the global routing table (v4) with all provider edge and provider routes. As outlined in the draft for IPv4 MPLS VPN (2547-bis), 6VPE routers maintain separate routing tables for logical separation. This allows the VPN to be private over a public infrastructure.

The VRF table associated with one or more directly connected sites (customer edge devices) form close IPv6 or IPv4 speaking communities. The VRFs are associated to physical or logical interfaces. Interfaces can share the same VRF if the connected sites share the same routing information. MPLS nodes forward packets based on the top label. IPv6 packets and IPv4 packets share the same common set of forwarding characteristics or attributes, also known as *Forwarding Equivalence Class* (FEC) within the MPLS core.

6VPE Operation

When IPv6 is enabled on the sub-interface that is participating in a VPN, it becomes an IPv6 VPN. The customer edge-provider edge link is running IPv6 or IPv4 natively. The addition of IPv6 on a provider edge router turns the provider edge into 6VPE, thereby enabling service providers to support IPv6 over the MPLS network.

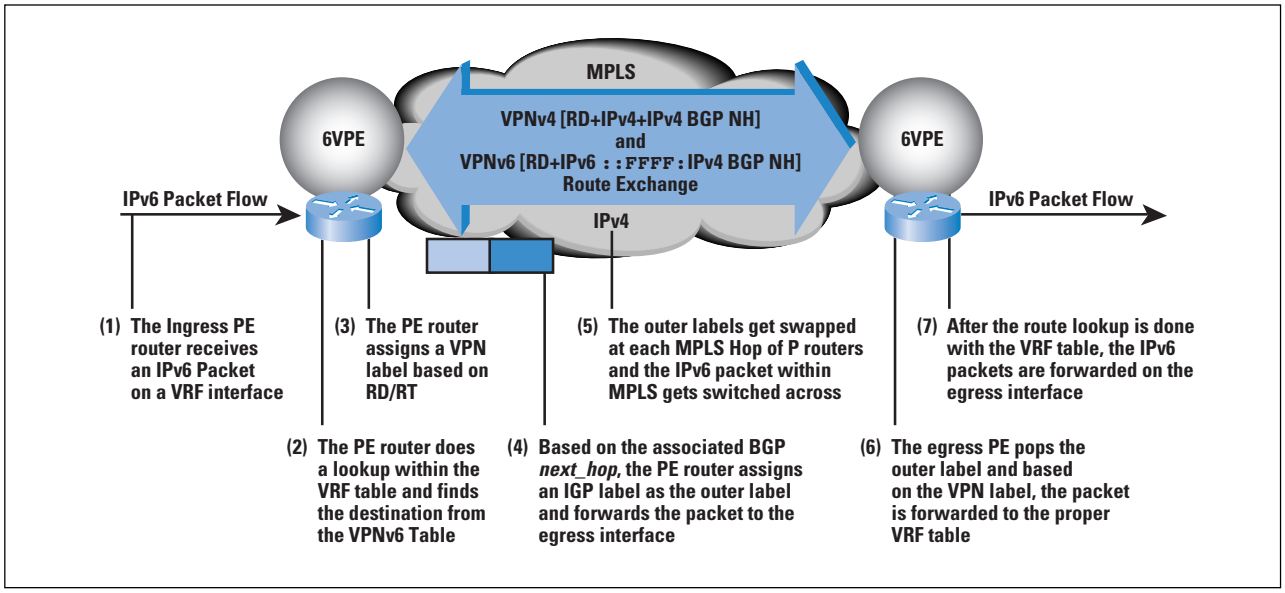
Figure 2: 6VPE Route Advertisement



As outlined in Figure 2, provider edge routers use VRF tables to maintain the segregated reachability and forwarding information of each IPv6 VPN. MPBGP with its IPv6 extensions distributes the routes from 6VPE to other 6VPEs through a direct *internal BGP* (iBGP) session or through VPNv6 route reflectors. The next hop of the advertising provider edge router still remains the IPv4 address (normally it is a loopback interface), but with the addition of IPv6, a value of **`::FFFF:`** gets prepended to the IPv4 *next_hop*. The technique can be best described as automatic tunneling of the IPv6 packets through the IPv4 backbone. The MP-BGP relationships remain the same as they are for VPNv4 traffic, with an additional capability of VPNv6. Where both IPv4 and IPv6 are supported, the same set of MPBGP peering relationships is used.

MPBGP is enhanced to carry IPv6 in a VPN fashion known as VPNv6, which uses a new VPNv6 address family. The VPNv6 address family consists of 8 bytes—a *Route Distinguisher* followed by a 16-byte IPv6 prefix. This combination forms a unique VPNv6 identifier of 24 bytes. The Route Distinguisher value has a local significance on the router, and the *Route Target* advertises the membership of the VPN to other provider edge routers.

Figure 3: 6VPE Packet Forwarding



In Figure 3, packet forwarding is explained showing end-to-end operation. When the ingress 6VPE router receives an IPv6 packet, destination lookup is done in the VRF table. This destination prefix is either local to the 6VPE (which is another interface participating in the VPN) or a remote ingress 6VPE router. For the prefix learned through the remote 6VPE router, the ingress router does a lookup in the VPNv6 forwarding table. The VPN-IPv6 route has an associated MPLS label and an associated BGP *next_hop* label. This MPLS label is imposed on the IPv6 packet. The ingress 6VPE router performs a PUSH action, which is a top label bind by the *Label Distribution Protocol* (LDP)/IGPv4 to the IPv4 address of the BGP *next_hop* to reach the egress 6VPE router through the MPLS cloud. This topmost-imposed label corresponds to the *Label Switched Path* (LSP). So, the bottom label is bound to the IPv6 VPN prefix through BGP and the top label is bound by the LDP/IGP. The IPv6 packet, now with two labels, gets label-switched through the IPv4/MPLS core router (provider routers) using the top label only (referred to as the *IGP label*). Because only the top label is of significance to the provider core, it is unaware of the IPv6 information in the bottom label.

The egress provider edge router, receives the labeled IPv6 VPN packet and performs a lookup on the second label, a process that uniquely identifies the target VRF and the egress interface. A further Layer 3 lookup is performed in the target VRF, and the IPv6 packet is sent toward the proper customer edge router in IPv6 domain.

In summary, from the control plane perspective the prefixes are signaled across the backbone in the same way as for regular MPLS/VPN prefix advertisements. The top label represents the IGP information that remains the same as for IPv4 MPLS. The bottom label represents the VPN information that the packet belongs to. As described earlier, additionally the MPBGP *next_hop* is updated to make it IPv6-compliant. The forwarding or data plane function remains the same as it is deployed for the IPv4 MPLS VPN. The packet forwarding of IPv4 on the current MPLS VPN remains intact.

6VPE Design Recommendations and Considerations

The following sections identify general recommendations that should be considered when deploying IPv6 in a service provider network:

Working with Enterprise Implementations

Typically *Customer Metropolitan-Area Networks* (C-MANs), also known as *Campus Networks* or *Customer LAN* (C-LAN) elements, form the enterprise network, whereas the 6VPE and customer edge provide the entry point into network access. IPv6 can be supported partially or fully on an enterprise network. In situations where enterprise-wide IPv6 deployment does not exist, network administrators can elect to tunnel the IPv6 traffic toward the provider's customer edge or 6VPE. This can be done with 6-to-4 tunneling methods currently[7]. So, if a site router within a C-MAN or C-LAN aggregates all IPv6 traffic and tunnels to a provider-managed customer edge or 6VPE router, then integration as well as migration becomes smooth. Therefore, it is important for the vendor and the customer to work together in determining the best approach.

Dual VRF Membership per Interface

RFC 2547 for IPv4 recommends one VRF per interface. When running dual stack on a 6VPE, multiple VRF configurations on a single physical or logical interface are required (IPv4 and IPv6). Each VRF instance configuration on a dual-stacked interface forms IPv4 and IPv6 address families. Each address family within VRF runs a VRF-aware routing protocol—such as static routing (static IPv6 unicast routing for IPv6), BGP (BGP with IPv6 enhancements for IPv6), OSPF (OSPFv3 for IPv6), or *Routing Information Protocol* (RIP) (RIPng for IPv6).

MTU Requirements

One important piece of information within the network elements is the capacity of the interface to transfer the size of datagrams. This is known as the *Maximum Transmission Unit* (MTU). The minimum link MTU for IPv4 packets is 68 bytes, whereas for IPv6 the minimum MTU should be 1280 bytes. While designing and planning for IPv6 support, the network elements should be examined along with interfaces and underlying network technologies to ensure the MTU requirements.

Dealing with Link-Locals

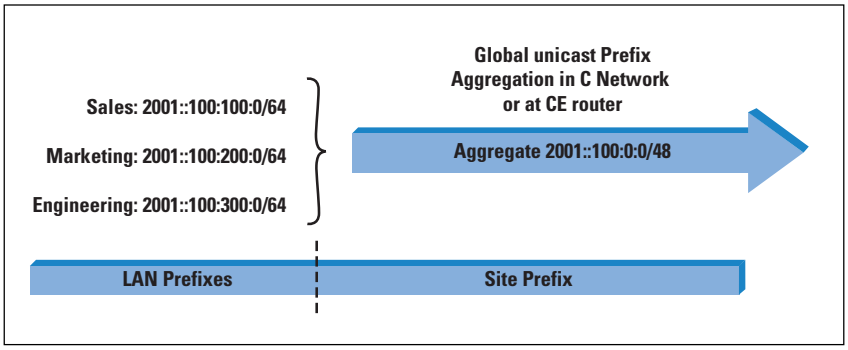
Because link-local scope addresses are defined as uniquely identifying interfaces within a single link, only those may be used on the provider edge-customer edge link.

However, they are not supported for reachability across IPv6 VPN sites and are never advertised with MPBGP to remote provider edges. As outlined in the RFC for IPv6 address assignments, the link locals (**`FE80::x`**) should not be advertised outside their local scope. Because the link-local addresses are embedded on the IPv6-enabled interface for certain local tasks, the link-local addresses are not and should not be advertised anywhere outside the local link scope, including the customer edge and 6VPE running IPv6. Globally unique aggregatable IPv6 prefixes are defined as uniquely identifying interfaces anywhere in the network. These addresses are expected for common use within and across IPv6 VPN sites. They are obviously supported by this IPv6 VPN solution for reachability across IPv6 VPN sites and advertised through MPBGP to remote provider edges.

Router Capacity Impact

Dual-stacking also introduces another task, namely hardware analysis to determine the resource capacity, that is, CPU and memory usage. Increased memory consumption may occur because of the dual-stack *Routing Information Base* (RIB). It also has implications for the *Interface Descriptor Block* (IDB) and *Routing Descriptor Block* (RDB) limits of hardware. The IDB limit is the capacity of particular equipment to support a number of physical and logical interfaces, whereas the RDB limit is the number of routing protocols and instances supported on such equipment. Typically these values (limits) are very high, but 6VPE is such an important element of the MPLS network that these facts must be considered. From a business case perspective, scalability, high aggregation, and rapid Return on Investment are expected, hence it is important to consider these factors in the design.

Figure 4: Route Aggregation



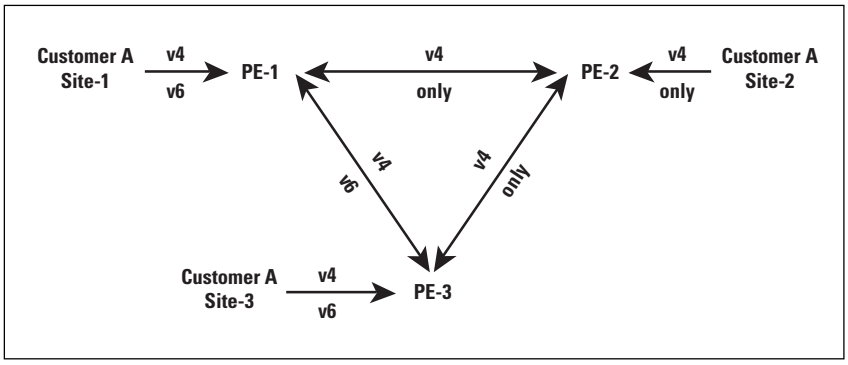
Router Memory Impact

The memory challenges can occur also when large numbers of IPv6 prefixes are advertising toward service provider network elements. In that event, the enterprise on the C-LAN or service provider on the customer edge router may elect to perform route aggregation. IPv6 prefixes can be aggregated to their higher-level significant boundary. Figure 4 shows an example of IPv6 prefix aggregation. Moreover, when a packet arrives on a dual-stacked interface (VRF-aware interface), the 6VPE router determines the packet version number by looking into the IP header. The per-packet header lookup is normally performed (it is a basic router function), but the extra work required by the router is to determine the version number. This additional task creates a longer processing cycle.

The Address Family Identifier and its Importance

All the elements referenced as dual-stacked, such as provider edge and customer edge routers, run IPv4 as well as IPv6 addressing and routing protocols. The 6VPE elements can also mix and match VPNv4 and VPNv6 peering sessions with other 6VPE routers or with route reflectors. What does the term "mix and match" mean here? It was an important enhancement to traditional BGP when MPBGP extensions were introduced. The address family within MPBGP is modular to facilitate distinct peering relationships, and is expressed using the *Address Family Identifier* (AFI). The regular BGP capabilities are exchanged after the peering sessions are turned on. In order for two provider edge routers to exchange labeled IPv6 VPN prefixes, they must use BGP capabilities negotiation to ensure that they both are capable of processing such information. When the service provider network is running VPNv4 peering sessions with other respective elements in the network, it exchanges the VPNv4 AFI capabilities with others. When the VPNv6 peering sessions are turned on, it renegotiates the capabilities and fresh peering sessions are established. The peering sessions established are based on common features if either of the peers does not agree on any of the capabilities.

Figure 5: VPNv4 and VPNv6 AFI



In Figure 5, three provider edge routers out of two need to exchange VPNv6 traffic, but all three provider edge routers need to maintain their existing VPNv4 capabilities. This is possible with the AFI configuration feature, which makes the migration steps very smooth. Service providers can mix and match VPNv4 and VPNv6 provider edge routers as required. Functions of 6VPE can be turned on when and where required. If the customer edge routers are dual-homed to different provider edge routers, the integration of customer IPv4 and IPv6 networks becomes painless. This scenario outlines hybrid environments, but it does not address the IPv4 and IPv6 communication. Consider techniques such as *Network Address Translation* (NAT) or application layer gateways for the IPv4 and IPv6 communication.

Route Reflectors for MP-IBGP

For advertising VPN membership, provider edge routers peer with VPNv4 route reflectors for scalability, thereby avoiding the need for full-mesh MP iBGP sessions among all provider edge routers. The same concept is supported for VPNv6. The same VPNv4 route reflectors can be upgraded to support VPNv6 address families.

Route reflectors can also make addition or removal of a provider edge router from a network simple and flexible. Alternatively, the BGP confederation option can also be deployed to provide MPBGP peering sessions among provider edge routers.

QoS Considerations

Service providers operating customers' MPLS VPN networks and also providing *Quality of Service* (QoS) should account for the new introduction of IPv6 and its impact. QoS and queuing of important application traffic requires distinct policies for IPv4 and IPv6, in turn possibly requiring additional operational tasks where IPv4 and IPv6 networks coexist. Other design considerations should be made to account for each individual network. Both IPv4 and IPv6 have a commonality, which is the 3-bit IP *Precedence* (or *Type-of-Service* [ToS]) field within the IP headers. Alternatively, the *Differentiated Services* (Diff-Serv)-compliant QoS models can also be employed. Irrespective of the technique, QoS is an important factor when low-speed links are concerned. However, there is no additional advantage of QoS on IPv6 versus IPv4. At some point in the future IPv6 can be different by using the flow label in the IPv6 header. QoS within the MPLS core remains *MPLS Experimental Value* (MPLS_EXP)-based and is untouched but still is effective with the addition of IPv6.

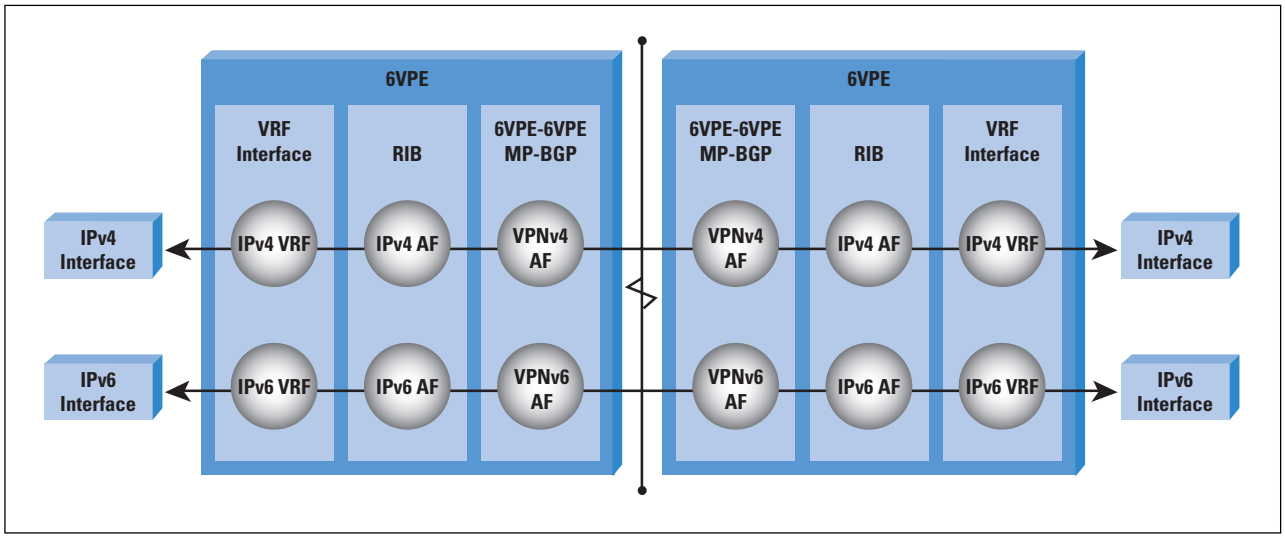
Device Management

Finally, device management is another important aspect that service providers must consider. Device management in a dual-stacked network can be done through an IPv4 or IPv6 address. Where the IPv6 VPN service is supported over an IPv4 backbone, and where the service provider manages the customer edge, the service provider can elect to use IPv6 for communication between the management tool and the customer edge for such management purposes. The management systems, including *Operations-Support-System* (OSS) servers, need to be aware of IPv6 and must run proper *Simple Network Management Protocol* (SNMP) stacks in order to perform IPv6-based management. From the VPN perspective it still remains transparent how the device and services are managed.

Enhancements to the Draft

The current MPLS VPN services that service providers have implemented are based on RFC 2547bis, the Internet Draft required to enhance the Layer 3 VPN approach further to address the IPv6 support. The "BGP-MPLS VPN extension for IPv6 VPN"[1] is the current Draft that addresses the need for IPv6 support over MPLS networks in a VPN environment. Also, to avoid an extra layer of signaling, the Draft addresses the scalable automatic tunneling of VPN-based IPv6 prefixes. The basic functions remain the same as outlined in RFC 2547. Some of the extensions outlined will require additional work in order to be effective in the service provider network.

Figure 6: Dual Mode 6VPE AFI Model



The standard RFC 2547bis introduces "address family" concepts, as well as MPBGP to carry VPN information across the MPLS network. This enables formation of a full mesh between customer sites. The provider edge routers advertise their VPN membership to other provider edge routers through direct iBGP or value(s). As shown in Figure 6, these new address families are introduced to support IPv6 within VPN, IPv6, and VPNv6. If configured for dual stacking, the interface belongs to multiple VRF instances, IPv4 and IPv6. Each instance maintains its own RIB. MPBGP is now capable of handling the VPNv6 address family to advertise the IPv6 prefix across the VPN.

Summary

"Staying abreast of the best" has always been challenging for service providers when it comes to technology deployment or support. Time to market is another challenge. This article provides a view of the service provider challenges. In this new era where explosive use of IPv6 is envisioned, it is extremely important for service providers to have a simplified, automated, fail-proof, and cost-effective network design. The Internet Draft discussed advances the capabilities to achieve this and allows service providers to take a practical approach in supporting IPv6 for customers' next-generation applications. The Draft brings service providers closer to the IPv4-to-IPv6 transition with a simple, cleaner, cheaper, and scalable solution.

Graph Overlays on Path Vector: A Possible Next Step in BGP

by Russ White, Cisco Systems

Over the past several years, much research and thought has gone into a replacement for the current interdomain routing protocol, *Border Gateway Protocol* (BGP)[1]. For instance:

- In 2002, the *Internet Research Task Force* (IRTF) published a set of requirements for a next-generation interdomain routing protocol. In fact, several sets of requirements documents have been published in this area.
- In December 2001, *The Cook Report* noted that BGP needs to be replaced[2]:
- In October 2003, the *Workshop on Internet Routing Evolution and Design* (WIRED) presented papers arguing that BGP needs to be replaced[3].
- In December 2001, the IETF published RFC 3221[5], authored by Geoff Huston, which provided some background information toward finding a replacement for BGP.

There are probably thousands of references in magazine articles, conference proceedings, and research papers, all stating that BGP should be replaced. Of course, all these discussions wind up at the same place: It is almost impossible to replace BGP, wholesale, in the public Internet, or even in any of the private networks running BGP today.

The basic problem is you cannot take the network down, and you cannot replace the routing protocol without taking the network down. Many very clever ideas have been proposed to get around this problem—complex transition schemes, moving partitions, and all sorts of other concepts. But, in the end, the idea of transitioning from one routing protocol to another on something as large—and as distributed in both geography and ownership—as the Internet, has been a hard wall against which all the proposals for new interdomain routing protocols pile up. In an article[4] here in *The Internet Protocol Journal,* Geoff Huston states:

> "Another approach is to consider the feasibility of decoupling the requirements of inter-domain connectivity management with the applications of policy constraints and the issues of sender- and receiver-managed traffic-engineering requirements. Such an approach may use a link-state protocol as a means of maintaining a consistent view of the topology of inter-domain network, and then use some form of overlay protocol to negotiate policy requirements of each Autonomous System, and use a further overlay to support inter-domain traffic-engineering requirements."

In this article, we propose building on this concept, but in a novel way: rather than replacing BGP, or attempting to solve all the currently perceived problems with BGP at once, we attempt to address two problems in a way that does not heavily modify day-to-day BGP operation. Rather than replace BGP, enhance it to account for new re-quirements by providing new capabilities. If done right, this avoids the problem of deploying a new routing protocol altogether, because BGP is already deployed throughout the Internet.

Problems with BGP

No discussion of replacing BGP would be complete without a discussion of why so many people think BGP needs to be replaced. We need to consider three main points in this area: *convergence speed*, *policy*, and *security*. Each of these is covered in the following sections.

BGP Convergence Speed

Through various studies, and through examining the way in which BGP works, it has been shown that BGP, in an interdomain environment, always converges roughly in:

(Maximum AS_PATH – Minimum AS_PATH) × Minimum Advertisement Interval

To understand why this is so, let's examine the following small internetwork as it converges.

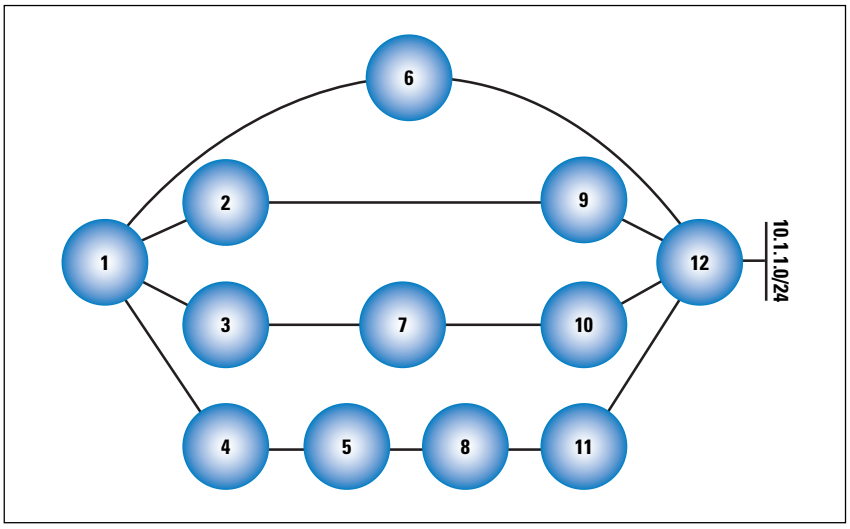

Figure 1: An Example Internetwork Using a Path Vector Protocol

Let's assume autonomous system (AS) 12 is advertising some destination, 10.1.1.0/24, and that every other autonomous system in the internetwork chooses the path to the right to reach that destination. So, for instance, AS4 chooses the path {5,8,11,12} to reach 10.1.1.0/24, AS3 chooses the path {7,10,12} to reach 10.1.1.0/24, AS2 chooses the path {9,12} to reach 10.1.1.0/24, and AS6 chooses the path {12} to reach 10.1.1.0/24.

At this point, let's examine what happens if AS12 loses its connection to 10.1.1.0/24. AS12 sends out a withdraw, which reaches AS6, 9, 10, and 11 at about the same time. These autonomous systems then send out withdraws, with the second set of withdraws reaching AS1, 7, and 8 at about the same time.

When AS1 receives this first withdraw, it examines its local table, and finds the next best path to reach 10.1.1.0/24 is through AS2, with the path {2,9,12}. AS1 does not realize that AS2 has received a withdraw for 10.1.1.0/24 at the same time it received the first withdraw for this destination from AS6. So, AS1 switches over to its next best path, and continues forwarding traffic to 10.1.1.0/24.

AS2, 7, and 8 now also send withdraws to each of their peers, including AS1, 3, and 5. AS1 now receives another withdraw, again for the path it is currently using to reach 10.1.1.0/24. AS1 examines its local tables and finds it has another path, through {3,7,10}, to 10.1.1.0/24, so it switches to that path, without knowing AS3 has just received a withdraw for this same path. AS3 and 5 now send withdraws to each of their peers, AS1 and 4. AS1 has again received a withdraw from the peer it is using to reach 10.1.1.0/24, so it examines its local tables, and finds it still has a path through {4,5,8,11,12} to reach this destination. It switches to this path, without realizing AS4 has just received a withdraw as well.

AS4 now sends the final withdraw to AS1, removing AS1's final path from its local tables. AS1 now removes all reachability information for 10.1.1.0/24, and the network is converged. Note that the actual convergence in this situation would be a bit more complicated, with AS1 sending updates at each stage, and all the other autonomous systems reconverging at each step along the way, but we have used only the simplest set of messages through the network, to illustrate the basic procedure BGP follows when converging.

This short example illustrates why BGP has the convergence characteristics described previously. BGP "hunts" through each possible autonomous-system path, from shorter ones to longer ones, until it finally converges. The rate at which it can hunt through each possible autonomous-system path is determined by the minimum advertisement interval, the rate at which new routing information is allowed to flow through the system.

This problem has several obvious solutions. The first is to simply increase the rate at which routing information flows through the system, by reducing the minimum advertisement interval. But, this plays against route flap dampening, and network stability in general, so, beyond some lower possible bound, reducing the minimum advertisement interval is not possible (without further modifications to BGP).

Another obvious solution is to simply add a "reason code" to the original withdraw. If AS12 originally stated it was withdrawing reachability to 10.1.1.0/24 because it had lost local connectivity to it, then all paths with AS12 in the path could have been discarded immediately, at the first step. The problem here is making certain the original withdraw message actually makes it through the network, from AS12 all the way to AS1. Because BGP is a very efficient protocol, many control messages of this type are actually removed from the network, through implicit withdraws, aggregation, and other mechanisms.

Policy

The second problem we encounter with BGP is its rather rough sense of policy. For instance, let's examine the following small network, and look at one specific example of where policy transmission and enforcement are problematic in BGP.

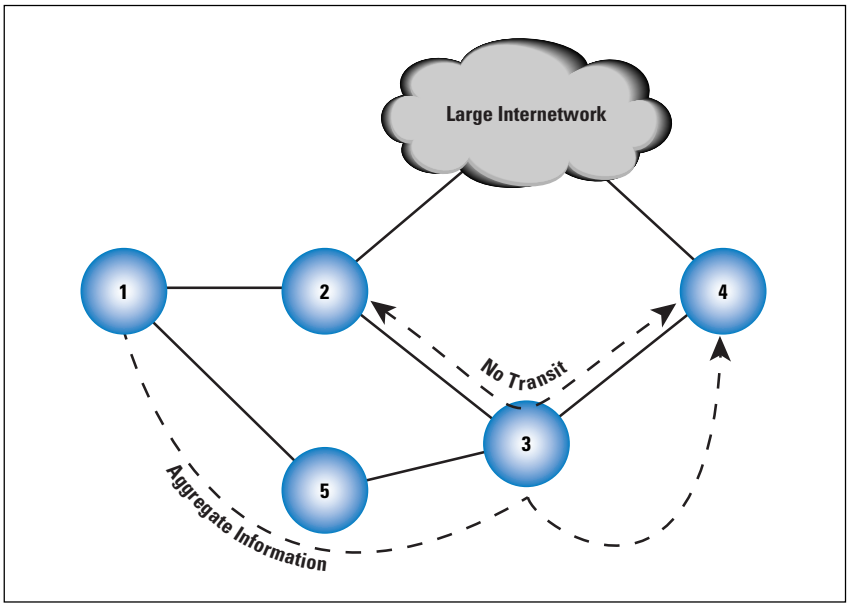

Figure 2: Issues with Policy Transmission in a Path Vector Protocol

Here AS2 has a policy that AS3 should never be used for transit. In other words, traffic originated in AS4 should always pass through the large internetwork rather than through AS3 to reach AS1. This type of situation is very common in the public Internet, such as when AS3 is actually AS2's customer. How can AS2 communicate this policy to AS4, however?

AS2 could simply mark the routing information it sends to AS3 so AS3 cannot readvertise it to AS4, but this is problematic. Simple mechanisms, such as marking the routes with the NO_EXPORT community, are easy for AS3 to simply strip off the routing information it receives. We could conceive of some way to cryptographically sign the included policy, so AS3 cannot disturb the policy and AS4 can see the policy when it receives the information from AS3, but this is problematic as well.

Suppose AS3 is receiving aggregated routing information directly from AS5, which includes some of the same destinations AS2 has advertised to AS3, but has blocked AS3 from advertising to AS4. AS3 could, conceivably, readvertise this routing information to AS4, and AS4 could prefer this shorter prefix aggregate to reach the destinations in AS1, rather than the paths through the large internetwork. AS4 would then forward traffic to AS3, which would then rely on its longer prefix routes, received from AS2, to forward this traffic to these destinations in AS1. AS3 is, contrary to AS2's policy, transiting traffic through AS2 to AS1. There is no simple answer to this problem.

Security

It has been widely acknowledged that BGP is an insecure protocol, with many areas where attackers can hijack, inject false routing information, and perform other attacks. The IETF's *Routing Protocols Security* (RPsec) working group is working on a set of documents describing vulnerabilities of BGP, and creating recommendations for systems to secure BGP. For the latest information about these Drafts, refer to the RPsec homepage at: **`http://www.rpsec.org`**

What sort of requirements are likely to come out of such an undertaking?

- Any proposed mechanism must be able to show that a specific autonomous system is authorized to originate specific routing information.
- Any proposed mechanism must be able to show that the AS Path carried in received routing information corresponds to a real path in the internetwork, beginning with the origin AS and ending in the advertising peer.

There will be many other requirements that proposed mechanisms for providing security for BGP will need to, or should, meet, but these two will be the largest areas of concern for our purposes.

Solving the Problems

Now that we have an idea of the three areas we want to solve problems in, how can we actually solve them? The most elegant solution would be a single mechanism that does not change the current semantics of BGP itself too greatly, would provide greater benefits as it is deployed throughout a large-scale internetwork, and would rely on existing—and understood—techniques within routing.

One perfect example of such a mechanism would be to simply overlay a link state-like graph of interconnectivity over the BGP protocol. This graph would provide information about the interconnections between autonomous systems, rather than between routers, and would be used to convey information about the topology and policies in the internetwork, rather than to find loop-free paths through the internetwork.

Let's go back through our three examples, and see how overlaying an internetwork connection graph would be able to solve some of the problems currently facing BGP.

Convergence Speed

Looking at our small sample internetwork again:

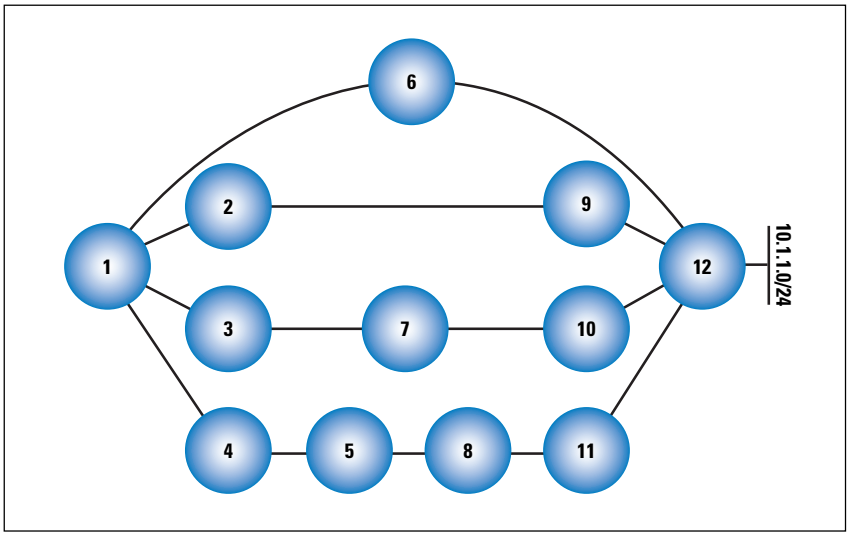

Figure 3: An Example Internetwork Using a Path Vector Protocol

What is the one thing we said would resolve the problems with BGP hunting through every possible longer autonomous-system path alternative to finally converge around loss of reachability to 10.1.1.0/24? Could AS12, somehow, communicate directly to every autonomous system in the internetwork that it has directly lost this connection, rather than waiting for AS1 to try every possible path to 10.1.1.0/24, and discover each one, in turn, withdrawn?

If we had a topological graph of the network, AS12 could simply remove 10.1.1.0/24 from its connectivity information. AS12 would then flood this information, on an interdomain basis, to all the other autonomous systems in the internetwork at roughly the same time. Thus, in the worst case, AS1 would receive this information at about the same time it received the first withdraw for 10.1.1.0/24, from AS6.

When AS1 receives this updated topology information from AS6, it will discover that AS12 is no longer connected to 10.1.1.0/24, and, therefore, it can remove every possible path to 10.1.1.0/24 containing AS12. This would allow AS1 to remove the paths {2,9,12}, {3,7,10,12}, and {4,5,8,11,12} at the same time. The internetwork now converges as soon as AS1 computes the new connectivity graph, and acts on it by examining each entry in its local tables and discarding the ones with AS12 in the autonomous-system path.

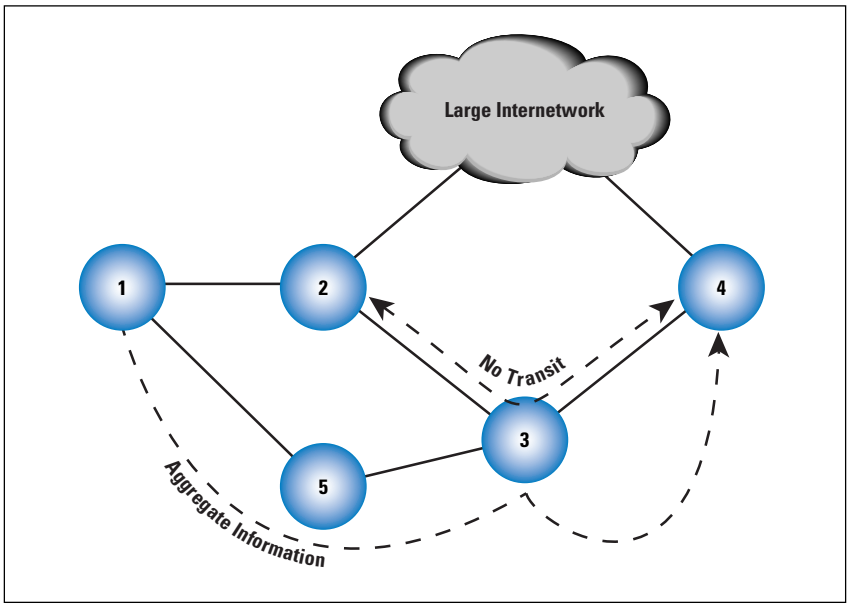
We have not changed the way BGP finds paths through the network—the path still is not valid unless we receive an advertisement from our connected peers. We have also not changed the format of any BGP updates, any peering state machines, or anything else. We have simply overlayed an interconnection graph on top of the current protocol mechanisms, which we can use to our advantage to speed up network convergence.

What about partial deployments in this situation? Suppose only autonomous systems 6, 7, 8, 9, 10, 11, and 12 are running this new extension. Would it still help us to speed up network convergence? When AS12 withdraws 10.1.1.0/24, AS6, 7, 8, 9, 10, and 11 would immediately discard any routes passing through AS12 to reach 10.1.1.0/24. At this point, they could each withdraw those routes, meaning AS1, 2, 3, and 5 would all receive a withdraw at about the same time. This short-circuits the number of possible paths for AS1 to hunt through, decreasing the amount of time the internetwork takes to converge. Even without a full deployment, we see some positive impact from this new technique.

Policy

Let's examine our policy problem after placing our interconnection graph on top of the internetwork.

Figure 4: Injecting Policy on an Interconnection Graph



Here, we see that AS2 could actually place its policy for AS3 not to transit traffic in the interconnection draft. AS4 would then be able to independently verify what AS2's policy toward AS3 transiting traffic is. AS4 could then examine the routing information it receives from AS3, and determine if it should install—or not install—routing information received from AS3, based on this policy.

Objections to an Interconnection Graph

When a link-state protocol has been proposed as a possible replacement for BGP in the past, two primary objections have been raised:

- Providers are reluctant to accept the wholesale replacement of a known working system with a new one.
- Many providers wish to hide their policies and connectivity to other providers or customers for policy reasons.

This article does not propose replacing BGP, just augmenting it, so the first argument is, to some degree, not valid against this approach. The second objection, that of using a link-state protocol for interdomain routing specifically, also does not apply, because we are not proposing changing the way BGP finds loop-free paths through the network. The proposed interconnection graph is not used for finding paths through the network, it is used only for faster signaling of path failure (by short-circuiting the slower withdraw mechanisms), and for providing a place to hang policy and security information.

Concentrating on a few smaller spaces allows us to design a smaller solution set that can be incrementally deployed in a simple way.

The second objection is harder to meet, simply because the concepts of policy within a routing system are hard to define and understand in all possible cases or respects. In fact, there are policy requirements not met by BGP today, but rather are met through contracts, packet filters, and other mechanisms (even sometimes by violating the BGP specification).

Consider two facts about this proposal that work around many of the specific objections we have heard in this area:

- The interconnection graph can be partial, in different parts of the internetwork. For instance, a given service provider might provide different views of who they are connected to to different peers, depending on their policy of revealing this information.
- The interconnection graph only contains autonomous system-level connectivity information, not specific peering-point information. For instance, two autonomous systems may be connected in a large number of places, or as few as one. The interconnectivity graph does not care about such details, only whether at least one connection exists. Such an interconnectivity graph would not reveal actual connection points between peering autonomous systems, how rich that connectivity is, nor any other information about the business relationship between the two peers.

  In fact, the types of interconnectivity information an interconnection graph could provide is already available by examining the autonomous-system paths of routes retrievable from various route view servers. Some mechanism would be required to collate this information into a usable graph, but a good deal of current research on the scaling and convergence properties of large-scale internetworks actually depends on the ability to build an interconnection graph before beginning any other work, so mechanisms to collate this data already exist, and are in use today.

Security

The internetwork interconnection graph can actually show whether a path exists from the origin to the advertising peer, through *signed certificates*. For example, soBGP[6] (**`ftp://ftp-eng.cisco.com/sobgp/index.html`**) uses this specific mechanism to validate the autonomous-system path carried in received routing information. Other research is currently being pursued in this area as well.

Summary

We have proposed a single step forward that could be used to resolve some of the problems facing BGP in the near term, and possibly provide the networking community with a path forward on other fronts as well. The concept of simply making incrementally deployable changes to BGP to solve pressing problems can provide us with options outside the normal lines of thinking: either making very small changes to BGP, making BGP more and more complicated, or simply replacing the BGP protocol, with all the deployment problems this would entail.

Book Reviews

A Brief History of the Future

A Brief History of the Future—The Origins of the Internet, by John Naughton, ISBN 0-75381-093X, 2000, Published by Phoenix, **http://www.orionbooks.co.uk**

This is a well-written book by a well-known Irish academic and journalist, which charts the growth of the Internet from a 1950s military project to the pervasive networking infrastructure that dominates the IT world today. It is relevant to the readership of this journal because it charts the growth of the technology that underpins the IP world—and it gives a sound understanding of the culture and approach that led to the development of the Internet as we know it.

Naughton takes the reader from the inception of the *Advanced Research Projects Agency Network* (ARPANET) through most of the major developments such as packet switching, mail, TCP/IP, and the Web, not only covering the technology, but also providing insights into the background of the Internet pioneers and the political environment.

Organization

The book is divided into three major sections, the first of which is largely concerned with scene setting and is aimed at bringing those less familiar with the subject area up to speed. In the first chapter, Naughton likens the evolution of the "Net" to that of amateur radio, moving on in succeeding chapters to cover basic technology and to provide some perception of scale and rate of growth.

The second part of the book covers the growth of the Internet up to the early 1990s. This starts by looking at the origins of the ARPA project, noting the influence of MIT and important figures such as Vannevar Bush, Norbert Weiner, and J.C.R Licklider. Naughton describes how ARPA was initiated and its relationship with NASA and academia, highlighting the desire to provide time-sharing systems and the breakthrough concept of the *Interface Message Processor* (IMP) as a solution to the "n-squared" problem. This is followed by two chapters that discuss the adoption of packet switching as the underlying technology, following its initial proposal by Paul Baran and further development by Donald Davies' team in the UK.

Naughton next examines how e-mail became the first "killer application" that drove up Internet usage, even telling the reader where the use of the ubiquitous "@" symbol comes from. He then considers the maturing network during the 1970s, discussing the formulation of the first *Request For Comments* (RFCs), the development of the gateway concept, and the evolution of TCP/IP. The discussion leaves the network area, concentrating on the evolution of UNIX and its impact, stressing the role of AT&T's regulatory situation. Then Naughton considers how this accelerated the development of USENET.

In a chapter called "The Great Unwashed," Naughton discusses the popularization of computing and networking, through the availability of the PC and the evolution of readily available file transfer tools such as X-Modem and the creation of bulletin board systems such as fidonet. He then considers the development of Open Source, telling the story of Linux and its derivation from MINIX.

The third section of the book deals with the emergence of the World Wide Web, tracing it back through the original ideas of Vannevar Bush and Ted Nelson, to its ultimate development by Berners-Lee at CERN. He links this to the subsequent development of Mosaic at NCSA and shows the dramatic impact this had on Internet growth.

Naughton concludes his book by looking at the prognosis for the "Net." Here he refuses to try to predict the future; instead he analyzes the forces that will drive the future of the Internet and discusses their impact in the past and hence their potential impact. At the end of the book, he provides notes and references for each chapter, a short section on the sources he consulted, and a comprehensive glossary.

Synopsis

I found this book provided excellent insights into the development of the Internet, adding a lot of perspective to the engineering field I currently work in. Naughton places appropriate emphasis on the technical, personal, commercial, and political factors that have steered its evolution. He is not afraid to disturb the reader's preconceptions by looking at things from unusual angles, and he emphasises the importance of *timing*. This is apparent when he points out that according to many sources, most of the important inventions around the Internet have come from graduate students, rather than the professors they work for. He similarly recounts the story that AT&T turned down the opportunity to run the "Net" in the early 1970s and reflects the view that if the Internet had not existed we could not invent it now.

This is an excellent read (it was nominated for the *Aventis Prize* in 2000), which helps the reader understand the How, When, Where, and Why of the Internet's development. It covers most of the major milestones in the evolution of our discipline and is very well-written.

The Author

John Naughton is Professor of Public Understanding of Technology at the Open University, and he writes a weekly column in *The Observer* Business Section, covering important developments and trends in the IT industry. He describes himself as a "Control Engineer with a strong interest in systems analysis and computer networks" and is a Fellow of Wolfson College, Cambridge.

Eats, Shoots & Leaves

Eats, Shoots & Leaves, by Lynne Truss, ISBN 1-592-40087-6, Gotham Books, 2003.

Eats, Shoots and Leaves is a book about punctuation, but boring it is not. Informative and delightful it is. Lynne Truss includes in the book—which she says is not about grammar—wonderful examples of misused and misplaced punctuation marks. She claims to have written the book to unite us sticklers who do care about the written word, and how we communicate through it. We sticklers cringe with many misuses of punctuation, and we are cringing more and more often it seems.

Truss defines punctuation as a tool to clarify the written word, and who can argue with helps for clarification? She suggests that punctuation is dying, but then asks what would happen without it? Just imagine all the words in the first paragraph with no punctuation marks and no capital letters. You might be able to figure out its meaning with some work, but it would not be easy. Also consider, she suggests, the following:

> A woman, without her man, is nothing.
> A woman: without her, man is nothing.

Punctuation makes all the difference!

The book begins with a discussion of the apostrophe. Meaning "omission," the apostrophe was first used in the 16th century. The most common egregious misuse of this tool is found in the word "it's." It's translates "it is," but it is often used as a possessive word, as in "The keyboard is useless; some of it's keys are missing," when it should be "The keyboard is useless; some of *its* keys are missing." As a test, if you cannot substitute the words "it is" or "it has," it should be "its;" if you can, it is correctly "it's." And the same is true for you're and your. You're translates "you are," and your is the possessive ("It's your turn").

Another amusing example Truss gives is: Member's May Ball. Of course it should be Members' May Ball, because who would just one member dance with? Truss asks.

In her discussion of the comma, we learn that commas were first used 2000 years ago by Greek dramatists to show the actors where to pause or breathe. Then when printing was invented and used increasingly in the 14th and 15th centuries, a Mr. Aldus Manutius (1450–1515) developed italics, the semicolon, the comma, the colon, and full stops (we call them periods in the U.S.).

Truss is a master of the metaphor. She calls the comma the "sheepdog" of words. The comma organizes words, phrases, and groups of words that fit together. Consider one of her comma examples, a properly placed comma: No dogs, please.

Now think about that sentence without the comma: No dogs please. Now consider this: But many dogs *do* please. Thus the importance of the properly placed comma.

Truss addresses all the other marks, including semicolons, quotation marks, brackets, hyphens, parentheses, the four attention-grabbers: *italics*, the exclamation point, the dash —, and the question mark, and finally the ellipsis (the three dots ...). She tells us that, amazingly, someone actually did a PhD thesis on the ellipsis!

One chapter discusses the fact that proper use of punctuation steadily declined in the 20th century, many blaming the decline on television; and that it will continue to decline in the 21st century because of the Internet. E-mail messages cry for brevity, and brevity they get. For example, "**CU B4 8.**" "Netspeak" is, no doubt, here to stay. Language usage also is trending toward the deletion of spaces between words, so that now we say healthcare, chatroom, and the like.

And finally, Truss discusses the newest job that punctuation marks have assumed: emoticons. Examples include the smiley face :–), the sad face :–(, and many others, all made with common punctuation marks.

I thoroughly enjoyed this book, and recommend it to anyone who wants to learn while being entertained. It is a wonderful read.

Read Any Good Books Lately?

Then why not share your thoughts with the readers of IPJ? We accept reviews of new titles, as well as some of the "networking classics." In some cases, we may be able to get a publisher to send you a book for review if you don't have access to it. Contact us at **ipj@cisco.com** for more information.

Fragments

Paul V. Mockapetris Wins 2005 ACM SIGCOMM Award

Paul V. Mockapetris, Chairman and Chief Scientist at Nominum Inc., is the winner of the 2005 *ACM SIGCOMM Award*. The SIGCOMM Award is widely recognized as the higheset honor in computer networking. The Award recognizes lifetime achievement in and contributions to the field. It is awarded annually to a person whose work, over the course of his or her career, represents a significant contribution to the field and a substantial influence on the work and perceptions of others in the field. The SIGCOMM Award is presented to Dr. Mockapetris "in recognition of his foundational work in designing, developing and deploying the *Domain Name System* (DNS), and his sustained leadership in overall Internet architecture development."

Paul Mockapetris created the original DNS protocol, wrote its first implementation, and worked with others to spread the DNS across the Internet. The design of DNS, which was the first major datagram protocol of the Internet, established a number of principles for key Internet infrastructural services. Its simplicity of design and fitness for purpose have stood the test of time. The strength of its design lies in a novel combination of hierarchy and caching that gives each organization absolute control over part of the namespace while simultaneously relying on caching to make the entire system efficient. Its success can be seen from the fact that DNS now handles many orders of magnitude more names and traffic than when it was first deployed, and yet the design and structure have remained intact. As a result the DNS design and caching mechanisms are often cited as two of the cornerstones on which the success of the Internet is built.

In addition to his work on DNS, Dr. Mockapetris' career has included pioneering work on multiprocessor operating systems, virtual machines, and ring LAN technology. Further, Dr. Mockapetris played an important role in the deployment of networking technologies internationally. Starting during 1990–1993 as a program manager at ARPA, Dr. Mockapetris fostered the international deployment of multimedia conferencing, multicast, and QoS. His strong leadership in development of Internet architecture continued as Chair of the Internet Engineering Task Force during 1994–1996, as member of the Internet Architecture Board during 1994–1996, and then as member of the Federal Networking Council. Dr. Mockapetris is also a recipient of the *IEEE Internet Award* and is an ACM Fellow.

In summary, through his sustained effort in support of the Internet archicture, beginning with DNS and continuing through work at ARPA, IETF, and industry, Dr. Mockapetris has made far-reaching and influential contributions to computer networking. The 2005 SIGCOMM award recognizes Dr. Mockapetris for this lifetime record of achievement.

SIGCOMM is the *Special Interest Group* (SIG) on *Data Communication* of the *Association for Computing Machinery* (ACM). SIGCOMM is a professional forum for the discussion of topics in the field of communications and computer networks, including technical design and engi-neering, regulation and operations, and the social implications of computer networking. The SIG's members are particularly interested in the systems engineering and architectural questions of communication. For more information please visit: **http://www.acm.org/sigcomm/**

Voice over IP (VoIP) And Government Policy

Voice over IP technology has the potential to provide much cheaper telephone service, particularly internationally. More importantly, it can enable exciting new services, such as voice-enabled Web pages and integrated phone, voice-mail, and e-mail. Unfortunately, some national governments are trying to limit its use. In late April, 2005, the *Advisory Committee on International Communications and Information Policy* (ACICIP) of the U.S. Department of State issued a very useful paper describing how VoIP works, the benefits it can provide, and what governments around the world are doing to promote or hinder its development.

Michael Nelson, the Internet Society's Vice President for Policy, represents ISOC on the Committee, and is helping draft "Version 2.0" of the paper, which will report on recent developments in additional countries. If you would like to make suggestions about the paper, please submit them to Michael Nelson at **mnelson@isoc.org**

For more information, see:
http://isoc.org/pubpolpillar/voip-paper.shtml

ISOC Commentary on the Status of the Work of WGIG, April 2005

When the first phase of the *World Summit on the Information Society* (WSIS) called on the UN Secretary General to set up the *Working Group on Internet Governance* (WGIG), it was in the context of supporting the WSIS *Action Plan*. The Plan calls for concrete actions to advance the achievement of internationally agreed development goals by promoting the use of ICT-based products, networks, services and applications, and to help countries overcome the digital divide. This is, by the way, something the Internet community has worked hard to achieve since the very first days of the Internet.

These goals include those described in the *Millennium Declaration*. The 8th goal of that document is to develop a global partnership for development, which would make available the benefits of new technologies—especially information and communications technologies—in cooperation with the private sector for the benefit of all. This is the context (making the benefits of ICT available to everyone) in which we initially engaged in the WSIS and WGIG efforts. The Internet has a huge potential as an enabler bringing these benefits to people everywhere and we remain excited about the WSIS mission. However, it is not clear how WGIG's actions to date have helped support achieving such goals.

The *Internet Society* (ISOC) believes that the best way to extend the reach of the Internet is to build on those aspects that have worked well, for example, the long established open, distributed, consensus-based processes and many regional forums for the development and administration of the Internet infrastructure. Decision-making about issues such as resource allocation or IP Address Policy has always been in the hands of the Internet community, in order to be as close to those who require and use the resources as possible. It is this participative model, close to the end users, that led to the phenomenal, stable growth of the Internet. The Internet community and its bottom-up processes are constantly evolving in response to changes in needs and availability. For example, in response to moves by the African Internet community, the African countries now have their own *Regional Internet Registry* [RIR] (AfriNIC) that helps coordinate users' needs and IP Policy in that region. Latin America has the same story to tell. Support for the development of both these RIRs (educational, financial and boot-strapping of various processes) came from the global Internet community and primarily came from the other RIRs.

Developing and maintaining the Internet infrastructure are just two aspects of what has come to be referred to as *Internet Governance*. WGIG has pointed out that there are many others, and has recognized the fact that Internet Governance encompasses a much wider range of topics than IP address and domain name administration. However, much of WGIG's focus has been on Internet infrastructure, thereby missing an opportunity to focus on those aspects of the Internet's development that are less developed and that could benefit from improved, lightweight mechanisms facilitating an exchange of information between policymakers and the Internet community. Examples here are issues con-cerning inappropriate usage of the Internet—cybercrime and spam being just two examples. Much work has already been done on technical solutions to these issues, and many legal frameworks already exist for handling criminal activity such as fraud. The challenge today is to bring the lawmakers and policymakers together with the Internet community to discuss the most appropriate mechanisms to ensure the continued development of the Internet.

Many players have a role, and this clearly includes governments and intergovernmental organizations. WGIG had a clear mandate to not only develop a working definition of Internet Governance, but also to develop a common understanding of the respective roles and responsibilities of governments, existing intergovernmental and international organizations and other forums, as well as the private sector and civil society encompassing both developing and developed countries. Unfortunately an inordinate amount of time has been spent focusing on challenging current structures (those that brought us the Internet and its rapid, stable growth), rather than looking forward to the potential benefits of extended cooperation with (and based on the proven success of) existing models and structures. WGIG seems to have lost sight of this larger goal.

Also, many of WGIG's premises seem to start with an assumption that the Internet needs a hierarchical top-down governance model, thereby ignoring the decentralized, distributed structure on which the Internet was so successfully built. Not only does this "governance hierarchy" model prevent an accurate understanding of the Internet's infrastructure and development (forcing key organizations to be classed in prescribed categories that do not fit with the reality of their actions or their role in developing and supporting the Internet) but it also will very likely lead to conclusions that will harm the Internet's development and growth.

While WGIG appears to ascribe the growth of the Internet to deliberate regulatory decisions to liberalize telecommunications, in reality regulatory measures have been a relatively small factor. A more significant factor in the growth of the Internet has been the fact that the Internet architecture has enabled many tens of thousands of users to develop their own applications independent of the underlying architecture, thereby empowering people to add true value to the global Internet network. The continued expansion of the Internet to developing countries though will be greatly aided in the future by a more competitive telecommunications environment. We urge WGIG to recommend more concrete and aggressive action in this direction.

Further, WGIG has put great focus on comparing the relative merits of established treaty bodies and intergovernmental organizations to undertake a central role in the development of Internet infrastructure while very largely overlooking areas where attention and support are required and where national governments more naturally have a role to play, areas such as misuse of the Internet (cybercrime and spam to name a few). The limited perspective of this approach displays an obvious bias in the characterization of the issues and seems to pre-suppose a solution. In conclusion, we would urge WGIG to spend more time looking at what is actually being done to enable more people around the world to take greater advantage of the power of the Internet. This includes a focus on the many regional and global education activities that different Internet-related organizations are undertaking to "connect the unconnected."

These same organizations are also working to make the Internet more secure, more accessible, more reliable, more affordable, and more versatile. The development of the Internet, as well as many well-established capacity-building efforts could be jeopardized by applying a too heavy-handed approach to the operation and administration of this unique network of networks. Decentralized, lightweight governance has clearly proven itself to be a positive feature not a weakness. We want to encourage WGIG and WSIS to work with the Internet community within the already well-established Internet model to improve co-operation between policy makers and the Internet community.

In the spirit of meeting the international development goals highlighted by WSIS, any review of today's Internet model or structures must be carried out in the context of how well they have worked in the past, how well they meet the needs of the people who depend upon them today, and how well they will adapt to changing requirements in the future; and not simply focus on a comparison to other historical telecommunications or governance models. These historical models have not been demonstrated to be well suited to the Internet. For more information, see:

An interview with the new IETF Chair

IBM Distinguished Engineer and former ISOC Chairman Dr. Brian Carpenter has just taken over the role of IETF Chair. In a recent interview, Brian describes the future challenges facing the IETF and the Internet in general. The full interview is available here:
http://resources.isoc.org/20503

Upcoming Events

The *Internet Corporation for Assigned Names and Numbers* (ICANN) will meet in Luxembourg City, Luxembourg, July 11–15, 2005 and in Vancouver, Canada November 30–December 4, 2005. For more information see: **http://www.icann.org**

The *South Asian Network Operators Group* (SANOG) will meet in Thimpu, Bhutan, July 16–23, 2005. More info at:
http://www.sanog.org

The *Internet Engineering Task Force* (m nn) will meet in Paris, France, July 30–August 5, 2005 and in Vancouver, Canada, November 6–11, 2005. For more information, visit: **http://ietf.org**

ACM's *SIGCOMM 2005* will be held in Philadelphia, PA, August 22–26, 2005. For more information visit:
http://www.acm.org/sigs/sigcomm/sigcomm2005

The *North American Network Operators' Group* (NANOG) will meet in Los Angeles, October 23–25, 2005. For more information see:
http://nanog.org

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

The Internet Protocol Journal is published quarterly by the Chief Technology Office, Cisco Systems, Inc.

From The Editor

Protocol transitions are never easy, particularly not when they involve something so fundamental as the *Internet Protocol* (IP). Organizations considering a move to IPv6 must consider many factors when deciding on the timing for such a deployment. One of the first questions that arises is: "When will the IPv4 address space actually run out, forcing us to use IPv6 instead ?" That question is not a new one; it was being asked in the early 1990s when the IPv6 effort was started. Several factors, such as the deployment of *Classless Interdomain Routing* (CIDR) and *Network Address Translation* (NAT), have "delayed the inevitable," and perhaps led to some complacency on the part of network operators. In this issue we examine the topic of IPv4 address space depletion in more detail. Our main article is by Tony Hain, and it is followed by a response from Geoff Huston and a roundtable discussion with Tony, Geoff, Fred Baker, and John Klensin. We would also like to hear from our readers on this important topic. Please send your comments to **ipj@cisco.com**.

As an old-time network and UNIX user, I am a big fan of tools that allow simple terminal access to remote host computers. My "Internet career" started in Norway in 1976, where I used *Telnet* to access machines in California through the ARPANET. Today, I still access remote servers through a simple terminal interface, but Telnet has been replaced by the *Secure Shell* (SSH) *Protocol* for all the obvious security reasons. SSH is used not just for terminal traffic—it also can be configured to provide secure tunnels to a variety of services such as Webpages and file transfers. Ronnie Angello explains the details in our second article.

In order to better serve our readers, we will be conducting an IPJ Reader Survey in the near future. Details will be available on our Website at **www.cisco.com/ipj**. We appreciate your cooperation in completing the survey.

Finally, let me remind you to visit the IPJ Website and update or renew your subscription.

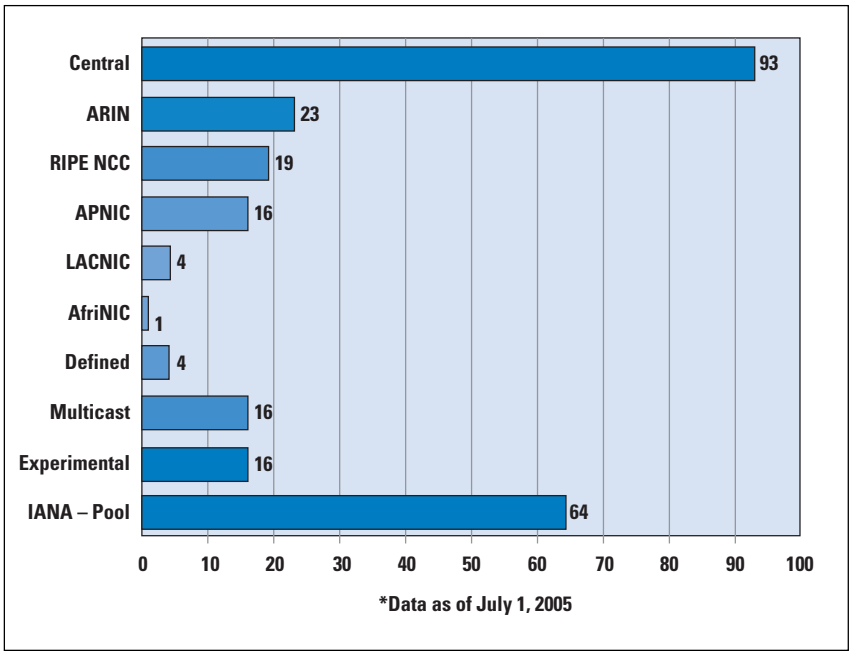
A Pragmatic Report on IPv4 Address Space Consumption

by Tony Hain, Cisco Systems

When I interact with people from all around the world discussing IPv6, there continue to be questions about the projected lifetime for IPv4. This article presents consumption rate and lifetime projections based on publicly available *Internet Assigned Numbers Authority* (IANA) data. In addition, there is discussion about why the widely quoted alternative projection may be flawed, thus leading everyone to believe we have much more time than we might.

Figure 1: IANA /8 Allocations



Allocations

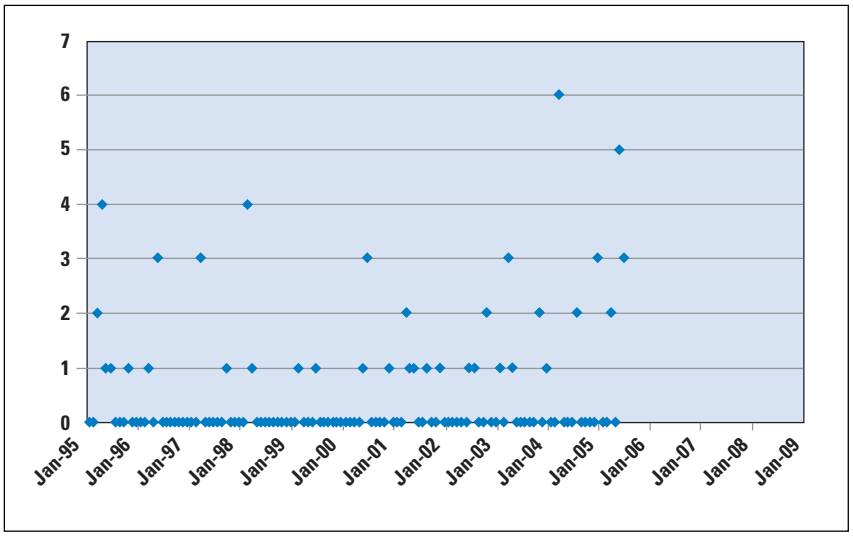
The chart in Figure 1 shows the distribution of all 256 IANA /8 allocation units in IPv4[1] as of July 1, 2005. The Central registry represents the allocations made prior to the formation of the *Regional Internet Registries* (RIRs). ARIN (North America)[2], RIPE NCC (Europe)[3], APNIC (Asia/Pacific)[4], LACNIC (Latin America)[5], and AfriNIC (Africa)[6] are the organizations managing registrations for each of their respective regions. RFC 3330[7] discusses the state of the Defined and Multicast address blocks. The Experimental block (also known as *Class E*—RFC 1700[8]) was reserved, and many widely deployed IPv4 stacks considered its use to be a configuration error. The bottom bar shows the remaining useful global IPv4 pool. To be clear, when the IANA pool is exhausted there will still be space in each of the RIR pools, but by current policy[9] that space is expected to be only enough to last each RIR between 12 and 18 months.

The projection published at **`http://bgp.potaroo.net/ipv4`**[10] is often quoted as the definitive reference for IPv4 consumption. This report presents a viewpoint consistent with that author's long-standing position that we do not need to change from IPv4 to IPv6 anytime soon, thus showing an extended lifetime for IPv4.

The approach used in the potaroo report is to take the simple exponential fit to the allocation data since 1995. As discussed later in this article, this approach includes the effects of the policy shift to *Classless Interdomain Routing* (CIDR) and subsequent digestion of prior allocations, the lull in IANA allocations to the RIRs for two full years, as well as the fact that the model used does not generate a particularly close fit to the actual run rate over the 10-year period.

Although this author agrees that over very long timeframes (20–50 years) there will be substantial variations in the consumption rate for any number of reasons, the opportunity for events that would reduce the recent rate in the timeframe of the remaining IANA IPv4 pool is not evident. That said, there are numerous things that could increase the consumption rate and exhaust the pool even sooner than this projection.

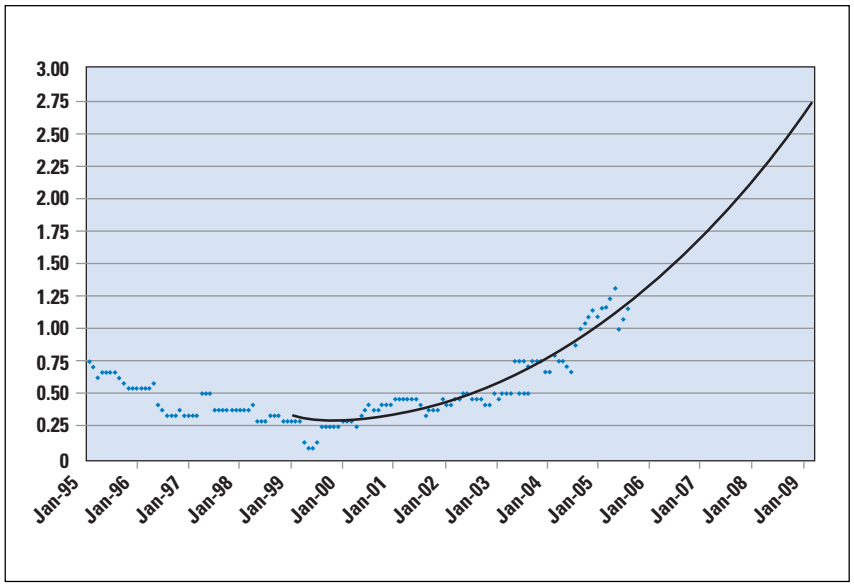
Figure 2: IANA Allocations to RIRs — Raw /8 Allocations per Month



The graph in Figure 2 shows the raw per-month IANA allocations since 1995. In raw form it is difficult to discern the trend, or develop an expectation about the overall lifetime of the remaining pool.

Taking a closer look at Figure 3, smoothing the data with a 24-month sliding window (averaging over 12 months back and 12 months forward) exposes the underlying reality that the combined rate and quantity of /8 allocations has been steadily accelerating since 2000 (the graphs for 12-, 18-, and 24-month sliding windows show the same fundamental trend). Though a few of the allocations may arguably have been "one-time" events, those are lost as statistically insignificant in the extended and continuing overall growth rate.

Figure 3: IANA Allocations to RIRs — Sliding-Window 24-Month Average



Taken by itself, the most recent allocation rate (22 /8s over the 18 months leading up to July 1, 2005) suggests that the remaining pool of 64 /8s will be exhausted in about 5 years, even if growth abruptly flattens out to hold around 1 /8 per month. Unfortunately at this point there is no reason to believe the allocation rates will slow or that they will turn downward again. All the gain of CIDR absorbing the pre-1995 allocations has already been incorporated, and there is no obvious economic bubble that might burst to lower demand within the time window of the remaining pool.

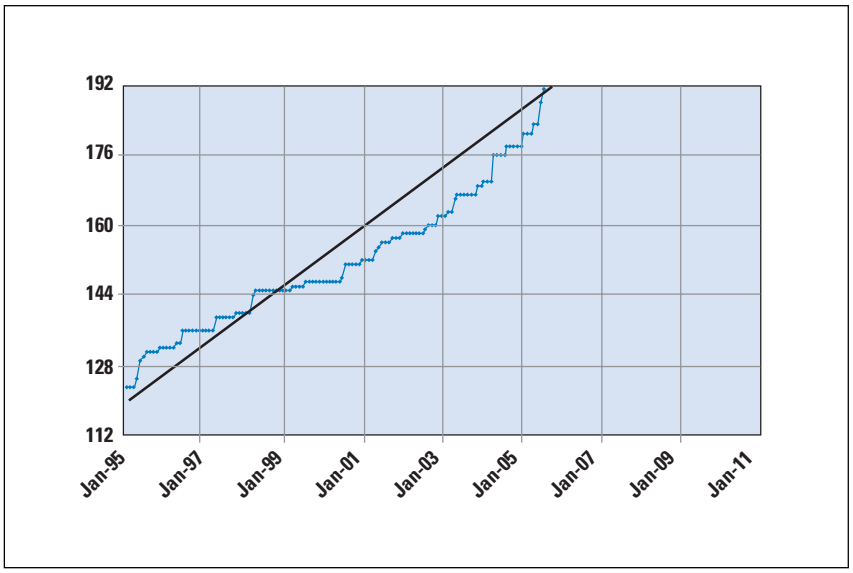
To the contrary, the following URL shows potential demand (to bring developing countries up to just 20-percent connectivity, which is half of what the existing Internet world enjoys today) that will swamp the remaining pool, even in the face of much stricter allocation policies.
`http://www.nav6tf.org/documents/e-Nations-data.pdf`

So this view of the sustained trend in allocation growth rate suggests that the lifetime of the remaining central IPv4 pool is 4 years +/-1.

Projections

Differing from recent articles and section 5 of the report at **`http://bgp.potaroo.net/ipv4`** that hint at linearity in growth, Figure 4 shows that the raw data after 1995 is clearly nonlinear. It starts with a decelerating rate through mid-1998 as the pre-1995 allocations were absorbed (precipitated by the allocation policy shift from class-based to CIDR), followed by a 2-year lull (only 1 /8 per year), then a return to accelerating growth from mid-2000 onward.

Figure 4: IPv4 Lifetime Projection — Non-Linear Nature of Raw Data



This suggests that using the past 10-year IANA data is likely to skew the projection toward a much longer period than the recent allocation data would support. Although a longer lifetime projection helps to avoid short-term panic, it can mislead people into believing there is substantial time to worry about this later, resulting in a much bigger problem when reality blindsides everyone sooner than they expected.

Figure 5: IPv4 Lifetime Projections — Order-N Polynomials, Post-2000 History Basis

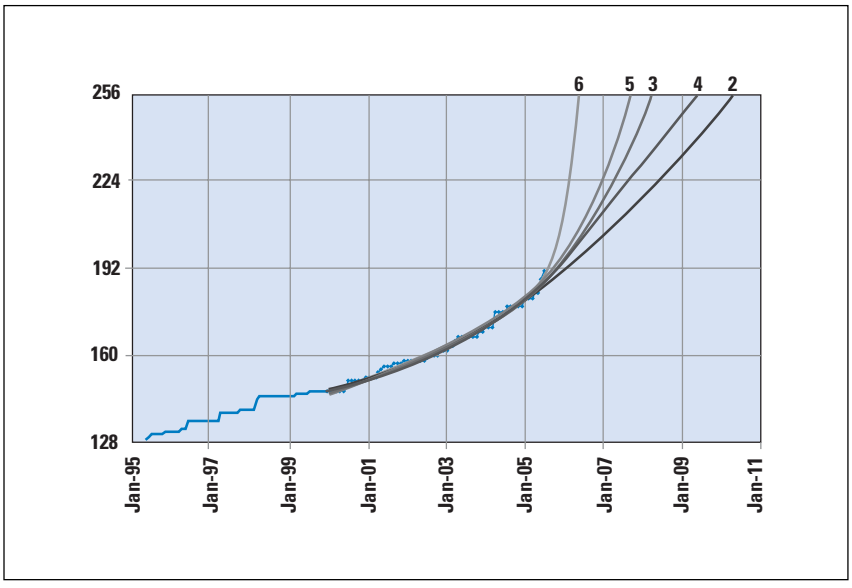


Figure 6: IPv4 Lifetime Projections — Polynomials and Exponentials

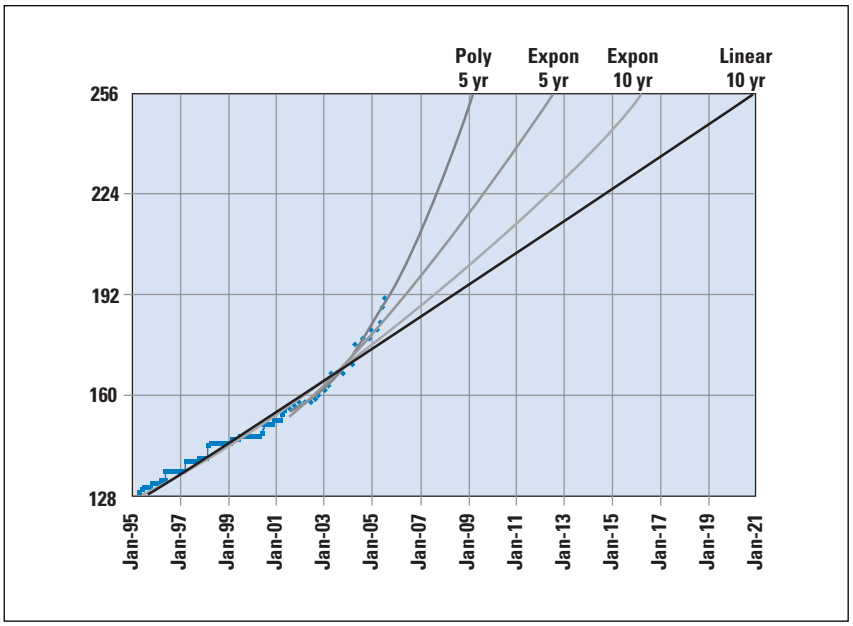
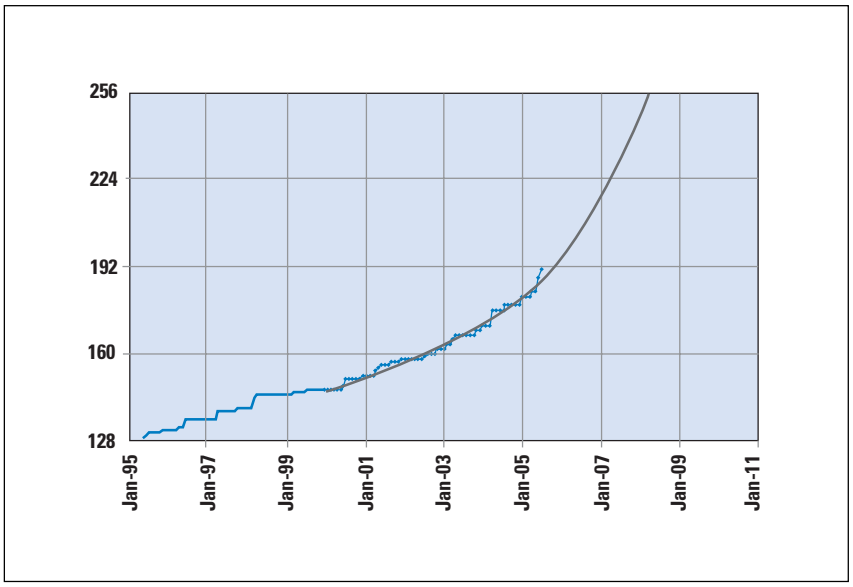


As in any statistical endeavor there are many ways to evaluate the data. The various projections in Figures 5 and 6 show different mathematical models applied to the same raw data. Depending on the model chosen, the nonlinear historical trends in Figure 6 covering the last 5- and 10-year data show that the remaining 64 /8s will be allocated somewhere between 2009 and 2016, with no change in policy or demand (though as discussed previously there are already reasons to err toward 5-year-based nonlinear models).

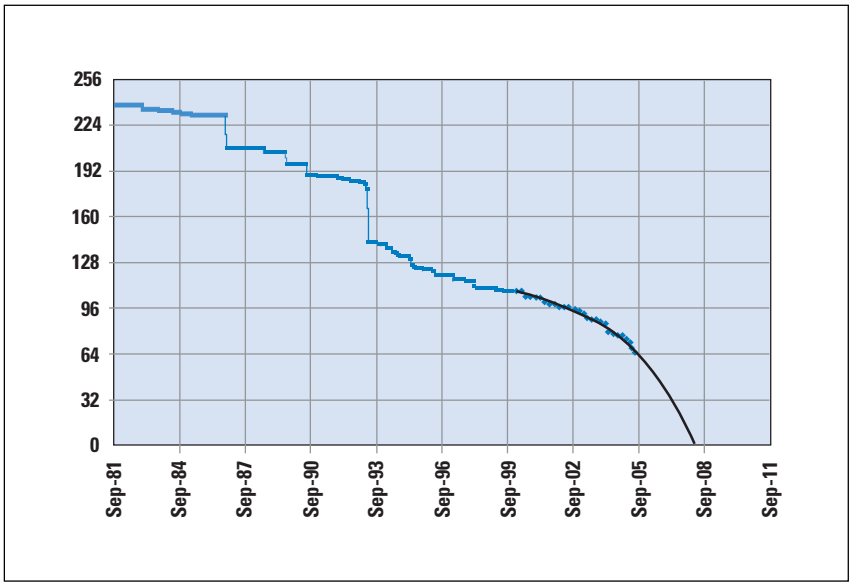
Adding to that, policy is continually changing. ARIN, for example, has recently clarified its policy allowing organizations that demonstrate they have exceeded the capacity of the private space defined in RFC 1918 to acquire IPv4 address blocks from the remaining public pool, even when it is clear these allocations will never be announced to the global Internet. The other regions already have similar policies or are likely to follow suit because the most vocal members of the RIR community have adamantly commented against expanding the private IPv4 range. This policy approach coupled with persistent demand means the actual run rate is going to continue increasing as the large organizations begin consuming public space where they had been using private to support their network growth. For example, one large enterprise has steady growth over 1 percent per month, which currently requires an efficiently managed /12 per year for its expanding network. The enterprise is less than a year from exhausting all the space provided in RFC 1918, so it was very interested in the ARIN policy that allows the enterprise to continue growing through public space. Additionally, multiple commercial service providers expect to reach the capacity of the 1918 space within 12 to 18 months, just supporting management addresses on their existing devices. This does not take into consideration their pending deployment of new services, which they expect will use several new IPv4 addresses per device with marketing targets measured in multiple millions of units.

Figure 7: IPv4 Lifetime Projection — 5-Year History Basis



The graph in Figure 7 hints at the likely outcome as word spreads about the perception of policy liberalization and the demonstrable exhaustion of the remaining global IPv4 pool landing within the *return-on-investment* (ROI) period for new equipment. It is based on the same raw historical data as the frequently quoted long-term projection on potaroo's Figure 2.4, but the more aggressive fit on the most recent data set describes a significantly higher consumption rate and shorter lifetime for the remaining pool.

Figure 8: IPv4 /8 Pool — 5-Year History-Based Projection



The graph in Figure 8 provides the exhaustion perspective, showing the entire address pool from the publication of IP Version 4[11] (note that data prior to 1995 is accurate as to where it was allocated, but with very coarse granularity as to exactly when). The projection curve is based on the IANA allocations from January 2000 onward.

Only time will tell which projection is correct, but it will already take a fairly significant stalling event to slow consumption and put the actual allocation curve back on the extended track in potaroo's Figure 2.4.

Reserved Space

There are occasionally arguments that the 16 /8s reserved in the experimental space could be used. Although this is likely to be possible for some IP stack implementations, for others it is not. At a minimum, some quick tests show that Windows 95 through Windows 2003 Server systems consider that block to be a configuration error and refuse to accept it. The operational ability to restrict the space to a select stack implementation is limited, and the amount of space there does not really help even if deployment and operations were trivial. Assuming the sustained growth trend in allocations continues, by the time the remaining 64 /8s in the IANA pool are finished the rate would be approaching 3 /8 allocations per month, so the entirety of the old Class E space would amount to about 6 months of run rate.

Reclaiming Allocations

Another debate occasionally resurfaces about reclaiming some of the early allocations to further extend the lifetime of IPv4. Hopefully this article has shown that the ROI for that approach is going to be extremely low. Discussions around the Internet community show there is an expectation that it will take several years of substantive negotiation (in multiple court systems around the globe) to retrieve any /8s. Then following that effort and expense, the likelihood of even getting back more than a few /8 blocks is very low. Following the allocation growth trend, after several years of litigation the result is likely to be just a few months of additional resource added to the pool—and possibly not even a whole month. All this assumes IANA does not completely run out before getting any back, because running out would result in pent-up demand that could immediately exhaust any returns.

Summary

Network Address Translation (NAT) and CIDR did their jobs and bought the 10 years needed to get IPv6 standards and products developed. Now is the time to recognize the end to sustainable growth of the IPv4-based Internet has arrived and that it is time to move on. IPv6 is ready as the successor, so the gating issue is attitude. When CIOs make firm decisions to deploy IPv6, the process is fairly straightforward. Staff will need to be trained, management tools will need to be enhanced, routers and operating systems will need to be updated, and IPv6-enabled versions of applications will need to be deployed. All these steps will take time—in many cases multiple years. The point of this article has been to show that the recent consumption rates of IPv4 will not be sustainable from the central pool beyond this decade, so organizations would be wise to start the process of planning for an IPv6 deployment now. Those who delay may find that the IANA pool for IPv4 has run dry before they have completed their move to IPv6. Although that may not be a problem for most, organizations that need to acquire additional IPv4 space to continue growing during the transition could be out of luck.

Another Perspective

Ed.: We asked Geoff Huston to provide some feedback on this article and he responded with the following:

Dear Editor,

There are, of course, many ways to undertake predictions, and over the millennia humanity has explored a wide diversity of them. In every case the challenge is to make predictions that end up being closely correlated to the unfolding story, and of course hindsight is always the harshest judge of such predictions.

Tony's work takes a different base point for making the projection from earlier work that I did in this area. Tony looks at the rate of allocation from the IANA to the RIRs, and bases his predictions on the trends visible in that time series of data. By contrast, I used the assumption that assigned addresses are destined for use in the public IPv4 Internet, and I used the trends visible in the amount of advertised address space as the basis for the predictions of consumption.

One of the more interesting data artifacts is the first-order differential of the rate at which the span of addresses announced in the IPv4 public Internet has increased over time.
(Figure 4.4 of **http://bgp.potaroo.net/ipv4/**)

One interpretation of this data is that there are two phases of recent activity: prior to March 2003 and post-March 2003. Prior to March 2003 the longer-term address growth rate was the equivalent of some 3.5 /8 blocks per year.

Post-March 2003 we see a different consumption growth rate, fluctuating between 5 and 8 /8s per year, with a mean value of some 7.5 /8s per year. There is no strongly obvious longer-term compound growth rate visible in this view of the data. Given some 64 /8s remaining in the IANA pool as of July 2005 and a base consumption rate of a mean of 7.5 /8s per year, the simple division yields 8.5 years, or 2014 as the time of forecast exhaustion of the IANA address pool. At that point the RIRs will be holding about 25 /8 blocks in their unallocated pools, and a further two years of allocations could be made from these pools.

So I would offer the view that the post-2003 data offers a perspective of exhaustion of the unallocated address pools in 2016, with the caveat that such a prediction assumes that the current address demand levels will continue, the actions of industry players are invariant, and the current address allocation policies will continue as they are at present.

Of course these three caveats represent relatively major assumptions about the future—and are perhaps unlikely to happen. It is likely that there will be changes in all these factors in the coming years, and these will obviously impact these predictive models.

To summarize, I observe that these different predictive approaches yield slightly different outcomes, but not beyond any reasonable error margin for predictions of this nature. Sometime in the forthcoming 5 to 10 years the current address distribution policy framework for IPv4 will no longer be sustainable for the current industry address consumption model because of effective exhaustion of the unallocated address pool.

When looking at this prediction from the perspective of the service provider enterprise, the prediction can be re-expressed as a problem relating to investment lifecycles. The ISP industry and the enterprise sector have already made considerable investments in IPv4-based infrastructure in equipment, infrastructure, and operational capability, and we are seeing some considerable reluctance to add to this with additional investment into IPv6 capability at this time. The direction of the use of various forms of NAT-based approaches and increasing use of application layer gateways in the public and enterprise environments can be seen as an effort to extend the lifetime of the existing infrastructure investment. In a volume-based market with relatively low revenue margins, this position certainly has some sound rationale from a business management perspective. But I agree with Tony here that such business approaches are ultimately short-term in nature, because they do not allow IPv4 to encompass indefinite further decades of Internet growth in a silicon-dense world.

However, in terms of understanding the next few years of a process of industry transition of protocol infrastructure into IPv6 deployment, perhaps the real issues here are more centered on competitive business factors and sector investment profiles than they are about detailed introspection of trends within various number series.

The numbers all indicate that this is not a matter that can be deferred indefinitely. Tony's call for some timely attention to the need to commence investment in IPv6-based service infrastructure is one that I hope the industry is listening to attentively.

—Geoff Huston
gih@apnic.net

A Virtual Roundtable

Ole: Let's open this discussion on the point of measurement methods. We invited John Klensin and Fred Baker to join Geoff and Tony in the discussion at our virtual round table. (We often all see each other at IETF meetings, but there is seldom enough time to gather everyone around a real table, hence this discussion took place with a few rounds of e-mail).

Geoff: As I said in my response letter, Tony's work takes a different base point for making the projection from the earlier work that I did in this area. My work has focused on the trends from the addresses used in the public IPv4 Internet, and then deriving projections on consumption based on this data. It assumes that the influencing factor for address consumption is the use of addresses in the public IPv4 Internet.

Tony: As Geoff noted, he and I have discussed over time that we are looking at different parts of the data set and coming to different conclusions. One specific point that distorts the approaches is the time delay between IANA allocation to the RIRs and the appearance of that space for public use. In particular, his comment about 5 to 8 /8s per year is based on the delayed public use data that will eventually catch up with the fact that IANA has allocated 13 /8s just since the beginning of 2005. If the allocation rates had close to linear growth, the delay would not be a big factor. Another point of distortion is the potential for some of the allocations to never show up as publicly routed.

Ole: So when do we actually run out?

Geoff: There are many specific milestones that will pass in sequence. The unallocated address pool held by IANA will exhaust first, and then the RIR pools of unallocated data will drain. At that point there is no stream of "new" addresses to fuel further growth, and that is probably a reasonable point in time to say that we have "run out." Assuming that the current business influential factors and allocation policies remain in place, then the projection models from recent data indicate that this "run-out" date is around 2016, or some 11 years from now. Of course these are unlikely assumptions as the prospect of exhaustion draws nearer, and there may be a "last-minute rush" of address allocation requests from the service provider industry that could draw in that projected "run-out" date. Such additional consumption pressures are difficult to factor in to trend-based predictive models, of course. It is also conceivable that the industry could shift its attention almost entirely to IPv6-based protocol infrastructure in the coming years, in which case the "run-out" projection for IPv4 would extend out further in time simply because of the translation of the consumption activity to the IPv6 address pool.

Tony: As I noted early on in my article, there will still be pool available at each of the RIRs when the IANA pool that I focused on is exhausted. In the past I have said we would never completely run out because nobody could afford that last address, but in light of the accelerating consumption of IPv4 coupled with the less-than-aggressive deployment of IPv6, I can see how the pool might actually run dry.

John: In practical terms, the point at which one has "run out" of address space is not tied to being the last applicant to the RIRs for an address pool. I have suggested that point will never arise: the RIRs (and, to the extent to which the *Internet Corporation for Assigned Names and Numbers* [ICANN] can make decisions, the IANA), will continually recalibrate policies to prevent "running out." Of course the inevitable consequence of those recalibrations is that, although one does not need to worry about approaching an RIR and being told "no space left," the combination of monetary, justification, and general aggravation costs is such that one does not even want to contemplate being the applicant for the next-to-last available block. That reasoning says that looking at the date on which near exhaustion is reached is relatively uninteresting. The more important question is when one enters the end game for IPv4 space because, as soon as the end game begins, the space is essentially exhausted.

I suggest that the criterion for entrance into the end game is not measured statistically but by looking at the point at which one needs to start designing networks and subnets, not in a way that is optimal from a network architecture or network management and growth standpoint, but in order to conserve address space and/or to avoid extended discussions with applicable RIRs (or one's ISP that deals with the RIR). From that point of view, we have already run out, and probably ran out a couple of years ago. Every time someone who has multiple machines is pointed to private address space because of a presumed shortage, it is an indication that we have already run out of space. Every time China manages to make a successful political point—regardless of the country's actual internal dynamics and economics—about its inability to get addresses for its population, it is an indication that we have already run out of address space. Every time an ISP decides to use private space to manage its backbone, it is an indication that we have already run out of address space.

Fred: I have made the same point, from a point of view of economics. In essence, when a commodity is common and demand is low, there are calls to squander it because it costs nothing—something one hears a lot of in the IPv6 community. When supply and demand are comparable, a market develops, and I need to tell you that I certainly pay for the IPv4 addresses at *my* house. When demand outstrips supply, we enter a regulated market of some kind, and our current allocation policies certainly reflect a regulated market. The step after a regulated market is a black market, and it is not too hard to find that either.

John: Actually, in our present situation, there is an intermediate step before things deteriorate completely into a black market. Although it is unlikely that any significant fraction of the early IPv4 academic, research, or commercial allocations could be recovered and reused, there are governmental allocations that might be recovered under significant political pressures. Unfortunately, in addition to politicizing the allocation process much more than we have seen so far, such moves might push the present users of those allocations toward NATs in ways that would make the ultimate transition to IPv6 more difficult while not gaining very much additional time for the IPv4 space.

Tony: Political pressure or not, simple logistics argues against this. Given the rate of growth in consumption, any reclaimed government space would be consumed in substantially less time than it would take to rebuild their network and release it. Even a small network sitting on a /16 would take at least a year to release that much space, and at the current spot on the escalating curve that /16 represents around 2 hours of IANA run rate. Getting back a whole /8 would logistically take several years, and then at that point on the curve the result would be about a week of run rate. If several of these government organizations have a mesh of direct interactions and head down the same path, the resulting overlap in the private address space would require creating a complex NAT system worthy of a Nobel Prize. Reclamation is a nice bar-room debate topic, but the return on investment is extremely low. If an organization were to consider rebuilding its network to release an IPv4 allocation, it would make much more sense for that organization to rebuild it as IPv6 than to move publicly addressed nodes behind a NAT.

Geoff: It would be strongly preferred by all, I would suggest, that the "black market" option be avoided. If the consequence of the exhaustion of the unallocated pool of IPv4 addresses is the trading of already-allocated IPv4 addresses, then a responsible way for the industry to support that scenario is to encourage such a market to operate with the support of some form of "clear title" that could legitimate trading transactions. Without structure and stability in a trading market, the value of the trade is meaningless, and in this case the potential for chaos in the network itself is undeniable.

Fred: We are in fact starting to see networks designed to be IPv6-only or IPv6-dominant (the latter being a network that might use IPv4 internally but offer only IPv6 services to some or all of its customers) in China, Japan, and other places. The economic argument is the one these operators are primarily giving—they state that they see a roadmap to the number of addresses that they need in IPv6, while in IPv4 they are significantly constrained. This sounds to me a lot like John's comments about network design, but the other way—rather than designing their networks to what they perceive as IPv4 addressing policy limitations, they are choosing a path that they perceive as giving them options.

We also see evidence of networks designing themselves to the limits of address allocation in IPv4, usually using multiple layers of NATs. For quite a while, for example, China Unicom used multiple layers of NAT in order to work around what the company felt was a deficiency in its ability to get IPv4 addresses from its national registry. As I understand it, the company has changed its strategy to include getting IPv4 address allocations directly from APNIC, and at the same time to deploy an IPv6 network in parallel to move away from IPv4 dependence.

John: There is another factor at work in this. Transitions are never free. If we are going to design and build out a substantially new network, we are rapidly reaching the point—some would say that we have reached it already—at which it is cheaper to design and build that network for IPv6, making whatever arrangements are needed at its interconnection points with IPv4 networks, than to build in IPv4 and face a transition later. As those decisions are increasingly made, it may both reduce pressure on new IPv4 allocations and create free pools of IPv4 space that could be recovered and reused. For example, the U.S. Department of Defense (DoD) has announced a fairly aggressive schedule for moving to IPv6. If they meet that schedule and were then willing to free up the IPv4 space that they would presumably no longer be using, it would free up the equivalent of several /8s. While I agree with Tony that this hypothetical case would be unlikely to make any significant difference in the long run, it illustrates another difficulty with trying to make assertions about what is happening by statistical projections alone.

Ole: It is frequently stated that North America is immune to the address exhaustion problem.

Tony: Well despite persistent rumors and press statements to that effect, ARIN continues to consume about 30 percent of the annual allocation from IANA. If the past allocations were sufficient to stave off global exhaustion, why the continued consumption? In any case, when the central pool is exhausted the North American region will be in the same situation as everyone else—unable to expand or acquire new IPv4 addresses.

Geoff: We are seeing growth in Internet-based services in all regions of the industry, including North America. And network growth needs to be fueled by network addresses. We are seeing a combination of a continued demand for further addresses, and the use of various forms of network configurations that attempt to make the most efficient use of already-allocated addresses. There is little data to suggest that any region, including that of North America, is in a position of immunity from these growth-related factors.

Ole: There is widespread opinion that NAT will solve the problems for a long time to come.

Geoff: The ISP industry certainly has made considerable investments there, and many millions of end users today use the Internet behind NAT devices. Given the size of this investment and the factors of inertia in large-scale service markets, it is reasonable to predict that NATs will be around for quite some time. But NATs add cost to network services. If we are talking about a network that is restricted to servicing the communications needs of people, then this is a relatively high-value activity, and the additional costs of the deployment of NATs are being absorbed within the cost base of the network service economy. And for such human activity-based services this may well continue for some time, given the existing levels of industry investment in service infrastructure that includes the use of NATs. Certainly any new application that is adopted by the Internet user population needs to work across a wide variety of NAT configurations. From this perspective it is likely that IPv4 and NATs will continue to be part of the Internet landscape for a long time to come.

But although this approach has the potential to service a portfolio of service markets for some time to come, it cannot service all forms of service markets—not in the future nor even today. It does not solve all the "problems" and certainly does not encompass all the opportunities that the Internet offers. The potential of IPv6 is one that includes an address span designed to match the full potential of the volume-driven silicon industry, both now and in a future that extends out for many decades to come. One likely scenario for IPv6 is in servicing a truly massive device-dense environment. This scenario encompasses far more than services that are primarily directed at human end users. And the associated service market will be more akin to that of a relatively undifferentiated commodity market, where simplicity and low cost are the dominant service provider discriminants. Because of their additional complexity and associated incremental cost, NATs are marginalized in such commodity markets directed at servicing device density, and it is there that the true leverage of the IPv6 address span becomes a major influential factor.

Tony: As Geoff notes, NAT has been widely available and deployed globally over the same timeframe as the recent consumption. Yet the accelerating growth trend continues, consuming to the point where only 25 percent of the total IPv4 space remains available. Although NAT does slow the rate of public address consumption from what it might otherwise be, it creates more problems than it solves. Geoff also raises the economic investment in NAT to date, which is an interesting contrast to many complaints I hear about the cost of deploying IPv6. Most people who look at what it will take to deploy IPv6 in their network are very quick to dismiss this investment in the array of costs associated with NAT. Often they insist on a demonstration of value for the IPv6 investment while at the same time they refuse to allow consideration of removing their development, and ongoing operational support costs for IPv4 NAT.

Although I agree that in the interim overlap period the costs are additive, in the long term staying on the IPv4/NAT path those costs only compound, whereas on the IPv6 path they disappear. The duration of that overlap is somewhat self-controlled as a direct trade-off between the costs for running both protocols in parallel versus the costs associated with aggressively moving the end systems and applications to IPv6.

Ole: Another area frequently discussed on various lists is that the U.S. DoD and Federal Government mandates for service availability in 2008 are just another instance of the *Government OSI Profile* (GOSIP) and that they too will disappear.

Tony: What these discussions miss is that the situation is entirely different now. In the early 1990s the U.S. GOSIP effort was directed by a strong desire to consolidate the array of protocols in use at that time toward a common one. Other governments had similar efforts that led them collectively toward a suite that was developed with international governmental input. IPv4 was an alternative to the mandate with applications already supporting it, while the OSI protocols existed in some router products but did not have many applications available.

At this point the existing government networks are already consolidated, and there is no alternative. Yes, IPv6 still has fledgling application support, but the IPv4 pool is no longer a sustainable resource to draw on, and there is no other option. So the government networks either stop growing or, as the U.S. DoD and Government agencies have announced, they will move to IPv6. This implies preparing the application community to meet the impending reality.

Geoff: Although the strategic directions of one single—but relatively large—market player does have some bearing on the direction of the global market in Internet-based service provision, I do not see evidence that this will be sufficient to influence the entire market in any particular direction. This was certainly evident in the case of GOSIP some years ago, and continues to be an aspect of the market today. The global communications sector carries the impetus and burden of massive investment in infrastructure, process, technology, services, and consumer product portfolios. The sector has already undergone a revolutionary change with the advent of the Internet over the past decade. Doubtless there is considerable reluctance on the part of many sector players to continue to invest in further change in the protocol infrastructure of Internet-based services. On the other hand, the upheavals in the service provider sector have also eliminated much historical complacency about the stability of these markets and the adequacy of the associated service portfolio. It is reasonable to suggest that this sector is now very attentive to the prospect of expanded markets and new service opportunities that can take advantage of the existing infrastructure to create new revenue streams. So I think it is the current dynamics of the service provider sector and the potential for new service markets that would be the most persuasive factor for service providers to invest in an IPv6 protocol infrastructure.

Ole: Closing thoughts?

Tony: As I said at the end of my article, now is the time to recognize that we have reached the end of sustainable growth in IPv4. For most existing organizations that can foretell they have as much space as they will need for the next decade, this is not really an internal problem. Where these organizations will have a concern is when they deal with newcomers or others that have been forced into IPv6 because of exhaustion of the pool. Those organizations that foresee expansion and growth should evaluate Geoff's analysis as well as mine and weigh their plans against the risks of either or both of us being wrong.

In any case it only makes sense to start IPv6 capability discussions with the product vendors now. Product development cycles can be lengthy, and the only way for the vendor community to mesh with an organization's deployment plans is to have sufficient notice about those plans and timeframes. It would also be wise for the organization's network architects to start thinking about the impacts of an IPv6 deployment. Both protocol versions are packet-based and the names start with IP, but there are enough differences in the details that it is worth taking a fresh look to see what might be easier or cheaper than just blindly deploying IPv6 identically to the IPv4 deployment.

Geoff: The Internet continues to present challenges to the communications sector, and I would suggest that the underlying influential factor is the combination of the silicon and software industries that continue to fuel the demand side with fascinating, innovative, and compelling uses of communications that continue to surprise us with their continual restatement of the size of the domain in which we operate. We appear to be moving beyond servicing devices that are activated and influenced primarily by direct human activity, such as e-mail and Web use, and we are now looking at various command, control, and monitoring functions that embed themselves deeply in other devices and in other elements of our infrastructure. This encompasses larger concepts such as "smart buildings" and "smart traffic control," and they reach all the way down to the level of embedding into consumer devices and even identification tags. This is not a world that can readily be serviced by an IPv4 protocol infrastructure, and we are already seeing various levels of network indirection in both NATs and various forms of overlay networks to attempt to compress this new scale of basic network addressing demands into the IPv4 environment. This appears to be a complex, and therefore costly task. But the expectation here is that the service industry is heading toward a commodity utility function, where the essential attributes of the underlying network are simplicity and efficiency. These factors suggest that the market characteristics that arise from the propulsion of the silicon and software industries are inexorably tugging the communications service industry to embrace simple, scalable, and efficient networking technologies. It is in this space that the essential attribute of IPv6, that of the size of the address pool, has its most effective leverage. Here the "run out" of IPv4 will inevitably focus our common attention on how best to engage with future needs and roles. And in this perspective the IPv6 technology has a critical and central role.

John: Tony, I think we need to assume that, when it comes down to translating the projections into an answer to the "when do we need to get serious about IPv6?" question, both you and Geoff are, to a considerable extent, wrong. Geoff's articles and projections have been interpreted by some people as containing a "there is no problem, we can continue with IPv4 until we all retire" message. Viewed from that direction, yours can be seen as "we cannot be quite *that* complacent." Instead, I think we should all be looking at going directly to IPv6 in newer network installations rather than concentrating on whether we can get enough IPv4 space for them. We also need to be examining—now, not a few years in some projected future—the applications and services for end networks and end users, not just backbone and ISP services and operations. One of my particular concerns is that we have enterprise and customer support people and protocols all over the world who are used to thinking about things in an IPv4 world, including the support advantages of "all NAT-based end networks look the same" architectures. The need to retrain them to think about things differently, and to design and build new tools for their use, may suggest a more time-consuming and expensive transition than changing over the networks themselves.

Fred: What is clear to me from this discussion, Geoff's prior analysis, and Tony's analysis here, is that there is a timeline. We are *not* debating whether IPv4 address availability is limited or whether it can be "saved" by address allocation policy, nor are we debating the economic or technical impacts of more or less draconian allocation policies. We *are* debating what constitutes the end game, when and why that end game will become important, and whether perhaps we are already seeing the first steps of it. We are also not debating whether perhaps some new architecture would be preferred over the one in IPv6; if we had an alternative on the table today we could discuss that, but experience tells us that the proposals being considered by the *National Science Foundation* (NSF) and others are sufficiently "researchy" to not be ready for wide-scale deployment in the necessary timeframe.

As such, from my perspective, there is a present call to action.

What U.S. DoD and recent congressional hearings have recommended is in keeping with the IETF's recommendation and with the IPv6 address allocation strategies of the RIRs. The simplest transition strategy involves presently procuring equipment, operating systems, and applications that are IPv6-capable in preference to systems that are limited to IPv4. At some point in the future, perhaps in the 2008–2010 timeframe, we should plan to turn on IPv6 networking capabilities throughout our networks, and this means gaining experience with IPv6 on a smaller scale in 2005–2007 in our networks, in server applications, and in user systems. Turning down IPv4 capabilities, which is the endpoint of such a transition, is a business decision that does not need to be made hastily; we should presume that coexistence will be important for a decade, and probably more.

Ole: Thank you, gentlemen!

TONY HAIN is currently the Senior Technical Leader, IPv6 technologies, with Cisco Systems. In addition to providing guidance to the various internal product teams, he was also co-chair of the IETF working group developing IPv6 transition tools. His IETF participation since 1987 includes a term on the Internet Architecture Board from 1997 to 2001. Named an *IPv6 Forum Fellow* in 2004, he is currently serving as Technology Director on the forum's North American IPv6 Task Force steering committee. Prior to joining Cisco in 2001, he spent 5 years at Microsoft, where his roles included Program Manager for IPv6 as well as Network Analyst for the CIO's office. Prior to Microsoft, he was the Associate Network Manager for the U.S. Department of Energy's Internet effort, ESnet. With this range of roles, spanning the space between the implementation technologists and senior management, he brings a real-world viewpoint to the deployment decision process. GEOFF HUSTON holds a B.Sc. and a M.Sc. from the Australian National University. He has been closely involved with the development of the Internet for the past decade, particularly within Australia, where he was responsible for the initial build of the Internet within the Australian academic and research sector, and has served his time with Telstra, where he was the Chief Scientist in the company's Internet area. Geoff is currently the Internet Research Scientist at the Asia Pacific Network Information Centre (APNIC). He served as a member of the Internet Architecture Board from 1999 until 2005, and currently co-chairs the Site Multi-homing and Routing Operations IETF Working Groups. He is author of *The ISP Survival Guide,* ISBN 0-471-31499-4, *Internet Performance Survival Guide: QoS Strategies for Multiservice Networks,* ISBN 0471-378089, and co-author of *Quality of Service: Delivering QoS on the Internet and in Corporate Networks,* ISBN 0-471-24358-2, a collaboration with Paul Ferguson. All three books are published by John Wiley & Sons. E-mail: **gih@apnic.net**

JOHN KLENSIN is an independent consultant based in Cambridge, Massachusetts. He has been involved in the design, development, and deployment of ARPANET and Internet applications, and occasionally lower-layer technologies, since the late 1960s and early 1970s. He has also been intermittently involved with Internet administrative and policy issues since the early 1980s. His current work primarily focuses on internationalization of the Internet on both technical and policy dimensions. E-mail: **klensin@jck.com**

FRED BAKER has worked in the data communications industry, building network elements such as switches and routers, since 1978. His involvement with Internet technology started in 1986, and with the IETF in 1989. He has contributed to the development of OSPF, QoS, PPP, SNMP MIBs, and a variety of other technologies. He has also held a variety of management positions, including chairing various working groups, participating in the IAB, and chairing the IETF. He currently serves on the Technical Advisory Board of the U.S. Federal Communications Commission and as the Chairman of ISOC's Board of Trustees. E-mail: **fred@cisco.com**

Practical Uses of SSH Tunneling in the Internetwork

by Ronnie Angello

While the growing popularity of broadband Internet services and elevated concerns with securing *Wireless LANs* (WLANs) have become major concerns for network administrators today, *Secure Shell* (SSH) *Protocol* tunneling has proven to be a secure and effective solution for addressing various needs and concerns of both network users and administrators. Making the transition from traditional dialup remote access to a broadband solution can bring along with it some roadblocks when trying to preserve functions and security. WLANs can be difficult to secure in the enterprise, mainly because of the various client types that must connect to the network. SSH tunneling can help alleviate both of these issues.

SSH tunneling, also known as SSH *port forwarding*, is the process of forwarding selected TCP ports through an authenticated and encrypted tunnel. These tunnels can be constrained to within two points of the company's enterprise network, or it can originate on a small office or home office (SOHO) computer on a given provider's network, and transit the Internet to a server on the enterprise network. Some practical uses for SSH tunneling are outlined in this article.

A Look Back at Traditional Remote Access

Remote access is the method of connecting from a SOHO computer that resides on a remote foreign network, or has no permanent network connection, to the enterprise network or central office. Usually this involves traversing the Internet. This can be for the purpose of telecommuting, providing on-call support from home, checking e-mail while away from the office, or for the old-fashioned workaholic who must work from home. Remote access used to involve simply accessing a network through an analog phone line or possibly ISDN. In either case, the user was authenticated by an access server that resides on the enterprise network and given authorization to certain resources.

When connected to the access server, users had the feel of being connected to their company's enterprise network. They were free to browse internal Web pages and access various Windows domain resources. They could connect to the network neighborhood and transfer files to and from the work computer. They could connect directly to internal UNIX servers with SSH and use a local X-server application to access UNIX applications from the SOHO.

PC remote-control applications such as VNC, etc. could be used to access files and applications that reside on a host computer on the enterprise network without extensive configuration on the home PC. In addition to the ease of configuration for the administrator or user, fewer applications need to be installed on the home computer to accomplish work tasks from home. This approach saves software licenses in addition to valuable company resources.

Most network administrators cannot let PC configuration consume a great deal of their time because they are busy enough as it is. From a function standpoint, users felt like they were working from their office at work. It was too slow though, so it did not really matter. Then broadband services were introduced, and they offer high bandwidth, but getting the same functions is a bit more challenging. Users benefit from the extra added bandwidth, but of course the administrator has to make sure that everything works as if nothing ever changed.

Broadband Services Emerge

Many users are now migrating from their traditional dialup connections for Internet access to a technology that offers more bandwidth such as cable or DSL. Broadband wireless services are now emerging in some areas as well. These services may even be cheaper than what the company or individual was previously paying for ISDN service, and it is "always on." Most users are no longer dialing a company access server to access the resources that are vital to their job. They are now permanently connected to a foreign provider's network, and often the only choice for secure remote access to the enterprise is through a VPN. Strict policies, however, may need to be enforced on the remote SOHO computer for it to be a comfortable solution for security administrators to implement.

For those organizations without the time, money, or manpower to implement and support VPN, Linux login servers can be opened up to the Internet to authenticate users that employ SSH to access the enterprise network from these remote networks. These servers are no more than relay points to access internal systems. They should be placed in the DMZ or on a "screened" network protected by a firewall. The other internal systems are not directly accessible from the remote networks. In cases where remote access is considered a valuable resource to the organization, more than one of these servers should be implemented for load sharing and redundancy.

However, certain functions are lost. Initiating an application from a UNIX computer and displaying it to your SOHO computer with a local X server has been proven to be slow and inadequate from some remote networks. In addition, internal domain PCs and network shares are no longer accessible through the network neighborhood, and file transfer is not available without an additional secure, standalone application. The remote-control applications that access the internal PC will no longer work without opening holes in the firewall. There is a simple solution to all this that is free, secure, and effective: SSH tunneling.

Securing Broadband Remote Access

The functions described in this section can be achieved with any SSH client capable of tunneling, any Web browser that supports HTTP and *Secure Sockets Layer* (SSL) proxies, and any PC remote-control application. The first step is always to connect to the remote login server that has been made accessible to the SOHO user. When connected to this login server, the user can use SSH to access any other internal machine, or take advantage of SSH port forwarding to accomplish their other tasks.

A proxy server may already be configured on your enterprise network. This server is configured to accept connection requests for Web pages and allow the clients to view them with little network overhead. The SSH client on the SOHO computer is configured to forward the specified local source HTTP port (such as 8080) to port 80 on the remote destination HTTP proxy server. It can also be configured to forward the specified local source SSL port (such as 4433) to port 443 on the remote destination SSL proxy server.

The browser on the client machine is configured to use the HTTP or SSL proxy server **`localhost`** on the specified local port(s). When the browser attempts to download a page, the SSH client forwards the request to the specified remote proxy server on your enterprise network through the established tunnel. Internal Web pages that would normally be available only on the enterprise local intranet are available without latency and without compromising security.

The same concept can be followed for tunneling PC remote-control application data through SSH. The remote-control host service is not changed, and it is waiting for a connection attempt from a remote computer as it normally would. A new remote-control connection is configured on the SOHO computer pointing to **`localhost`**. Using any additional encryption offered by the remote-control application is possible, but not necessary. Additional encryption will add latency, and SSH provides strong encryption itself with *Triple Digital Encryption Standard* (3DES), Blowfish, etc. The SSH client is configured to forward the local source ports used for the remote-control data (that is, port 3389 for RDP) to destination ports on the host computer on the enterprise network.

Once again, all the functions that the user had when dialing up the enterprise network directly are now available. With SSH, an additional layer of security is provided. Because the desktop of the internal computer is available on the SOHO computer's desktop, users have access to all applications, files, and network resources that they would if they were physically working from their office at work. No additional software applications need to be installed on the office computer to satisfy requirements of working from home, and minimal software needs to be installed on the users' personal home computers. Some of these remote-control applications also provide a file transfer tool that can be used to transfer or synchronize files between the two PCs.

SSH Tunneling for WLAN Security

Securing WLANs has become a monumental problem today for most network administrators. Many organizations are resorting to proprietary solutions or are simply avoiding the implementation of WLANs entirely. An entire article could be dedicated to the importance of securing wireless and the details of accomplishing such a feat.

In addition to the uses described in the previous sections, SSH tunneling can also be used to supplement or replace weaker, more vulnerable encryption found in other network applications. Consider *Wired Equivalent Privacy* (WEP) encryption, for example.

Although other alternatives such as *Wi-Fi Protected Access* (WPA) are available, most WLANs have been implemented with either no encryption or with static WEP only. Static WEP has been highly criticized because of vulnerabilities in the protocol that have been discovered and widely documented. Even when implemented at the 128-bit level, there are tools circulating the Internet that exploit a well-known vulnerability that allows a hacker to crack WEP keys. Even with a WPA solution in place, there will be clients that support only static WEP. These traditional clients can be secured in the meantime by restricting network access with an *Access Control List* (ACL) and tunneling insecure protocols through SSH. Once again, the same functions can be achieved with a VPN solution, but some organizations have neither the money nor resources to implement it.

Summary

In conclusion, SSH tunneling can be used well beyond the scope of the methods explained this article. The particular uses outlined in the previous sections have been practical in my experience and have been very successful implementations. When users decide to change to a provider that offers broadband, I have found that simply providing a procedure for configuring tunneling has been successful for getting them operational from home.

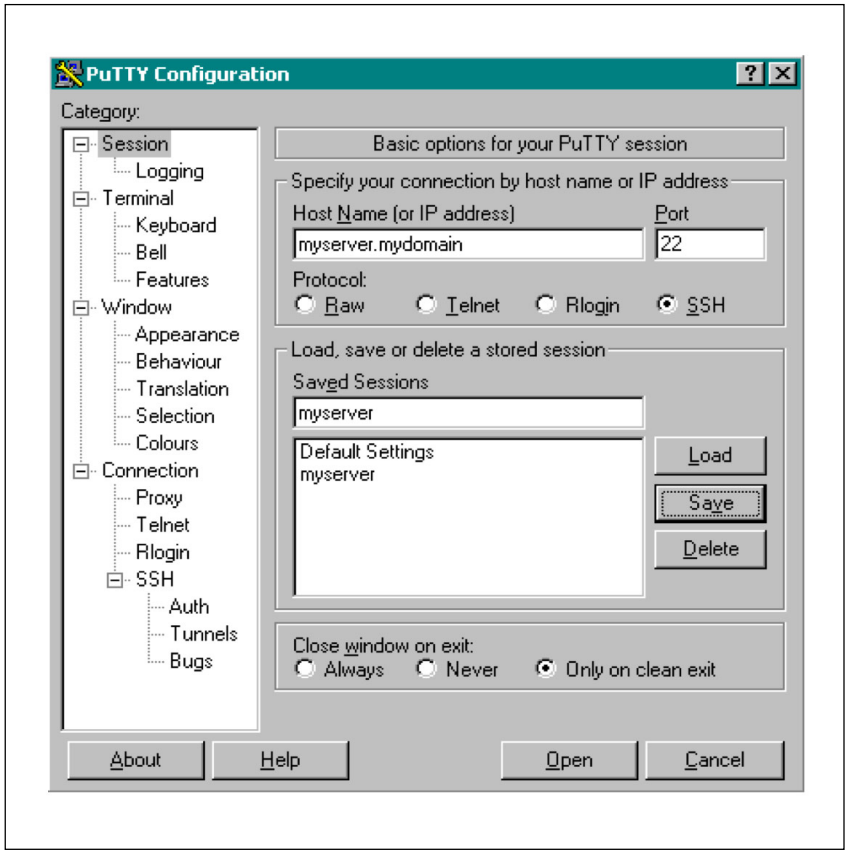
SSH tunneling should be of interest to any organization that wishes to allow its users secure access to all the resources that they may need to accomplish their job functions—especially from a remote location. While exploring possibilities to make a particular application or protocol secure, always consider SSH tunneling an option. SSH provides authentication and encryption that has been proven to be effective for any application.

Securing Remote Access to Internal PCs, Web Pages, etc.

The following is a short example procedure for configuring tunneling for this specific function. It does not include detailed instructions for configuring specific applications, but it outlines the important steps that must be followed in order for it to work properly.

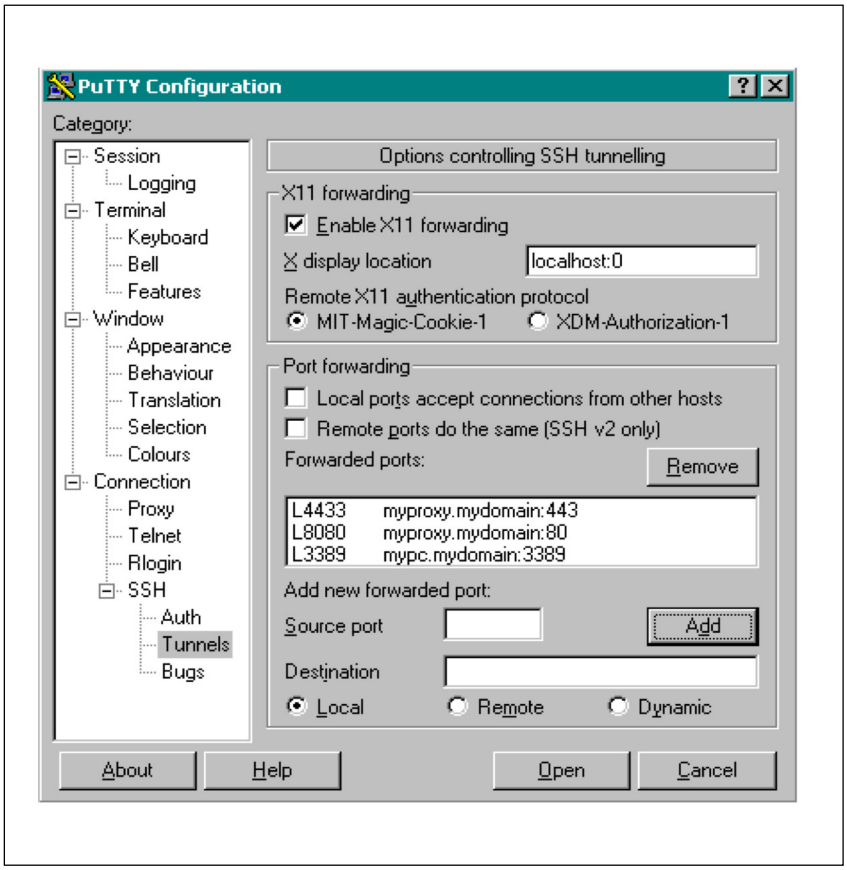
- Any SSH client that supports tunneling can be used. You can download the PuTTY SSH client (**`putty.exe`**) from: **`http://www.chiark.greenend.org.uk/~sgtatham/putty/download.html`**
- Make sure that you select port 22 (SSH). (See Figure 1.)

Figure 1: PuTTY Configuration Screen — Sessions



- Choose your preferred encryption cipher; enable compression and X forwarding if desirable. Click "tunnels" in the tree menu. Add the local source port(s) and the remote destination port(s) for the ports that you would like to forward through the tunnel. (See Figure 2.)

Figure 2: PuTTY Configuration Screen —Tunnels



- Make sure that the LAN settings in your Web browser are configured to use the HTTP/SSL proxy server **`localhost`** on the local port that you specified.
- Make sure that your remote-control connection is pointing to the computer "LOCALHOST." If you have trouble connecting, make sure that the host service is running on the host PC.

Book Review

Network Algorithmics

Network Algorithmics: An Interdisciplinary Approach to Designing Fast Networked Devices, by George Varghese, ISBN 0120884771, Morgan Kaufmann, 2004.

This is not a generic algorithms book (that is, it does not overlap much at all with Sedgewick or Coleman as an introduction to algorithms), nor is it a typical introduction to TCP/IP networking book (for example, there is no chapter defining the TCP/UDP/IP header fields, thank goodness). It might best be described as an algorithms analysis book set in the context of networking and also in the context of implementations that mix hardware and software solutions. For those familiar with Radia Perlman's book *Interconnections,* I found aspects of the writing style and approach to be similar. George Varghese—in addition to having been a networking professor for many years—has had a lot of industry experience from licensing algorithms to networking companies, to consulting with Procket Networks in the company's early days of architecting its core router, to starting a security company that was recently acquired by Cisco Systems. I have been doing architecture work at Cisco for several years and can say that George's book has real grounding in how systems are built and analyzed today.

Organization

Chapter 2 presents abstractions for networking protocols, hardware design, routers, memory technology, and Internet end nodes (servers). This is a great introduction into "systems" thinking. In section 2.2.7, "Final Hardware Lessons," one thing I thought George should have mentioned along with metrics of chip size, speed, I/O, and memory is *power*. Power is becoming a major systems concern in many platforms and deserves mention as an optimization constraint.

Chapters 3 and 4 go through a list of 15 implementation principles to use in approaching algorithmic design in systems and then give examples of these principles in action. What I find interesting about this section is that from working with George in the past, he really does believe and practice "principle"-based architecture thinking. I remember discussing several of the principles with him several years ago, and you can see how his many years of experience working in the networking field have shaped these principles. Many have probably employed some of these, but as George says in the chapter introduction, having them explicitly documented with examples is useful to help clarify our thinking. Some of the principles (and both the short examples in this chapter as well as examples cited in more detail in later chapters) are really fundamental, and I think reading through examples helped clarify in my mind when to use them.

Chapter 5 covers copying data, for example, in a server design. I really like this type of chapter, in which a subject (in this case the effect of packet copying on Web server performance) is explored in detail but with a focus on where algorithms and systems design play an important part.

My biggest question about this chapter is that I was unsure how applicable this is to, say, modern server design using Linux and with latest Gigabit Ethernet *network-interface-card* (NIC) designs. I know there was a lot of interesting work in the late 1990s, but this chapter without any data is more along the lines of an extended example of how to apply implementation principles.

Chapters 6 through 9 are not what I would consider the meat of the book; they treat the topics of implementation and analysis for servers, timers, parsing/classification of packets, and buffer management (memory allocation).

Chapter 10 covers exact match lookups. There is not a lot of meaty algorithmic discussion, but the history of scaling performance of bridges is used to elegantly show an evolution of algorithmic approaches to exact matching.

Chapter 11 is an awesome overview of the state-of-the-art in longest prefix match (used for destination address matching in routers and switches). A good read of this chapter will yield an understanding of the trade-offs in all major published algorithms, although there may be variations or tuned versions of these algorithms in use at companies like Cisco. I believe this chapter covers all the major categories of solutions.

Chapter 12 extends the prior chapter into more general packet classification (which is used in applications like extended access lists). Like the lookup chapter, this chapter addresses one of George's prime core competencies. There is good discussion on leading published approaches (Grid-of-Trie, cross producting, geometric, and decision tree-based approaches). I strongly recommend this chapter.

Chapters 13 and 14 cover packet switching (that is, architecture of fabrics like crossbars for connecting line cards in a router or switch) and then packet scheduling. These topics get a good academic treatment (after all, George is one who introduced *Modified Deficit Round Robin* (MDRR) to the industry as well as academia), and although there are gaps between what many networking markets are defining as requirements for packet scheduling and what is in this chapter, the chapter is still useful.

Chapter 15 is a short chapter that tries to treat at a high analytic level the algorithmic problems involved with routing protocols. It covers this topic without getting very specific into nonrelevant (to the analysis) networking details.

Chapter 16, which addresses measuring network traffic, was probably one of my least favorite chapters. Some of it is academically interesting but requires network level changes that I just do not think will occur. There are some cute tricks relative to counters and such, but I think they are similar to approaches already being used.

Chapter 17 is a network security chapter and seems to serve as an early introduction to the topic of algorithms in network security; this is not a major focus area of the book.

Areas for Improvement

There is always room for improvement, and I list here three areas in which this book could have been improved:

1. There is a running thread in the book of prefacing technical discussions in some cases with an example from the "normal world," like comparing packets to envelopes in the postal system. I estimate this is less than 1 percent of the content of the book and fairly easy to ignore if it annoys you.
2. I would have enjoyed better (more detailed) figures. A well-done, detailed figure can incorporate multiple concepts in the text around it and make it much clearer. On the positive side, there are numerous figures in the specifications, even if they do tend to be simple and high level.
3. Another area that I would have enjoyed seeing more on is empirical data (tables of data and graphs). I enjoy detailed empirical data of the type that Hennessy and Patterson so effectively use in their *Computer Architecture* book. There are many places (for example, Web server optimizations in Chapter 5) that I think could have benefited from detailed empirical data. However, I think folks often rely on empirical data too much when a simple analysis like the type done throughout the book could be done to help optimize the problem.

Recommended

Many chapters in this book are directly relevant to the development of networking equipment and software, as well as what is "under the hood" of networking equipment. The book is fun to read and I believe succeeds in trying to convey an organized systems approach to thinking about problems in the networking space.

—*Will Eatherton*

Read Any Good Books Lately?

Then why not share your thoughts with the readers of IPJ? We accept reviews of new titles, as well as some of the "networking classics." In some cases, we may be able to get a publisher to send you a book for review if you don't have access to it. Contact us at **ipj@cisco.com** for more information.

Fragments

Internet Governance Report Available

The *Computer Science and Telecommunications Board* (CSTB) of the National Academies has recently published a report entitled "Signposts in Cyberspace: The Domain Name System and Internet Navigation."

A summary report, as well as links to the full report can be found at:
`http://www.cstb.org/dns/signpost.html`

From the summary: "The *Domain Name System* (DNS) enables user-friendly alphanumeric names to be assigned to Internet sites. Many of these names have gained economic, social, and political value, leading to conflicts over their ownership—especially names containing trademarked terms. Congress, in Public Law 105-305, directed the Department of Commerce to request the *National Research Council* (NRC) to perform a study of these issues. When the study was initiated, steps were already underway to address the resolution of domain name conflicts, but the continued rapid expansion of the use of the Internet had raised a number of additional policy and technical issues. Furthermore, it became clear that the introduction of search engines and other tools for Internet navigation was affecting the DNS. Consequently, the study was expanded to include policy and technical issues related to the DNS in the context of Internet navigation. This report presents the NRC's assessment of the current state and future prospects of the DNS and Internet navigation, and its conclusions and recommendations concerning key technical and policy issues."

The report was produced by the Committee on Internet Navigation and the Domain Name System: Technical Alternatives and Policy Implications, National Research Council.

First Protocols for Policy Makers Forum to be held October 28

The Internet has achieved the same global economic significance that propelled issues of international trade and finance onto the front pages of newspapers and the forefront of international policy thinking twenty years ago. This change is raising the profile of specialized issues and "obscure" policies for a rapidly expanding circle of public and private-sector stakeholders. Increased general understanding will be vital to assuring that Internet's growth, development, and coordination mechanisms continue to serve important public interests.

In recognition of this growing need for public education, Packet Clearing House is organizing a series of day-long roundtable fora to encourage sharing of technical and institutional know-how between prominent Internet architects, policy makers, and leading opinion leaders from related sectors. With the support of the *American Registry for Internet Numbers* (ARIN), the forum, to be called *Protocols for Policy Makers* (PfP), will meet for the first time on October 28, in conjunction with the NANOG 35 and ARIN XVI Internet operations and policy meetings in Los Angeles, California.
See **`http://nanog.org/arinattend.html`**

PfP will explore themes of competition, coordination, and possible conflict between new alternative Internet naming and addressing systems which are challenging the status-quo, such as the national registries recently proposed by the International Telecommunications Union and competitive private-sector "alternate roots." What outstanding problems are these new mechanisms intended to solve, and what goals might they achieve? How will these innovations contribute to the advancement of Internet public interests? What risks, costs, and complications may be imposed on the Internet by the emergence of multiple divergent systems? At PfP, these issues will be examined through a day of structured round-table discussions, interspersed with comments from leading experts on the Internet's current naming and addressing systems and prominent advocates of the current restructuring proposals. A complete agenda and list of speakers will be published shortly at **http://www.pch.net**

PfP will be open to the public, but space is very limited. For more information, or to request an invitation, please e-mail **pfp@pch.net**. Expressions of interest from potential speakers, meeting hosts, and institutional co-sponsors are also welcome. Plans for future PfP meetings are already underway, with a second meeting, tentatively titled "When Voice Goes to Bits" to focus on technical, commercial, and regulatory implications of the migration voice telephony to IP. Suggestions for future meeting themes, venues, and contributions should be directed to PfP Forum Chair Tom Vest at **pfp-sponsor@pch.net**

Jun Murai Recognized with Postel Award

Professor Jun Murai is this year's recipient of the Internet Society's prestigious *Jonathan B. Postel Service Award*. The award recognizes Professor Murai's vision and pioneering work that helped countless others to spread the Internet across the Asia Pacific region.

The Postel Award was presented during the 63rd meeting of the *Internet Engineering Task Force* (IETF) in Paris, France by Daniel Karrenberg, chair of this year's Postel Award committee, and Lynn St. Amour, President and CEO of the Internet Society.

"Jun Murai has always encouraged, inspired and helped others, particularly his students and his colleagues in other parts of the Asia Pacific region," said Karrenberg. "He has also played a key role in creating structures for Internet coordination in the region (particularly the *Asia Pacific Network Information Centre* [APNIC]), and he is widely recognized for his recent pioneering work in IPv6 implementation."

Jun Murai is currently Vice-President at Keio University in Japan, where he is a Professor in the Faculty of Environmental Information. In 1984, he developed the *Japan University UNIX Network* (JUNET), and in 1988 established the WIDE Project (a Japanese Internet research consortium) of which he continues to serve as the General Chairperson. He is President of the *Japan Network Information Center* (JPNIC), a former member of the Board of Trustees of the Internet Society and a former member of ICANN's Board of Directors.

The Jonathan B. Postel Service Award was established by the *Internet Society* (ISOC) to honor those who have made outstanding contributions in service to the data communications community. The award is focused on sustained and substantial technical contributions, service to the community, and leadership. With respect to leadership, the nominating committee places particular emphasis on candidates who have supported and enabled others in addition to their own specific actions.

The award is named after Dr. Jonathan B. Postel, who embodied all of these qualities during his extraordinary stewardship over the course of a thirty-year career in networking. He served as the editor of the RFC series of notes from its inception in 1969, until 1998. He also served as the ARPANET "Numbers Czar" and the *Internet Assigned Numbers Authority* (IANA) over the same period of time. He was a founding member of the *Internet Architecture Board* (IAB) and the first individual member of ISOC, where he also served as a trustee.

Previous recipients of the Postel Award include Jon himself (posthumously and accepted by his mother), Scott Bradner, Daniel Karrenberg, Stephen Wolff, Peter Kirstein and Phill Gross. The award consists of an engraved crystal globe and $20,000.

ISOC is a not-for-profit membership organization founded in 1992 to provide leadership in Internet-related standards, education, and policy. With offices in Washington, DC, and Geneva, Switzerland, it is dedicated to ensuring the open development, evolution and use of the Internet for the benefit of people throughout the world. ISOC is the organizational home of the IETF and other Internet-related bodies who together play a critical role in ensuring that the Internet develops in a stable and open manner. For over 13 years ISOC has run international network training programs for developing countries and these have played a vital role in setting up the Internet connections and networks in virtually every country connecting to the Internet during this time. For more information visit: **`http://www.isoc.org`**

Internet Root Servers Deployed in India

APNIC recently announced that three new Internet DNS root name servers are now operational in India.

These servers, launched in an official ceremony in New Dehli, India, on 25 August 2005, are the first root name servers deployed in India and South Asia and are already bringing significant improvements in speed and reliability to Internet users in India and the surrounding region.

APNIC has coordinated these deployments with the *Department of Information Technology* (DIT) and the respective root server operators.

F-root, operated by *Internet Software Consortium* (ISC) has been installed in Chennai; I-root, operated by Autonomica, has been installed in Mumbai; and K-root, operated by RIPE NCC, has been installed in Noida, near Delhi.

The installation of the root servers in India has been made possible by DIT, the *National Internet Exchange of India* (NIXI), and the *Internet Service Provider Association of India* (ISPAI), with financial and logistical support from APNIC. The three deployments in India bring the total number of root DNS servers in the Asia Pacific region to 24, 16 of which have been made possible with APNIC's support.

"We are pleased that India is able to contribute to the deployment of the first root name servers in South Asia," said Mr Pankaj Agrawala, Joint Secretary of DIT. "These three root servers will not only benefit the Indian Internet community, but also Internet communities in the surrounding region."

Paul Wilson, Director General of APNIC, added, "The deployment of these three root name servers in India is a positive example of Internet community coordination. The installation has involved the private sector, not-for-profit organizations, and government bodies working together to improve DNS stability and Internet response times for developing countries in South Asia."

Amitabh Singhal, Acting CEO of NIXI, said, "India is among the top ten countries in Internet usage, with over 35 million current subscribers and a five year target for 40 million, translating into more than 200 million total users by 2010. Sustainable infrastructure capacity building is imperative. As a budding intellectual capital of the world, with conducive socio-economic and political environments, India is justifiably proud of hosting three root servers, visibly putting our country, as well as the South Asian region, firmly on the world Internet route map."

More information about the participants can be found below.

- *APNIC* is one of five Regional Internet Registries currently operating in the world. It provides allocation and registration services which support the operation of the Internet globally.
  http://www.apnic.net
- *Autonomica AB* is responsible for **i.root-servers.net**, the first root name server to be installed outside the United States of America. **i.root-servers.net** has been operational since 1991 and is now anycast from more than 25 locations around the Internet.
  http://www.autonomica.se
- *DIT* operates under the Ministry of Communications and Information Technology, *Government of India* (GOI).
  http://www.mit.gov.in
- *ISC* operates one of the 13 root DNS servers as a public service to the Internet. ISC has operated F-root for the IANA since 1993.
  http://www.isc.org
- *NIXI* is joint effort between the GOI and the ISP industry to localize Internet traffic in India. NIXI has nodes in Delhi, Mumbai, Chennai and Kolkatta. **http://www.nixi.in**
- The *RIPE NCC* is one of five Regional Internet Registries currently operating in the world. It provides allocation and registration services which support the operation of the Internet globally.
  http://www.ripe.net

IETF Journal Announced

The Internet Society (ISOC) is pleased to announce the *IETF Journal,* a new publication produced in cooperation with the IETF Edu team. Our aim is to provide an easily understandable overview of what is happening in the world of Internet standards, with a particular focus on the activities of the IETF *Working Groups* (WGs). Each issue of the journal will highlight some of the hot issues being discussed in IETF meetings and in the IETF mailing lists.

The focus of this first issue will be a look back at the accomplishments of the recent 63rd meeting of the IETF in Paris.

We trust that this publication will give all those with an interest in the increasingly important Internet standards development process an opportunity to keep abreast of many of the topics being debated by the IETF. Articles will cover issues such as:

- Reports from the IETF and IAB Chair
- News from the IETF Edu Team
- Update from the IASA and the IAD
- Summary of the plenary discussions
- Highlights of IETF developments related to topics such as Routing, DNS, and IPv6
- Recently published RFCs.

The journal will be available shortly at the following URL:
`http://www.isoc.org/pubs/IETF-Journal`

Upcoming Events

The *North American Network Operators' Group* (NANOG) will meet in Los Angeles, October 23–25, 2005. For more information, see:
`http://nanog.org`

The *American Registry for Internet Numbers* (ARIN) will meet (jointly with NANOG) in Los Angeles, October 26–28, 2005. For more information, see: **`http://arin.net`**

The *Internet Engineering Task Force* (IETF) will meet in Vancouver, Canada, November 6–11, 2005. For more information, visit:
`http://ietf.org`

The *Internet Corporation for Assigned Names and Numbers* (ICANN) will meet in Vancouver, Canada, November 30–December 4, 2005. For more information, see: **`http://www.icann.org`**

The *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT) will be held in Perth, Australia, February 22–March 3, 2006. For more information, see: **`http://www.2006.apricot.net`**

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

From The Editor

Perhaps the greatest challenge facing the Internet is the ever-increasing amount of unwanted e-mail, commonly known as *spam*. It is tempting to compare electronic mail to its paper counterpart, but there are some important differences. First, "junk-mail" is relatively self-limiting in scope because it costs real money to print and distribute even the most modest flyer. Second, advertisers in the real world are interested in *targeting* their audience. It makes little sense for a supermarket in Boston to advertise weekly specials on produce to consumers in Tokyo. Bulk mail—when delivered by the local postal service—is also quite carefully regulated. It is somewhat rare that you cannot locate the sender of paper-based advertising. None of these observations can be applied to spam. Sending spam is more or less "free," spammers often target "the entire world," and spammers can easily hide behind fake or transient addresses.

To date, spam has been tackled largely by applying sophisticated filtering techniques for incoming e-mail, but this does nothing to decrease the amount of actual spam sent. Anti-spam legislation has been passed in some countries, but it remains difficult—if not impossible—to pursue spammers through legal means, especially in an international context. It is therefore natural to look at technological solutions to the spam problem. If we can secure our network and authenticate its users, would it not be possible to allow only "authorized and verified" senders to send e-mail? Dave Crocker examines this problem in our first article.

Of course, no simple technical solution for spam exists, and not surprisingly there are divergent views on how the problem should be tackled. Our second article, by John Klensin, looks at spam from a different perspective and suggests some possible avenues towards a solution.

Our final article looks at routing protocol testing. Russ White examines testing mechanisms and discusses guidelines for realistic testing.

Many of you have already responded to the *IPJ Reader Survey*. There is still time to participate. If you received an e-mail invitation to take the survey, simply follow the link in the message. You can also take the survey by following the survey link on the IPJ home page: **http://www.cisco.com/ipj**. If you prefer to just drop us a line with your comments and suggestions you can do so by sending e-mail to: **ipj@cisco.com**.

—Ole J. Jacobsen, Editor and Publisher

Challenges in Anti-Spam Efforts

by Dave Crocker, Brandenburg InternetWorking

It is said that the Internet teaches us one lesson. That lesson is "scaling." The Internet comprises perhaps one billion users, millions of machines and many tens or hundreds of thousands of independent service operators. It operates in, and between, virtually every country on the planet. It is used for personal, organizational and governmental services. Therefore, it must be compatible with many different cultures, many different styles of communication and many different methods of administration. The Internet has no central point of control and operates according to no set schedule. Hence, changes must be gradual and voluntary—when we agree on what those changes should be.

In the early 1990s, the Internet grew from a small research community into a global mass market. Imagine a small town changing into a large, undisciplined city. In a large city, most people are strangers, and the strangers have a diverse range of values and behaviors. Hence, people must use much more caution with each other. In other words, the problems are not with the original way the town operated, but with changing requirements. So, spam is merely an unfortunate—but frankly predictable—example of the Internet's success, not its failure.

This article explores the system-level complexities of the spam problem, as the intersection of social diversity, complexity of e-mail technology and operations, and specific lines of attack that seek to control spam. On the question of control methodologies, most prior work has been on analytic tools that are used by sites receiving spam, to evaluate the mail content, associated addresses or traffic flow. Recent efforts focus on assignment and assessment of an accountable identity that is responsible for individual messages or for the transit of aggregate message traffic.

The Nature of Spam

People agree that spam is a serious problem, but they have difficulty agreeing on its definition. *Unsolicited Bulk E-mail* (UBE) is probably the most useful.[1] A spammer sends a large number of messages to many different recipients who have not requested the content. (Interestingly most spammers do not care whether a particular addressee receives the message; they merely seek to get a sufficient percent of their postings delivered to some of the addressees.)

Spam can conform to Internet technical standards and can contain no technical differences from legitimate—desired—messages. Hence, spam that violates standards or has other peculiarities might be common today, but detection efforts that are based on these anomalies offer no long-term benefits. Spammers are highly adaptable and use the easiest method that works. However what spam *always* violates are our *social* conventions. Therefore, any long-term, proactive, technical responses to it, such as formulation of standards, must follow, rather than lead our social decisions about it.

Like other social problems, we probably can control spam, even if we cannot eliminate it. This means that we must adjust to having spam as a permanent part of our social landscape, even as we seek to limit it to tolerable levels. Efforts to detect and eliminate spam have been underway for quite a few years. Some techniques have shown useful, localized results, but most only for a short time. In other words, none of the many spam control attempts, over the years, has yet reduced the amount of global spam! So we must be cautious about our expectations for any new anti-spam proposal. It also is likely that controlling spam requires an array of complementary techniques and continued efforts to adapt them, as spammers continue to adapt their own methods. This means that we need to assess any new proposal in terms of its likely *incremental* benefit, rather than as a candidate to be the *Final Ultimate Solution to Solve Spam* (FUSSP).

Changing a global infrastructure takes a long time and is very expensive. Some proposals require complex technology, while others require substantial, on-going administrative effort. Worse, some impose onerous requirements on end-users. Therefore we need to ensure that the mechanisms we deploy will have significant, long-term benefit, even after spammers try to adapt to their presence. They also must have reasonable development cost, require limited, on-going administration and be sufficiently easy to use. In evaluating the likely efficacy of a proposal, a useful heuristic is to ask whether it would be desired even if spam were not a problem. If the answer is yes, then it provides general, strategic benefit, so that counteracting spam merely adds urgency to its adoption.

The Internet provides us all with vastly better access to each other. For collaboration, or the formation of specialized communities or for personal interaction, this is wonderful. For intrusions into our privacy and threats to our online security, this is problematic. Unfortunately, the benefits and the detriments are tightly coupled. Our efforts to control e-mail's problems need to be made cautiously, lest we also reduce its benefits. Worse, our efforts need to limit the damage that might be done to innovative benefits that we have not yet envisioned.

The sender of spam incurs almost no incremental cost for a single message. It is easy to think that we should simply make e-mail be the same as sending letters or making phone calls, by directly charging the sender for every message. This cost provides a barrier against abusive, bulk use. In reality e-mail is a different kind of service, with an extensive history, and it is subject to different choices. Telephones and postal service have highly centralized, formal operational authorities, and the fees charged for their use are based on offsets to direct, real expenses. By contrast, e-mail is a highly decentralized service, with correspondents' private systems contacting each other directly, rather than having to be mediated by state-regulated utilities. If additional fees are charged, they also need to be based on the costs of real services; an arbitrary "tax" will simply create its own problems. For example, who gets the money, and why?

To retain its flexibility and its ability to support new human communication uses, we must retain the current, open model of spontaneous e-mail exchanges. Therefore, over time, it is likely that Internet mail will evolve into two logical subsets. One comprises trusted, accountable participants and the other includes everyone else. Trusted participants may be subject to less stringent checks and filtering. Perhaps more importantly when there is a problem, it is likely that mail from a trusted identity will still be delivered, while the origination agent is consulted, rather than rejecting the mail automatically.

E-mail Architecture

Internet mail is based on a simple model. It distinguishes the world of users from the world of transmission. Anyone may send a message to anyone else. The basic service does not have a central authority and does not require authentication by the Originator, the Recipient or the operators. (It is worth noting that the telephone and postal services usually do not authenticate those sending letters or making calls.)

As shown in Figure 1, this model has grown to distinguish:

- *Mail User Agents* (MUA), which represent end-users
- The *Mail Transfer Service* (MTS) comprising a sequence of one or more *Mail Transfer Agents* (MTA), using the *Simple Message Transfer Protocol* (SMTP)[2,3]
- Posting new mail via a *Message Submission Agent* (MSA)[7]
- A *Notification Handler* or *Bounce Handler*, is an MUA that processes returned transmission reports such as a notice about failure. The Handler's address is specified by the MSA, during message posting.[11]
- Delivering mail via a *Message Delivery Agent* (MDA), possibly with user-specific delivery behaviors[8, 9]

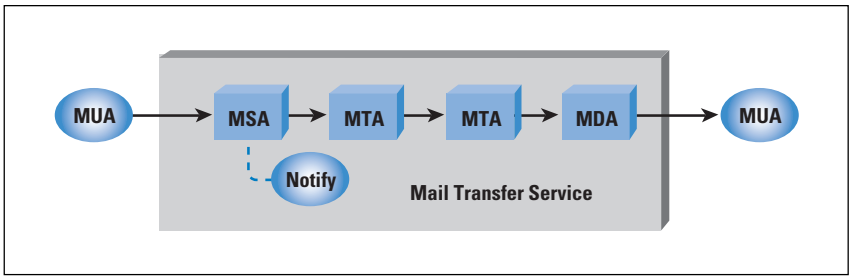

Figure 1: Internet Mail Architecture

The purpose of e-mail is to exchange messages among MUAs. For users, their e-mail client—the MUA—is all they directly experience. For most network administrators, the MTS software is their scope of concern.

The core e-mail message object also has a simple framework. Its *content* comprises:

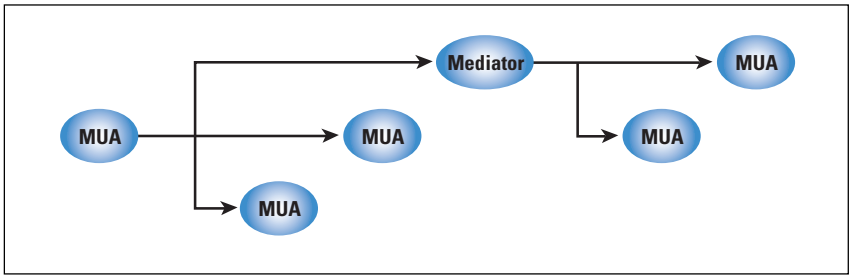
- Structured, textual meta-information, called the *header*, including *fields* for addressing, posting date, unique message identifier and a free-form description of the content[4,5]

- Lines of free-form ASCII text, called the *body,* which has evolved to support a potentially complex, structured set of multi-media, multi-character set attachments[12]

Figure 2 demonstrates a simple user-to-user example, with a message sent to three addressees, one of which is a special MUA that re-mails it to two additional recipients. The purpose of the Figure is to emphasize the user-to-user nature of e-mail and to provide a basis for considering the combinatorial explosion that marks the aggregate interactions of Internet mail components even in very simple uses. It further introduces another architectural construct:

- A *Mediator* is an MUA that re-posts messages, such as for a mailing list.[10] It preserves much or all of the original message, including author address, but can make substantial changes or additions to the content, which an MTA cannot. Therefore, a Mediator's role is user-level content responsibility, rather than MTS-level transit responsibility.

Figure 2: Simple Multi-Recipient Scenario

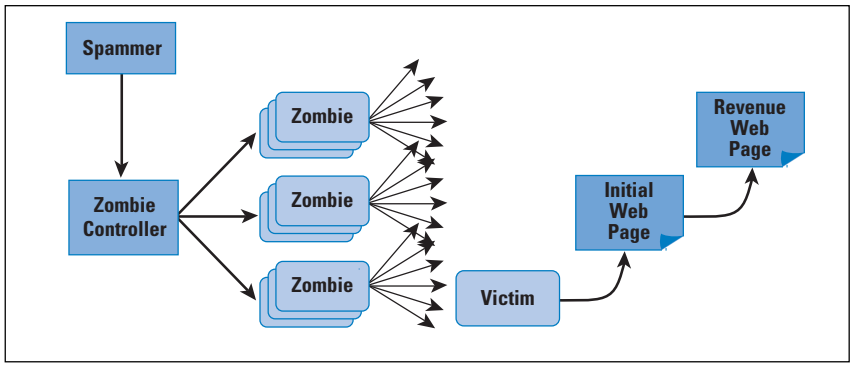


Spamming Architecture

Some spammers are legitimate businesses, engaged in overly aggressive marketing efforts, because there are no formal limits on their actions. In spite of the challenges created by needing to work at an international level, there is a reasonable expectation that legal strictures, both laws and contracts, will constrain in these businesses to a tolerable level. In contrast, *rogue* spammers actively seek to avoid accountability, to subvert barriers to their traffic, and to acquire unwitting and unwilling participation of machines owned by others. Independent of the legal details, the best social model to use for analyzing this latter group is crime. Often the activities do not violate particular laws, but what is most important is that the style of a spammer's conduct is the same as that of a criminal.

Unfortunately, the technical and operational world of spamming has also developed in scale and sophistication. Spamming used to entail one sender and one sending machine. Its performance was limited by the capacity of that machine and the bandwidth of its Internet connection. Today, rogue spammers control vast armies of compromised systems, called *zombies,* as shown in Figure 3. Zombies are owned by legitimate users who are unaware that their system has been compromised and is being used for spamming.

Figure 3: Rogue Spammer Control Network



The community of rogue spammers is remarkably well organized; it has become an extensive, underground economy. Some participants specialize in developing methods for breaking through filters. Others take over machines and turn them into zombies. Others sell the use of a zombie collection for periods of spamming. The estimated number of zombie systems is in the many tens of millions. After spam delivery, recipients often "click" to a transaction Web page. Web hosting is provided at multiple levels, in order to obscure the server side of the process, further reducing accountability.

Typically, spammers have the classic goal of selling products. However, they also can have political or religious motivations or even blatantly criminal intent, such as extortion. The ability to send very large number of messages to a specific destination gives spammers a tool that can be used to threaten an organization with a denial of service attack on their network.

Practical Efforts at Spam Control

It is tempting to believe that spam is an easy problem to solve, but history teaches us to be cautious. A web page located at **`http://craphound.com/spamsolutions.txt`** takes an irreverent approach in challenging simplistic proposals, by providing a checklist for the common weaknesses. In spite of its apparent whimsy, the checklist is surprisingly useful for screening proposals quickly.

The most common mechanism for spam control is a localized mechanism, the "filter"[14], named for its conditionally permitting mail to flow through it. Filters typically are used within the recipient's network (or Administrative Management Domain, as described later in this article.) However they may be placed anywhere along the path, notably including the MSA. Filters at the reception side cannot reduce Internet spam traffic. At the outbound side, they can. Filters have choices in the way they treat suspect messages. They can:

- Add a special annotation to the message
- Divert it into special storage
- Reject it back to its Handling Notification (RFC 2821 **`MailFrom`**) address or to the Client SMTP during the transfer session
- Simply delete it
- Accept it slowly, with "traffic shaping," to control the rate of SMTP transmission

The difficult question is: What are the criteria that a filter should use? The difficult answer is: Many. This need to support a wide, and changing, variety of decision criteria has caused filtering engines to evolve into extensible platforms for spam detection and handling modules. As the mixture and complexity of filtering algorithms become more sophisticated, the overhead they entail has grown substantially larger.

It is convenient to divide techniques into three, basic classes of criteria, although each is complex:

- *Content analysis,* such as Bayesian statistics tracking of vocabulary and content hashing, to detect bulk duplication
- *Responsible Agent assessment,* either for permission (whitelist) or rejection (blacklist)
- *Traffic analysis,* such as rates at which messages come from the same author address or IP Host Address

Content analysis is always a matter of partial success (and partial failure.) It is usually statistical and depends upon a database of training messages, to establish vocabulary norms. Spammers are constantly developing techniques for bypassing the current analysis technologies. Further, different recipients on the same e-mail service can have wildly different statistical patterns of acceptable content. This makes fine-grained filtering by their service provider problematic.

It is clear that these tools for evaluating individual messages, or aggregate traffic flow, can have significant transient utility. However they cannot be effective, long-term tools, even with continuing enhancement. Notably they have little or no effect at reducing spam at its source. These post-hoc analysis tools have two inherent deficiencies, both of which are coupled to their using heuristics, rather than reliable, accurate and objective rules. The first is one of "false positives" in which legitimate mail is incorrectly labeled as spam. As an example, this could mean that an essential business transaction is not delivered, instead being classed as junk mail. Perhaps the most insidious example of this problem occurs when spammers send mail that purports to be from a well-known, legitimate business. This is called *phishing* and results in making *all* mail with the address suspect, so that legitimate postings of essential mail are not delivered.

The second problem with using heuristics is in the nature of an "arms race" between spammers and anti-spammers who must each constantly adapt techniques, consume more resources, yet never win. It does not help that those fighting spam have been losing the war, since spammers have tended to be more aggressive, more innovative and better organized…

A different line of effort is based on the social assessment that the sender of an e-mail should be held accountable for it. The goal is to identify such an agent and then evaluate the agent's acceptability. This approach requires three enhancements to Internet mail:

- A clear sense of the boundaries between independent operational authorities
- A means of verifying an accountable identity that is associated with the message
- A means of formulating and sharing assessment information about accountable identities

Although e-mail operators often refer to *boundary* MTAs that face the open Internet, there is no accepted term for a region of e-mail components under unified authority. This article suggests a term derived from the OSI X.400 e-mail effort: *Administrative Management Domain* (ADMD) to mark these trust boundaries. They distinguish a collection of operational components subject to the same administrative policies, as discussed in [13].

An example of ADMDs is shown in Figure 4, and is derived from the scenario shown in Figure 2.

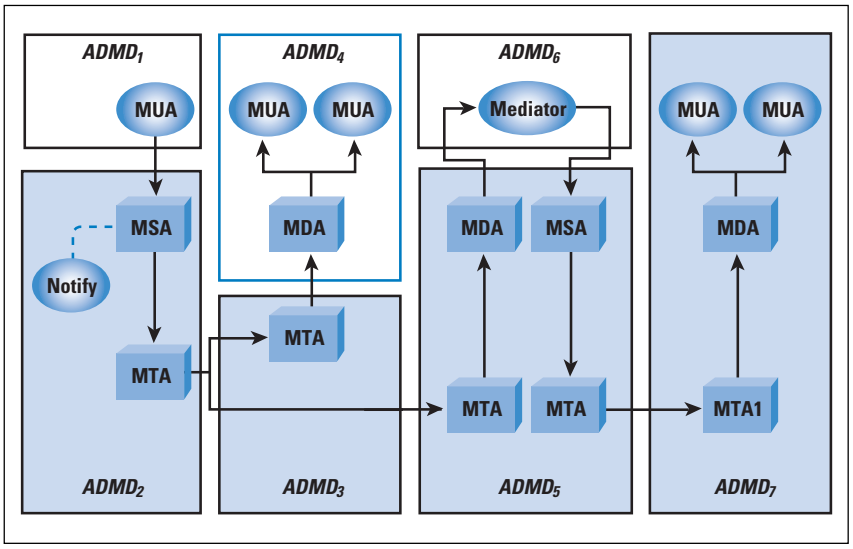


Figure 4: Independent Administrative Management Domains (ADMD)

The implied complexity of responsibilities and interactions is striking, even for this relatively modest case. For simplicity, think of the ADMDs labeled at the top of the Figure as representing users or value-added services, whereas the ADMDs labeled at the bottom could be a variety of classic Internet service (access) providers. The "boundary" agents are the ones with lines connecting over to another ADMD.

The increased diversity among Internet participants and ADMDs results in abuses such as spam. Proactive efforts to deal with these abuses require that we make changes in the nature of the trust between ADMDs and the way that that trust is enforced.

Accountability

Agent assessment seeks to hold an entity (agent) accountable for problematic e-mail. Who is a responsible agent for the content or for injecting the message into the MTS, and are they assessed as trusted or problematic?

There are two broad classes of accountable entities:

- *Content agents* comprise authors (RFC 2822 **`From`**) and those who are responsible for posting individual messages, as specified in the RFC 2822 **`Sender`** field. If the content agent is validated for a message, then the content probably reflects their intent. That is, it is unlikely that some other entity changed the content. Because the Notification Handler address (RFC 2821 **`MailFrom`**) appears in the SMTP protocol but is associated with the posting agent, it is often considered useful for analysis. Unfortunately the address often has no obvious relationship to the From field author or the Sender field posting agent, so its use for filtering can be problematic. However spammers often specify false Handling Notices addresses, in order to direct the mass of failed deliveries elsewhere. Consequently, it can be useful to validate the **`MailFrom`** address.
- *Operations agents* provide MTA or basic Internet access services. They are often held accountable for the impact of the bulk traffic their systems generate. Although they do not create the content, it is possible for them to enforce strict rules on their customers and to detect patterns of violations among them. Recommended practices for operators are beginning to obtain some consensus, such as with [15]. More are needed.

Assessment of agents can be proactive or reactive:

- *Accreditation* is the proactive registration by a sender, who aligns with a registry that extracts quality assurance commitments; any trust of the sender is therefore inherited from trust of the accreditation agency.
- *Reputation* refers to reactive evaluation of a sender's prior postings; for these, independent third parties evaluate the sender's history.

The functions that are combined, to establish useful accountability, comprise:

Identification: An identity label provides a unique reference to an entity.

Authentication: Validates the use of the identity label.

Authorization: Determines that the user associated with the identity is authorized to perform a particular function.

Assessment: Obtains an analysis of the trustworthiness or "quality" of the agency that is providing the authorization, or of the validated entity itself.

Unfortunately, many identities are involved in e-mail creation or transmission, as shown in Table 1.

Table 1: Roles for Internet Mail Identities

Type	Provided by	Identity of
MTA IP Host Address	Network-level service	SMTP client
EHLO Domain Name	RFC 2821 SMTP command	SMTP client
MTA Provider's IP Network Address	Network-level service	Site of SMTP client
Mail-From Mail Address	RFC 2821 SMTP command	Handling notices
From Mail Address	RFC 2822 header field	Author
Sender Mail Address	RFC 2822 header field	Posting agent
Received Domain Name	RFC 2822 header field	Relaying MTA site

Relative to an SMTP Server that is being asked to accept a message, the SMTP Client is an agent of the operator of the previous hop. Since the e-mail operator might be different from the operator of the IP access network that is hosting the e-mail service, it might entail a different identity. This highlights an interesting aspect of Table 1: Most of the identities associated with e-mail handling can be called "the sender." Consequently, that term has become nearly meaningless, in anti-spam discussions.

Because identity listings are made explicitly in a database, they are capable of producing almost no false positives, although there might be many identities not listed and a listing might be inaccurate. Still, there are significant challenges with the use of identity-based filtering:

- Which identity should be used and how does it relate to spamming behaviors? Note that Table 1 listed quite a few choices. In addition an author can create bad content, but the identity listed in the RFC 2822 **`From`** field of that content might not be the actual author, even if that field is validated. The message might have originated on a compromised machine and used the identity associated with it, unbeknown to the owner of the machine. Also the operator of the mail-sending network might have nothing to do with creating content, but it might be reasonable to hold the operator accountable for aggregate traffic problems.
- How is the identity validated (authenticated)? What entity is doing the validation? How does it relate to the identity being validated? And why is it trusted? Can the validation mechanism, itself, be tricked?
- How is an identity determined to be a spammer or non-spammer? What entity is vouching for the quality of that identity and why is the vouching entity trusted?

Authentication Standards

Accountability requires having an accurate, reliable identity of the agent that is to be accountable. Authenticating an identity is, therefore, a prerequisite for assessment efforts. However it does not, by itself, ensure a positive assessment. Spammers can register and authenticate their identities, too.

Early anti-spam identity schemes use the IP Address of the client SMTP MTA that is sending directly to the server running the filter. The Address is provided by the underlying network service, and therefore has been trusted. However, spammers are becoming proficient at stealing IP Address space, such as by advertising routes that use allocated-but-unused blocks of IP Addresses! Also an IP Address changes as the host changes its attachment to the Internet, and it is affiliated with operators, not authors. This makes the IP Address obscure and unreliable, when attempting to assess e-mail.

A more recent focus is on the use of Domain Names, for references that are more stable and align better with the authority boundaries of Administrative Management Domains. Broadly there are two lines of effort at using Domain Names for validating messages being relayed. One associates the identity with the systems that handle the message along its path. These "path registration" schemes include Sender Policy Framework, Sender-ID, and Certified Server Validation. The other schemes tie a Domain Name identity to the message object. These include DomainKeys Identified Mail, and Bounce-Address Tag Validation.

The *Sender Policy Framework* (SPF)[16] has evolved over time, attempting to encompass multiple identities. It primarily uses the Domain Name in the RFC 2821 **`MailFrom`** command. It queries the *Domain Name System* (DNS) with that name and determines whether the IP address of the previous-hop MTA is registered under that name. Since any SMTP server along the transit path may choose to perform this query, SPF requires that the Domain Name contain a registration for every MTA along every delivery path for a message. (A common simplification for this model is to use it only between boundary MTAs, but this considerable constraint is not specified in SPF. Rather, its use is usually characterized as being more general.) Although the software overhead for SPF is quite small, the administrative overhead can become substantial, as the number of paths increase and as paths change. In addition, some sender SPF DNS configurations can trigger a very large number of queries per addressee. Lastly, the role of the RFC 2821 **`MailFrom`** command is to specify the Notification Handler address. This address might be entirely different from other origination information, making registration of all of the MTAs in the path problematic. SPF therefore has significant administrative problems with redirected traffic, such as when going through a third-party forwarding service.

Sender-ID (SID)[17] uses a model similar to SPF, but it is based on the posting address Domain Name in the RFC 2822 **`Sender`** field (or RFC 2822 **`From`** field, if no **`Sender`** field is present.) Both SID and SPF sought IETF standardization in 2004 but the working group effort failed, due to lack of rough consensus convergence among participants and due to concerns over intellectual property claims.

Certified Server Validation (CSV)[18] covers only the current client/server SMTP hop. The client specifies an operator's Domain Name in the RFC 2821 **`EHLO`** command. The server uses this name to query the DNS. It then validates the IP Address of the SMTP client and determines whether the Domain Name administrator has authorized the client to send mail. CSV also specifies a standard mechanism for querying an assessment service about the client's Domain Name.

DomainKeys Identified Mail (DKIM)[19] specifies an accountable Domain Name that applies to a message during transit. It uses public key cryptography to digitally sign the message and provides guidance when the signing Domain Name differs from the Domain Name in the RFC 2822 **`From`** field.

DKIM Domain Name validation represents a significantly different goal from that of the strong authentication methods, such as [20, 21] which focus on long-term protection of message content. Also DKIM places its parametric information in a special RFC 2822 header field, rather than in the message body, so that it does not have any impact on recipient user agents that do not support DKIM. Although public key cryptography has relatively high computational cost, e-mail processing is usually i/o-bound, so that the real-world use of DKIM appears to have little impact on the aggregate message-handling capacity of a server.

Bounce Address Tag Validation (BATV)[22] attacks the problem of misdirected handling notices, such as bounces. It permits the creator of an RFC 2821 **`MailFrom`** bounce address to digitally sign it. When the bounce agent of that creator receives a message purporting to be a bounce, the agent can validate the address. Standardization of its format is needed so that e-mail intermediaries—such as some mailing list software—can determine the "core" of the mailbox portion. Since the creator of the signature semantics is the only consumer of the signature semantics, any signature algorithm can be used, including one based on symmetric keys. For convenience—and an existence proof—the BATV specification provides an example algorithm already in use.

Collaboration Support

Fighting spam must be a collaborative effort, which will benefit from using tools and standards that aid in exchanging information and performing coordination. To this end, standard methods of reporting spamming events, of characterizing particular spam, and of sending spam control data can be helpful. Some work in that direction is already underway.[23] Fighting spam requires global operations collaboration; this will be aided by services to facilitate interactions between network administrators speaking different languages. It is also likely that there should be standards for the syntax and semantics of whitelists and blacklists.

Acknowledgement

The author wishes to express particular appreciation for the unusual amount of dialogue that took place with the reviewers of this article. It produced a substantially clearer and more concise article. It also highlighted the extraordinary diversity of views on the topic, in case one had had any doubt. In fact, the article by John Klensin which follows this one is a direct result of the dialog.

Taking Another Look at the Spam Problem

by John C. Klensin

The problem of unsolicited bulk e-mail on the Internet has been widely discussed, and many classes of solutions have been proposed. Dave Crocker's article discusses some of the background for the solutions generally, points to a semi-humorous list of ways in which proposed approaches fail, and compares several approaches based on source authentication. This article takes a somewhat contrarian view. It argues specifically that the traditional models for defining technological solutions and then letting the policy and legal communities work out the details of how to utilize them are seriously wrong in this particular case and that partially-effective methods of fighting spam actually cause more spam.

This article makes two main suggestions. First, attempts to design technological countermeasures to spam without a clear understanding of how far, and in what directions, the setters of social policy are willing to go are futile. The requirement is not just that there be social recognition that a problem exists. In order to design effective technological countermeasures with predictable and acceptable side-effects, we must first understand what measures society is willing to take—what laws it is willing to pass and enforce to make spam a criminal or civilly-punishable act—to set an appropriate context and set of boundary conditions. Without those conditions, design of technological countermeasures is likely to constitute poor engineering practice, not just futility. Second, deployment of spam counter-measures that are not completely effective largely shifts the burdens of spam from one recipient population to another while *increasing* the total amount of spam on the network.

His analysis and mine agree on several critical points. Solutions that discard important characteristics of today's e-mail environment permanently in order to make some short-term gains against spam are not acceptable. Approaches that require drastic and simultaneous changes to the ways in which e-mail works in order to function are not going anywhere. There is a difference between legitimate businesses who have decided, within the limits of existing legislation, to engage in mass, unsolicited, electronic mailings to promote their products and those bulk mailers who prefer to cover their tracks, hide linkages between sending addresses, hosts, and web sites (or create deceptive ones), and who use zombie mailers and other ways to avoid cost and detection. We also agree that spammers, or their tool suppliers, are creative, technically-knowledgeable, and able to react much more quickly than the spam-fighting community (especially the standards-based part of that community) to changes in operating conditions and countermeasures.

I suggest a further guideline to help us think about the problem: however small they might be on a per-message basis, there are costs associated with sending e-mail and costs associated with receiving it and eliminating undesirable content.

If an anti-spam "solution" is developed that permits the spammers to vastly increase the costs to the recipients without a proportionate increase in their own costs, that solution is not tenable. A serious effort to predict the impact of a proposed solution to spam, including costs to the end user and load on the network as the spammers adapt to it, should be a critical component of such efforts. But, while equivalent analyses of measures, likely responses, and countermeasures are standard with any (other) technique designed to enhance network security, they have been largely absent when new technological approaches to spam are proposed.

This is a different aspect of the so-called "arms race" problem. In a classic arms race, no one can really win, as Dave points out. But, more important, when such races stop, it is only because one party simply stops, is forced out of the game by external pressures, or becomes exhausted economically. As long as there are no economic constraints, every escalation is met with a counter-escalation, which is met with a counter-counter-escalation, and so on. It is this positive feedback cycle that characterizes a true arms race. The battle against spam demonstrates a particularly unfortunate variation on that pattern in which the incremental economic costs of trying to deploy new spam abatement measures appear to be much more severe than the costs to the spammers of the most obvious counter-measure to improved spam abatement procedures, simply sending out more traffic. This is discussed further and in context below.

Social Problems and Technological Solutions

In the technical and protocol design community, our normal model is to develop technology and then use it to inform the policy, social, and legal parts of the society who then need to sort things out on their side. One of the classic arguments for this approach, which does not seem relevant to the spam situation, is that the potential use or misuse of a technology will not, and should not, constrain its development. For spam, the situation appears to be exactly reversed: we need to understand what is feasible and plausible from social, political, legal, and regulatory standpoints in order to define the engineering solution space. If we do not know what behaviors society is willing to make illegal or subject to effective civil action and whether it is willing to enforce those laws or equivalent positions, we cannot adequately define the engineering solution space. That results, in turn, in a high risk of solving the wrong problem or an irrelevant one. Of course, recent history has shown a variety of irrelevant and costly solutions to spam proposed, and sometimes deployed.

The solution to spam is identical to the solution to most other significant social problems: society must determine that it is a problem, create effective rules prohibiting the problem, and then enforce those rules aggressively and consistently. Technical solutions that make it easier to identify spam and its sources can then be immensely useful, but they are only useful if designed to be effective within the framework set by those rules.

If, by contrast, societies are, in practice, unwilling to take effective social or legal action against spam and those who benefit from it, then this article suggests that anti-spam measures will tend to make the overall situation worse.

The question of spam beneficiaries provides a particularly good illustration of this point. So far, most legal systems in the world have taken the position that the act of spamming is the offense (if there is any offense at all). Operating a domain or web site to which the spam recipient is directed to buy a product or obtain another benefit is rarely considered a problem by either law enforcement or by the relevant ISP. While establishing cause and effect—that the spam was authorized or encouraged by the web site owner—can be quite difficult, there has, appropriately, been little examination of tools to detect or identify beneficiaries because doing so seems pointless. On the other hand, on the same theory that it is more useful to try to arrest the drug importer than the street dealer, a different set of laws about beneficiaries and spam-authorizers—those who, in at least some cases, pay the spammers to spam—might dramatically change the landscape.

Reducing Spam by the Percentages

A new technique or group of techniques that claims to be beneficial can have either positive or negative value with regard to the amount of spam that gets through, either overall or to the mailbox or a particular sample user. A technique can also result in significant increases in the amount of network bandwidth or server resources consumed if it is neutral or better with regard to the end user mailbox. As long as the spammers can increase the number of messages they send out, almost arbitrarily and at low or zero marginal cost, the percentage of spam that is filtered out is ultimately irrelevant. The key measurement is how the amount of spam that gets through to some exemplar user (or a statistical aggregate of them) changes. That change pattern can be net either positive or negative. Suppose a technique is introduced that causes an initial small incremental reduction in the amount of spam delivered. The patterns of the last several years suggest that the spammers will respond by making a large increase in the amount of traffic they send out. Since the costs of doing so are very low, it would arguably be irrational for them to do anything else. If the increased volume is enough larger than the amount of spam the new technique was able to stop, there is a net loss to the Internet overall: the small improvement may represent a percentage decrease in the amount of spam that gets through, but the amount seen by the representative user increases and the percentage claims are largely irrelevant.

Unless whatever methods that are used in an attempt to reduce the amount of spam actually stop it at, or very near, the point of origin, the net effect on users is to shift the amount of spam received from those who have deployed the latest and most effective countermeasures to those who have not yet done so. The total amount of spam-related traffic on the network just continues to rise. And, since most countermeasures have costs—either in processing time or in software licensing fees—the cost burdens on end users also continue to rise.

This would seem to argue for methods that cut off spam traffic close to the source, but attempts to design such methods have been fairly unsuccessful, sometimes because of another policy problem: the spammers argue that some people like receiving unsolicited bulk commercial e-mail so that cutting off bulk traffic near the point of origin prevents legitimate and desired traffic from transiting the network. Source-oriented techniques include not only technical approaches but efforts—by law or social pressure—to hold ISPs and mail providers responsible for all traffic emanating from their networks, thereby encouraging them to refuse to have spammers as customers, to aggressively enforce terms and conditions of service, and so on. The strongest advocates of the "blacklist" variation of those techniques continue to claim that they are very effective although some others in the community are not completely convinced.

The House-Burglar Analogy

In the absence of a coordinated approach that is oriented toward legal or social enforcement, most anti-spam techniques appear to induce more spam on the network. They do this by making simply sending much more traffic out the most rational behavior for a spammer who is faced with an abatement technique to adopt. They may enable shifting the burden of dealing with that spam from one person to another—in the same way that aggressive locks and alarm systems on one house slightly increases the relative burglary risk to the less-protected neighbor—but, as Dave's article points out, we have no realistic plan for making it too expensive for the spammers to simply increase output.

Deterrents to burglary work moderately well because they increase the costs (in time, sophistication of the required tools, and so on) to the burglar. Equally important, they increase the risks of being caught and punished. In the present spam environment in most countries, we have no effective mechanism to increase costs and, at least statistically, the odds of being effectively punished even if caught are insignificant.

Shifting Burdens and Creating Preferred Classes of E-mail

The argument Dave presents for authenticated mail is ultimately that it can get expedited handling while non-authenticated mail is put aside for other methods of spam detection. That approach could be immensely effective at expediting receipt of some mail by the recipients who apply the needed checks, at least until the spammers begin authenticating their mail in a way that tricks the trust-establishment techniques. Prioritization of some messages and content will be effective as long as the fraction of such messages remains relatively small relative to the total number of messages received. As the percentage rises, one probably ends up either trusting all mail from a particular source, regardless of the author, or with a situation quite analogous to "whitelists," although one that is much harder to trick than the original. Either is subject to attacks and scaling problems.

There is also the risk of abuse by providers who conclude that mail that cannot be authenticated well enough that their users can prioritize it should simply be rejected and who then define the conditions for adequate authentication in terms of a small circle of cooperating mail providers. Even if the types of authentication outlined in Dave's article are used only as intended, the costs to recipients will rise, perhaps rapidly, over time as percentages of messages bearing authentication information rises and sender authentication and authorization become just one more tool to distinguish probably-desired messages from probably-undesired ones.

Maybe there is not Enough Spam Yet

One of the depressing consequences of the reasoning discussed previously is that perhaps we have yet to see sufficient spam for governments and regulatory bodies to take the spam problem seriously—seriously enough to deploy effective laws and enforcement mechanisms. If spam-fighting methods shift the burdens of receiving spam away from those who have the resources to protect themselves they may simply place the spam impacts on others who have fewer resources. That pattern may, in turn, also reduce pressure on governments to take effective action and to do so in a way that would make the design constraints for effective technological approaches clear. If a collection of anti-spam methods have the effect of simultaneously increasing the amount of total spam on the network and of decreasing pressures on societies and governments to take effective action, are they really ones we want to deploy?

Conclusions

This article presents a rather grim view of the future if we continue on our present course. If we fail to examine the actual actions that societies and their governments are willing to take to deal with spam and spammers and to treat those actions and their limitations as design constraints on the technical and engineering approaches, we are likely to continue to see an ever-increasing amount of spam on the network. Spammers will not only adopt technical countermeasures to new techniques but they will also take advantage of their ability to simply increase message volumes (at almost no cost) to counter the effects of those techniques on the percentage of spam that is delivered. It may be time to finally deal with the spam problem as the difficult social issue that it is, rather than permitting societies and governments to continue to believe that a technological "silver bullet" is right around the corner and that no real social or political action, or commitment of law enforcement resources, is needed.

Caveats in Testing Routing Protocol Convergence

by Russ White, Cisco Systems

In general, the main problems we find when testing routing protocols lie in generating accurate (or rather, realistic) data, as well as understanding the limitations of tests geared towards measuring routing protocol performance. Three areas of specific interest are covered in this article: defining convergence, taking realistic measurements, and creating realistic data.

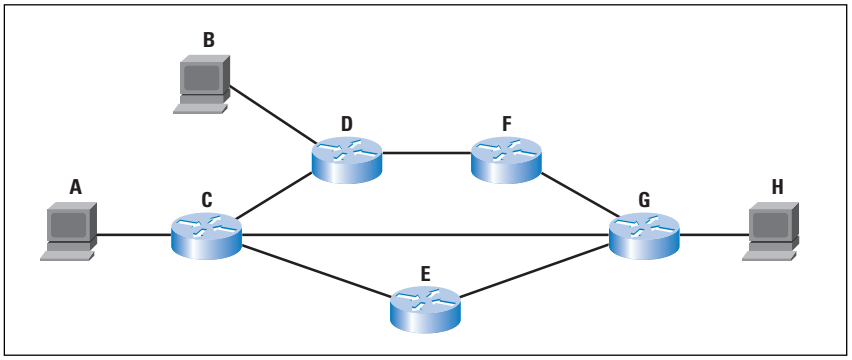
Defining Convergence

The first problem we face when trying to test routing is to define *convergence*. It seems like a simple question, but it's not, because there are so many different ways to measure convergence:

- How long does it take to begin forwarding traffic once a topology change has occurred?
- How long does it take for every router in the network to adjust to a topology change that has occurred?
- How long does it take for the forwarding information on a specific router to be updated once a topology change has occurred?
- How long does it take for the routing protocol to adjust to a topology change?

Each of these questions is actually completely different, as a short examination of the network in Figure 1, below, shows.

Figure 1: Test Network



Assume A is the traffic source for a test, and H is the sink, or the convergence measurement point. To measure the convergence time of this network, you send a stream of traffic from A to H; when the traffic stabilizes, the C to G link is taken down, and the length of the gap in traffic at H is measured. In this environment, we assume the path fails off of the C to G link, and onto the path through E.

This test assumes the traffic between B and H, or between A and B, will not be impacted by the link between C and G failing, but we do not know this will always be the case. In fact, it's possible that D and F will end up forming a *microloop* until they receive all the information needed to converge without the C to G link.

This microloop could last longer than C requires to recompute a path to H, so while the traffic from A to H may be successfully delivered, the network may not be in a fully converged state. The topic of microloop formation and avoidance is beyond the scope of this article.

In this small network, the time it takes for A to continue forwarding traffic to H may not be the same as the time it takes for the entire network to stabilize after the topology change. How long it takes for A to be able to reach H, and how long it takes for all the routers in the network to adjust to the topology change are two different questions. In this case, the concept of convergence is unclear, with several possible meanings; to properly build and understand the results of the test, we need to better understand the question being asked.

You could alter the test so only A, C, E, G, and H are in the network. This would provide a "clean" test of just the failover capabilities of the routing protocol being tested, as it's implemented on the specific routers in the network, across the specific link types connecting the routers, in the simple failover situation. While the limited topology does limit the number of outputs being measured in the test, it also limits the closeness of the tested network to a real network design. The test can provide some very specific data points, but, once the test topology is simplified, it cannot provide a true picture of convergence in a larger, more complex topology.

Another option is to refine the test procedure so the traffic between B and H is tested as well as the traffic between A and H. Measuring traffic flow from every possible connected end point to every other possible connected end point on the network provides a number called *goodput,* which is the relation between the traffic injected into the network versus the traffic the network delivers across all paths.

Although this type of testing does provide more data in a more complex topology, it also has its drawbacks. For instance, if you are trying to compare two different implementations of a single protocol, or compare two different routing protocols, this test not only counts the amount of time required for the routing protocol to converge, it also tests the amount of time required to note the topology change, the time required to install the newly computed routes into the local routing table, and the time required to pass the changes from the routing table to the local forwarding tables. This might—or might not—be a good thing.

Isolating just the routing protocol can provide information about the performance of a specific implementation of the protocol in specific network designs, and under certain conditions. Including platform and media-specific issues—such as the installation of information into a local table—may cloud the picture. For instance, if the routing protocol can converge in milliseconds, but it takes seconds to determine that the link between C and G has failed, any changes in routing protocol convergence time will be lost in the much larger link failure detection time, reducing the value of the test.

In short, numerous tradeoffs are involved in designing a test to measure routing protocol convergence; you need to begin with the right questions, and understand the tradeoffs in the various tests you could, or might, run. There's no "simple" way to run a single test that will give you all the information you need to know to understand all possible implementations of a routing protocol on all possible platforms.

In the same way, it's important to keep these types of limiting factors in mind when reading, or using, test results provided by outside companies. It's fairly easy to look at a specific test for one measure, such as the number of neighbors a specific implementation of the *Border Gateway Protocol* (BGP) can support in specific conditions, and attempt to generalize those test results to much larger and varied real world networks. Quite often, the mapping isn't all that simple.

Taking Realistic Measurements

Assume you determine you want to test for protocol convergence by checking the routing tables at each router in the network in Figure 1, rather than trying to measure convergence by measuring traffic flow through the network. How would you go about doing this? There are two general types, or classes, of tests, that you could consider:

- *Black Box:* Treat the device as a black box, only using outside signals and controls, and never any output provided from the device itself.
- *White Box:* Use available output provided from the device itself, possibly with tests using signals outside the device, to determine when specific events on the device occur.

Obviously, black box testing is much more difficult, maybe impossible in some conditions, but, at the same time, can provide more "objective" measures of a devices' performance. Examples of black box tests for the *Open Shortest Path First* (OSPF) protocol are outlined in RFC 4061, RFC 4062, and RFC 4063. White box testing typically depends on *debug* and *show* commands to provide timestamped infor-mation about when specific events occur, such as when the routing protocol has received information about the topology change, when the routing protocol has finished computing the best path to each destination, and other events.

For simplicity, the network is reconfigured with a test measurement device, as shown in Figure 2, below.

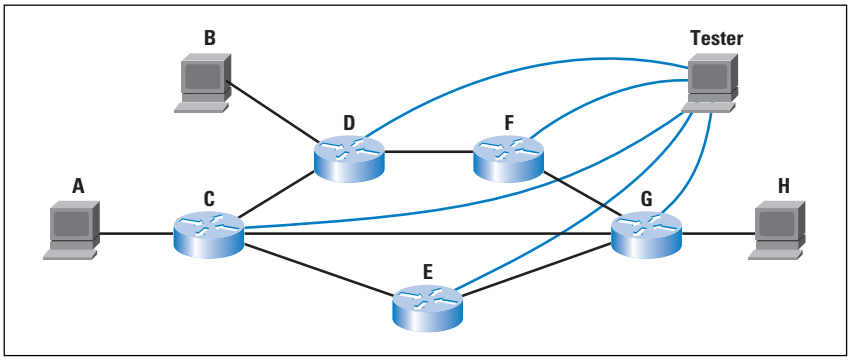


Figure 2: Reconfigured Test Network

Some mechanism is used to determine when the routing protocol on each router has computed the correct routes; the network is connected, and allowed to converge. The link between C and G is taken down, and the time between the link failure and the correct routes being computed on C, D, E, F, and G is taken as the total convergence time in the network. This appears to be a straight forward test; what sorts of problems can we run in to here?

There are two possible mechanisms for determining when each device has correctly computed the routes after the C to G link fails:

- Some sort of "continuous output," such as a *debug*, can be configured on each router, and the results collected and analyzed.
- The Tester can poll each device, using *show* commands, or some black box testing technique, to determine when device has recalculated the routes correctly.

Let's examine each of these techniques separately.

Gathering Results from Continuous Router Output

The first, and simplest, mechanism is to gather the results from each router through debugging information provided by the protocol implementation which is generally used for troubleshooting and monitoring the routing protocol. There are three primary issues related to using this information you need to be aware of:

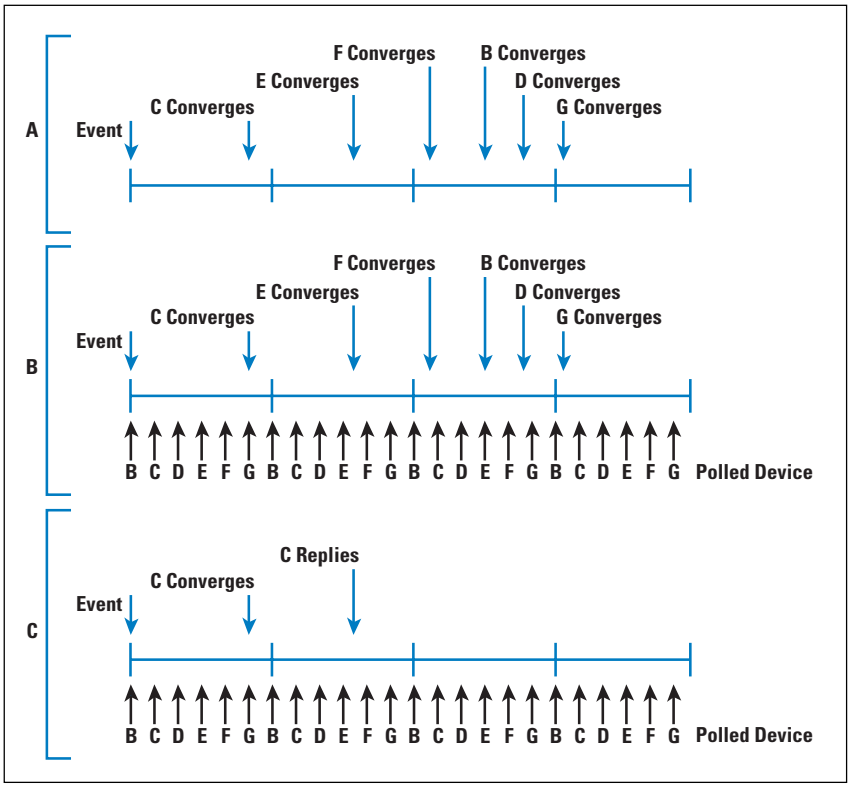
- The continuous stream of information provided by the device being tested can actually impact the test results, primarily because of the processor cycles required to record and display this information. In some situations, the additional cost is negligible, and in others, it's simply not important (for instance, if the test is designed to show the differential between two situations, rather than provide absolute convergence times).
- If the timestamps injected by the devices being tested in the network are relied on, then the time clocks of every device must be synchronized. This synchronization must generally be within about 1/10th or less of the total variation in the test time for the results to be meaningful. In other words, if the timeclocks on all the devices are synchronized within one second of each other, and the results of the test are expressed in milliseconds, the actual test results are going to be lost in variations in the synchronization of the timeclocks.
- If the devices feed their information to the Tester, and the timestamp on the Tester is used to compare the event times within the network, the timestamps can be skewed by the packet processing requirements of the devices, as well as queuing delays in the Tester. Most routers prioritize routing traffic over switched traffic, and switched traffic over management traffic. There could be significant lags between an event occurring, and the router actually building a packet noting the occurrence of that event. Again, this is a matter of time differentials; if the test results are expressed in milliseconds, queuing delays alone can bury the results in noise.

We need to be careful when using *debug* or other continuous output to measure network convergence times in any given test, then. Quite often, we need to compare the granularity of the test results with the measurement technique used, and consider how much noise the measurement technique is actually likely to inject into the testing environment, compared to the test results granularity.

Polling Devices

Another common technique is to run some sort of process on the Tester which polls each device, either using some black box or white box measurement, to determine when each device finishes recalculating routes after the topology change has occurred. This type of test is also constrained by various factors that might not be obvious when you are designing a test, or examining the results of a test that uses it. Assume events in the network occur as Figure 3 illustrates.

Figure 3: Poll Testing Scenario



In Figure 3A, we assume that the Tester is able to poll every device in the network at the same time, once a second. The test shows the network converged at 4 seconds after the event, although the last router to converge, G, does so just after the 3 second mark. There can be a variation of the entire polling interval in the actual results without the test showing any difference in the convergence time of the network, implying that the polling interval must be much faster than the expected (measured) test results for the results to be meaningful. We normally suggest that the polling interval be about 10 times faster than the expected measurement rate, or that the Tester should poll every 1/10th of a second in this test, if the results are to be measured in seconds.

However, in real test environments, a test device cannot actually poll every device in the network at the same time. Instead, the Tester will poll one device periodically, rotating through the polled devices, so the longest time between any specific device being polled is the polling rate. We can call this rotating polling *serialization,* and the time it takes to rotate through all the devices the *serialization delay*. Here, we've spread out the polls across the total one second polling time, to illustrate, in Figure 3B. Three anomalies show up in this illustration:

- The total time for the network to converge is still just over three seconds, while the recorded test time is still in the four second range. This is similar to the problem we noted when we assumed the Tester was polling all the devices in the network at the same time.
- It appears, from our test results, that E and F have converged at about the same moment. In reality, their convergence is separated by almost one second. In some extreme cases, the devices may actually converge in the opposite order from the order they appear to converge.
- If the convergence order of D and G were to be reversed, the network would appear to converge almost a half a second faster, although the actual convergence time would remain constant. This could cause a widely diverging set of test results over multiple runs in what is, actually, a fairly consistent network convergence time.

Adding the serialization delay of polling isn't enough, however, to understand polling in real test environments. We also need to remember that each device which is polled must also answer each one of the polls, thereby introducing another variable amount of delay into the test results. For instance, in Figure 3C, C is polled once before and once after it converges. If we take the time that C answers as its convergence time, then we are also including processing time on C, which is variable, into C's total convergence time. However, if we take the polling time as C's convergence time, it's possible that the poll was received before C converged, and was processed, and answered, after C converged, skewing the results in the opposite direction.

Unfortunately, there are no simple answers to these problems. Instead, when you are designing a test, or examining the results of a test, the mechanism used to determine convergence, the rate at which that mechanism is used, and the reported final results, should be taken together, and considered closely. A test which reports results in milliseconds, but polls a large number of devices from a single test device, should be examined closely for serialization delay errors.

Use Real-Life Configuration Parameters and Prefix Attributes

Finally, we need to consider what is probably one of the most widely disregarded concerns in testing routing protocol implementations: building accurate and repeatable data sets to feed into the test. Let's examine a common test, to help in understanding this problem.

A network engineer sets up a router connected to a router testing device using a SONET link. The router tester is then configured to feed one million routes, through BGP, to the router being tested. The test is run, and the amount of time it takes for the router to accept and install all of the routes into its local tables is measured. The router is disconnected (we'll call this first router A), and another router (B) is connected. The same test is performed. In the end, the network engineer proclaims A has a better BGP implementation than B, because A accepted and installed the routes fed to it faster than B.

This sort of test, and these results, should raise a lot of red flags for anyone who's ever tested routers before. Many questions here are not answered:

- Were both routers tuned to optimum parameters for this specific test? Most routers are installed in a number of different situations in various networks, and most will perform better if they are tuned to fit the role they are playing in the network. This is similar to tuning a server for database use, or web server use.

- BGP is very sensitive to the data transmitted from one router to another; BGP implementers are generally aware of this, and use differing models of BGP behavior in different networks to tune their implementations. Specifically, in the case of BGP:
  - What percentage of the prefixes transmitted were of specific prefix lengths? What percentage of the routes transmitted were /24s, /23s, and so on?
  - How many different attribute sets were represented in the routing information transmitted? What number of unique attribute sets were included in the routes? For each attribute set, what percentage of the table did that attribute set represent?

Each of these questions can, and should, be compared to real world measures in the network the router is going to be installed in. There are some instances where protocol implementers have tuned their implementation for use in an Internet *Point of Presence* (POP), for instance, and the implementation doesn't fare as well as a route reflector, or the other way around. For some vendors, this tuning could even be on a platform by platform basis, making the job of characterizing a specific implementation through a simple test, like that described above, very difficult.

Conclusion

Designing, executing, and evaluating the results of a test attempting to measure network convergence is much more complex than it appears on the surface. In any given test situation, we need to ask:

- What was the test designed to measure? Is it measuring the appropriate outputs, in the correct ways, to actually measure this?

- What is the granularity of the test results and the actual network events, compared with the measurement techniques used in the test? Will normal test results get lost in the noise introduce by the measurement techniques?
- What is the data set used to build the test? Does it accurately reflect the data the routing protocol implementation will be handling in a real network (or more specifically, the real network the router will be installed in).

When designing, or evaluating, test results, there's a strong tendency to be dogmatic about the results, to say some specific test proves, in some way, a specific vendor, platform, protocol, or implementation, is "better." When evaluating tests in the real world, however, we need to be cautious of such statements, and try to examine the entire environment, considering test results with skepticism, and try to understand their limits—as well as their results.

Book Review

Running IPv6

Running IPv6, by Iljitsch van Beijnum, ISBN 1-59059-527-0, Apress, 2005. **http://www.apress.com/**

I've read a lot of books about emerging standards that read like "How I spent my summer vacation at a Standards Body." *Running IPv6* is *not* one of those. While van Iljitsch van Beijnum has been an active part of the IPv6 standards community, he has clearly done the homework of making it all work together. Weighing in at a compact 265 pages, *Running IPv6* really gets right to the point. The reader is assumed to have a working knowledge of IPv4.

Organization

The book starts off with a fairly typical introduction that explains why the author believes IPv6 is necessary. I find such introductions tedious, because if you've already forked out US $44.95 for the book, the chances are that you're already motivated enough. This is, however, the only tedious chapter in the book.

What follows is a well written and organized primer for network administrators that covers how to configure end hosts, how get address space allocated, set up tunnels, and configure routers and the *Domain Name System* (DNS). The author covers in detail Linux, Windows, MacOS, Cisco's IOS (as well as that of other routing vendors), and Bind. We next move on to applications, IPv6 internals, transition strategies, and transit services.

Throughout, van Beijnum provides practical tips and advice on some of the pitfalls he found so the reader can avoid them. I particularly liked one case of whether to use eui-64 for the lower 64 bits of the address, pointing out the conflict between reducing configuration information (a good thing) and reduced readability (a bad thing).

The book primarily highlights differences between IPv4 and IPv6. This is important because it helps competent IPv4 administrators build on their existing knowledge. I know the last thing I want read about is how routing works when routing itself hasn't changed between versions. And I enjoyed reading, for instance, how *Dynamic Host Configuration Protocol Version 6* (DHCPv6) and stateless address auto-configuration differ from DHCPv4. I did not need nor want a primer in DHCP, but I did want to know about prefix delegation, which is not present in DHCPv4.

The author wastes no time on fluffy protocol niceties. Who cares, for instance, *how* a flow identifier is selected? What's important is that firewalls of the future may take advantage of it to determine flow direction, a major advance. Packet formats and semantics are only provided as they are needed by engineers to determine whether each component is performing correctly. The book is perhaps, therefore, best commended for what it lacks.

Unfortunately it lacks some subject matter I would like to have seen. Although van Beijnum covers how some common user applications, such as *telnet, ftp,* Web browsers and servers, and media players can use IPv6, business applications folks will be disappointed as there is no discussion of Oracle, SAP, or the like. The same is true for network management applications. And this may be a key roadblock to deployment of IPv6, as no self-respecting IT manager would deploy a service that cannot be managed. Such an obvious absence begs the question of whether those applications are IPv6 capable. On the bright side, you can try just about everything mentioned in the book because just about every tool mentioned either comes with the operating system or is freely available on the Internet. This book is not just theory.

A Must Read

It therefore shouldn't surprise anyone that I consider *Running IPv6* a "must read" for network engineers who have not yet played with IPv6. Even though Network Management Systems and business applications aren't covered, necessary protocol internals, semantics, operations, and troubleshooting are covered, therefore giving the reader a good knowledge base.

Read Any Good Books Lately?

Then why not share your thoughts with the readers of IPJ? We accept reviews of new titles, as well as some of the "networking classics." In some cases, we may be able to get a publisher to send you a book for review if you don't have access to it. Contact us at **ipj@cisco.com** for more information.

Letters to the Editor

A Pragmatic Report on IPv4 Address Space Consumption

Ole,

Thanks for a great round up in IPJ Volume 8, No. 3 on IPv6. This really helps focus where the state of the discussion needs to be in terms of addressing IPv6 deployment. You might be interested to know that this edition of the IPJ received tremendous interest in the UK. Within 24 hours of it arriving on your website, it was being distributed widely by several mailing lists serving communities from the *Ministry of Defence* (MoD) to important communications industry membership organisations. I received it myself at least three times from different lists!

Over recent months, I've seen a continuing trend to try to sideline IPv6 as not relevant to a particular discussion. IPv6 is either too low level for applications providers to think about, or too far off, or doesn't support some essential infrastructure service today. Some communities feel they have more than adequate IPv4 addresses to meet their foreseeable needs. These factors continue to drive debate on "if ever" rather than on "when" and "how" to deploy. That is, if the debate happens at all. All those who are investing in future IP-related services and networks need to read this edition of the *Internet Protocol Journal* for a reality check.

Tony Hain's article provides a compelling addition to the work you've already published by Geoff Huston on the analysis of IP address allocation, and is important food for thought that I think justifies increasing the urgency with which IPv6 support is treated. The discussion you hosted between Tony, Geoff with John Klensin and Fred Baker I think dealt very clearly with why the debate needs to be focused on the *how* and the *when* rather than on the *if*.

In the UK, we are seeing some significant investments made to enable IP level infrastructure with the intent of delivering profoundly new services into the twenty-first century, but none of these major investments appears to have included a vision for IPv6. So I think the point that was made concerning the current failure in making like-for-like investment decisions between v4 and v6 is hugely important for Chief Information Officers and Chief Financial Officers to take to their boards, or we will continue to find people investing for the past, rather than as they apparently believe, their future.

—*Christian de Larrinaga*
cdel@firsthand.net

Ole,

The analysis undertaken by Tony Hain and debated by some recognised experts makes it abundantly clear that the deployment of IPv6 is an immediate natural growth path to sustainability and global mass-market penetration of the Internet, beyond its worldwide current rate of less than 15%.

Tony has presented his study in the recent *IPv6 Forum Summits* (Seoul, Taipei, San Jose and Canberra) and obviously took a lot of people by surprise as previous studies maintained the suspense that the deployment of IPv6 should be an incremental transition and not an imminent and real migration. It was therefore decided to responsibly and morally act on this and renew a global Call to Action to set 2008 as a milestone of inevitable smooth transition in a softer form as a Y2K or Yv4 (The Year when IPv4 addresses will become hard to get) and get engineers to plan for it.

A global worldwide press release was published October 11, 2005 and can be read on the web site of the IPv6 Forum:
http://www.ipv6forum.org

The IPv6 Forum would like to recognise the work of *The Internet Protocol Journal* in watching diligently this space for the past couple of years and for initiating and orchestrating the constructive and consensual debate included at the end of the study, a contribution we trust is of great significance to the global good of the Internet.

From The Editor

Autonomous Systems Numbers (ASNs) play an important role in the routing architecture of the Internet. An *Autonomous System* (AS) is, according to RFC 4271, "… a set of routers under a single technical administration, using an *interior gateway protocol* (IGP) and common metrics to determine how to route packets within the AS, and using an inter-AS routing protocol to determine how to route packets to other ASs." AS numbers are—like IP addresses—a finite resource, and predictions exist for when the AS number pool will be depleted. In our first article, Geoff Huston explains how ASNs work, and introduces us to the 4-byte ASN scheme that will allow for future growth beyond the currently predicted depletion date.

Our second article looks at another aspect of Internet routing and addressing—the IPv4 number space itself. Designers and operators of internets are often required to perform various address calculations in order to properly configure their networks. Russ White takes us through several exercises and introduces some "tricks of the trade" to make such calculations easier.

Our articles on spam in the last issue of IPJ prompted some feedback from our readers, and promises of more articles from other authors. This problem space clearly has more than a single solution. We look forward to bringing you more coverage of this topic in future editions.

The second issue of the *IETF Journal*, published by the Internet Society, is now available. Some people have asked me if I think of this new journal as a "competitor" to IPJ. I am happy to say that the *IETF Journal* is very much complementary to IPJ and covers important news from the IETF that we hope our readers will find interesting. You can access the *IETF Journal* by visiting: **http://ietfjournal.isoc.org**

The *IPJ Reader Survey* will soon close. We are grateful to the many readers who took the time to tell us about their reading habits, ideas for future articles, and other suggestions. Of course, we always welcome your feedback on any aspect of IPJ. Just drop us a line via e-mail to: **ipj@cisco.com**

Exploring Autonomous System Numbers

by Geoff Huston, APNIC

So what are *Autonomous System Numbers* (ASNs), and what role do they play in the technology of the Internet? This article explores the role of ASNs as a critical element of the Internet routing architecture. We will first explore how the AS number space is structured, examine how ASNs are used in the interdomain routing environment and then look at the consumption rate of these numbers, and finally examine our options when we get to the point of likely ASN pool exhaustion. However, in order to put this into context, a brief overview of Internet routing architecture follows.

Internet Routing Architecture

Internet routing architecture is structured as a two-level hierarchy. The environment is first partitioned into *domains* with each domain using an internal routing environment. These network domains use an interior routing protocol (commonly referred to as an *Interior Gateway Protocol* [IGP]), which maintains a complete mapping set for the current internal topology of the domain, together with the set of "best paths" between any two points within the network domain. Although this approach of having a routing protocol automatically maintaining a comprehensive view of the current topology can be made to work within even quite large routing domains, such an approach does not scale to the size of the entire Internet. Fine-grained topology information is useful only in "local" situations, and is best omitted when forming a larger view of the network. Commonly used interior routing protocols include *Open Shortest Path First* (OSPF), *Intermediate System-to-Intermediate System* (IS–IS), and *Enhanced Interior Gateway Routing Protocol* (EIGRP).

The second level in the routing hierarchy is the *interdomain* routing domain. The interdomain routing environment describes how domains interconnect, but avoids the task of maintaining transit paths within each domain. In the interdomain space, a routing path to an address is described as a sequence of domains that must be transited to reach the domain that originates that particular address prefix. Today this interdomain space is maintained using Version 4 of the *Border Gateway Protocol* (BGPv4).

Each routing domain is a single administrative domain, operated within a uniform set of routing policies, and is operated independently from any other domain. The domain is in effect an autonomous unit in the overall routing architecture, and is termed an *Autonomous System* (AS). Each of these ASs is uniquely identified using an *Autonomous System Number* (ASN).

What Is an Autonomous System?

One of the best definitions of an Autonomous System can be found in an IETF document, RFC 4271[4] that describes BGPv4:

> "The classic definition of an Autonomous System is a set of routers under a single technical administration, using an *interior gateway protocol* (IGP) and common metrics to determine how to route packets within the AS, and using an inter-AS routing protocol to determine how to route packets to other ASs. Since this classic definition was developed, it has become common for a single AS to use several IGPs and sometimes several sets of metrics within an AS. The use of the term Autonomous System here stresses the fact that, even when multiple IGPs and metrics are used, the administration of an AS appears to other ASs to have a single coherent interior routing plan and presents a consistent picture of what destinations are reachable through it."

The AS Number Pool

ASNs are drawn from a 16-bit number field, allowing for 65,536 possible values.

AS 0 is reserved, and may be used to identify nonrouted networks. The largest value—AS 65,535—is also reserved. The block of ASNs from 64,512 through 65,534 is designated for private use. ASN 23,456 is reserved for use in ASN pool transition. The remainder of the values, from 1 through to 64,511 (less 23,456), are available for use in Internet routing. The number space is unstructured, because there are no internal fields in the number structure, nor is there any aggregation or summarization capability for ASNs.

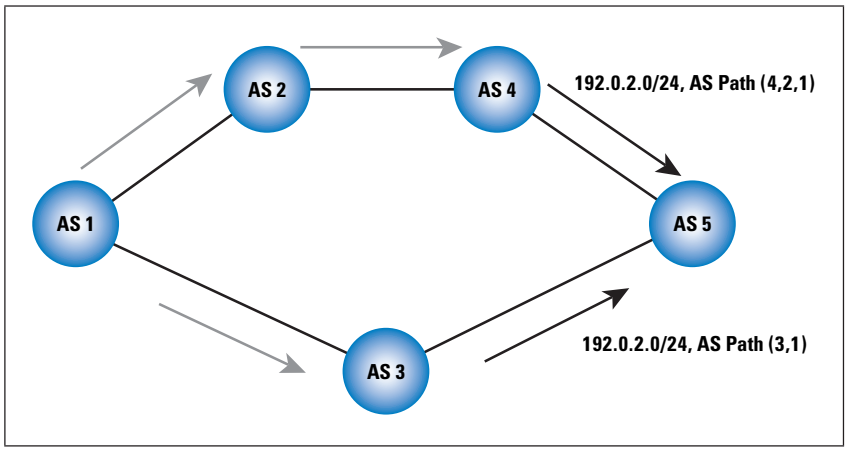
How AS Numbers Are Used in BGP

The interdomain routing space is constructed using two components: *address prefixes* and *AS numbers,* which are used as domain identifiers. Every prefix has an originating domain, known as the *Origin AS* from which reachability for the prefix is propagated across the interdomain space.

As the routing advertisement is propagated across the interdomain space, each prefix accumulates an associated "AS path." When an address prefix advertisement transits a domain, the domain effectively "signs" the prefix advertisement by prepending its ASN to the AS path associated with the address prefix. At any point in the network the AS path describes a sequence of connected domains that forms a path from the current point to the originating domain. This setup is shown in Figure 1, where AS1 originates an advertisement for the address prefix **`192.0.2.0/24`**. At AS5, the AS receives two BGP advertisements for this prefix. One has the AS path (4, 2, 1), and the other has the AS path (3, 1).

The left-most number in the AS path list is the ASN of the adjacent AS from which the address prefix advertisement was received. The sequence of numbers indicates the sequence of ASs though which this update was propagated. The right-most, or final ASN, is the AS number of the AS that originated the address prefix advertisement, or *Origin AS*.

Figure 1: AS Path Generation in BGP



The AS path serves two purposes in interdomain routing: that of a *path length* metric and a *loop detection* mechanism.

The AS path is used as a path metric in the BGP path selection algorithm. When a domain receives two different BGP advertisements for the same address prefix, the default BGP selection process is that of selection of the advertisement of the minimal-length AS path, with each AS in the path counting as a single unit of "cost." In the case of the example network in Figure 1, AS5 prefers to use the path through AS3 to reach the originating AS1, in preference to the longer path of AS4 and then AS2.

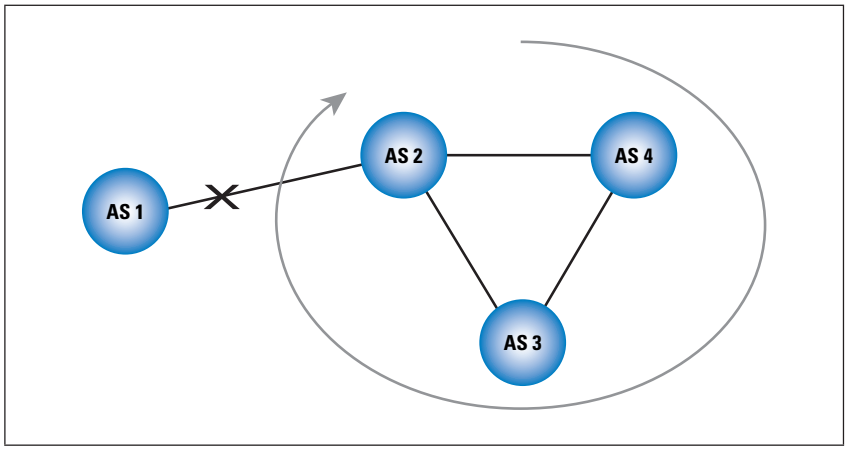
Although enumerating the AS path vector within the routing protocol is one way of passing the path cost through the routing domain, it may appear that the best path selection function could just as easily be supported by carrying a simple path cost metric of a domain transit counter, similar to that used by other distance vector routing protocols, such as *Routing Information Protocol Version 2* (RIPv2). However, the problem with distance vector protocols is the "count-to-infinity" dilemma.

To illustrate the need for explicit AS path enumeration in BGP, consider what happens when the AS path vector is replaced by a simple path cost metric. In the configuration shown in Figure 2, AS1 originates a routing advertisement toward AS2. AS2, AS3, and AS4 are interconnected in a simple loop configuration. When AS2 receives AS1's advertisement with a path cost of 1, it passes the advertisement on to both AS3 and AS4, with a path cost of 2. Both AS3 and AS4 select as their best path this advertisement from AS2 with a path metric 2, corresponding to the AS path (2, 1).

Now if the connection between AS1 and AS2 is broken, then AS2 no longer sees AS1, and withdraws its best path to the prefix through AS1. AS2 then stops advertising a path to AS3 and AS4. But AS3 is already advertising a path to AS4, with a metric of 3, corresponding to the AS path (3, 2, 1). Upon the withdrawal of the advertisement from AS2, AS4 then selects this as its next best path, with a path cost of 3. AS4 then advertises this prefix to AS2 with a path cost of 4, corresponding to the AS path (4, 3, 2, 1).

At this point, without the explicit AS path in the advertisement, AS2 cannot deduce that this advertisement is, in fact, a loop. Accordingly, AS2 accepts this path with a metric of 4 as its best path. AS2 then advertises this to AS3 with a metric of 5, corresponding to the AS path (2, 4, 3, 2, 1). AS3 updates its best path to AS1 with this new metric and then sends an update to AS4, and so on. This process continues around the loop until the path cost metric reaches some defined maximal value. The higher the maximal value for the path cost metric, the longer the time taken to detect the loop condition. The smaller the maximal path cost metric, the smaller the span of network that the protocol can encompass. Setting the maximal path cost parameter requires some considerable care, and the operation of the protocol can be extremely slow to converge in terms of loop detection.

Figure 2: Loop Formation in Distance Vector Protocols



This form of loop can be averted by replacing the path cost counter with a fully enumerated AS sequence. Continuing the example in Figure 2, when AS2 withdraws its route to AS3 and AS4, AS4 still selects the other route it has heard, but this time the selected prefix has the path (3, 2, 1). When AS4 attempts to pass this advertisement to AS2, AS2 sees its own value in the associated AS path and rejects the advertisement. At the same time AS3 withdraws its advertisement to AS4, and at that point the prefix is dropped from the entire routing system. In this way the AS path acts as an efficient routing loop detector.

The use of ASNs and AS path vectors in BGP provides an effective solution to this classic problem of loop detection, as well as providing a simple and effective path-selection process.

Who Needs an AS Number?

Not every network needs to have its own ASN. The guiding principle is that ASNs are used to express distinct interdomain routing policies, and not every network has the requirement to express its own unique set of routing policies.

In the case where a network has a single upstream connection, the routing policies of the network are precisely the same as those of its upstream service provider, and there would normally be no need for the network to use a distinct ASN. Even if the network domain uses BGP for its upstream connection, the originating domain can use a private ASN (from the number range 64,512 – 65,534) to support the BGP session to the upstream network. The upstream network strips off the private ASN when it readvertises the prefix, and the upstream network appears to the rest of the Internet as the originating AS. Even if the AS has "downstream" networks it can still use a private AS, even when the downstream ASs are using public ASNs. The stripping of the private AS removes only the instances of the private AS from the AS path, and not the public ASNs (Figure 3).

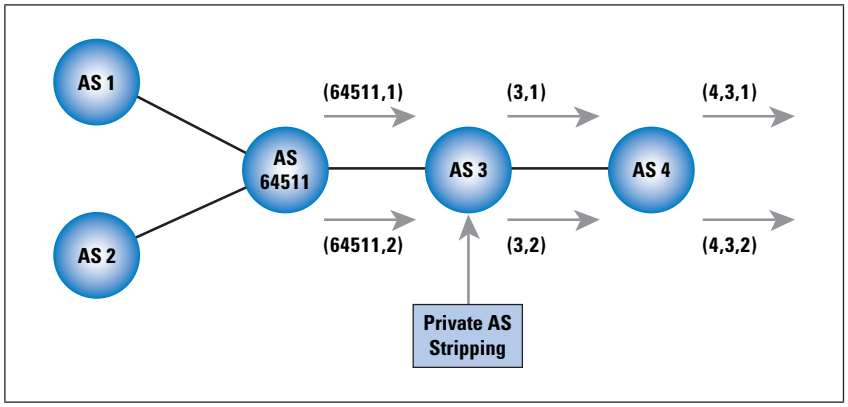


Figure 3: Use of Private AS Numbers

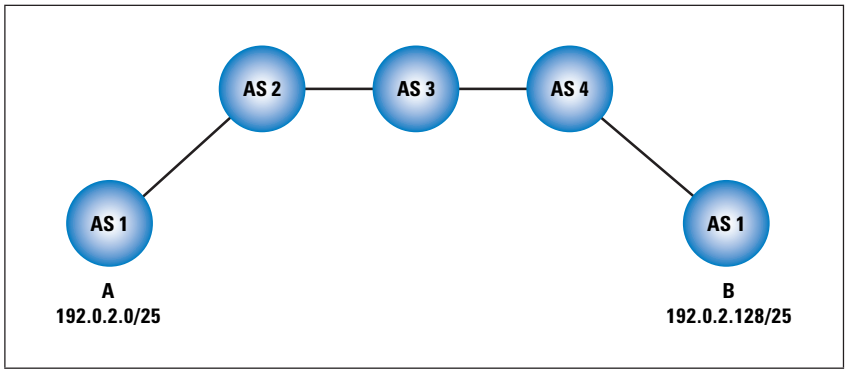
In the case where a network has two or more upstream transit connections, it is more likely that the network will use its own unique ASN. It is not always the case that a distinct ASN is required here, and the distinguishing factor is that of the network wanting to express particular routing policies. Where the network has no particular preference as to which of the upstream services should be used for incoming traffic, the network can also use a private ASN for each of its routing sessions. In such a case the external routing view would be that the prefix appears to be originated from multiple ASs.

In the case where there are multiple paths to reach the network, and where these paths need to be distinguished in the routing system by different AS paths that have the same originating AS (that is, there is a need to express a routing policy), then the network needs to use a unique ASN within the interdomain routing system.

Can an ASN Be Split Across Separated Subdomains?

There are many cases of dispersed networks that exist in multiple locations. If these locations are all administered by a single entity, it may be desirable to use a single ASN across all these domains. This scenario is possible, but considerable care needs to be exercised when designing the routing configuration. Figure 4 shows two distinct subdomains of AS1, and they are not interconnected internally.

Figure 4: Split AS



AS1 (A) advertises the prefix **`192.0.2.0/25`** to AS2, and this advertisement is propagated to AS2, AS3, and AS4. When AS4 passes this advertisement to the other segment of AS1 (B), this router rejects the advertisement because the associated AS path (4, 3, 2, 1) indicates that the route has already passed through AS1. Similarly, the first segment of AS1 (A) rejects the advertisement of **`192.0.2.128/25`** from AS2, because its path (4, 3, 2, 1) also indicates that a loop has formed. To restore complete connectivity between the distinct parts of AS1, AS1 needs to configure static routes at its edges. If AS1 (A) configures a static route to **`192.0.2.128/25`** pointing toward AS2, and AS1 (B) similarly configures a route to **`192.0.2.0/25`** through AS4, then the configuration enables full connectivity.

In more complex configurations where each of the segments of the network is multiply connected, the static route configuration becomes more complex. However, with very careful configuration, a single ASN can be distributed across multiple distinct networks.

AS Path Prepending and Path Poisoning

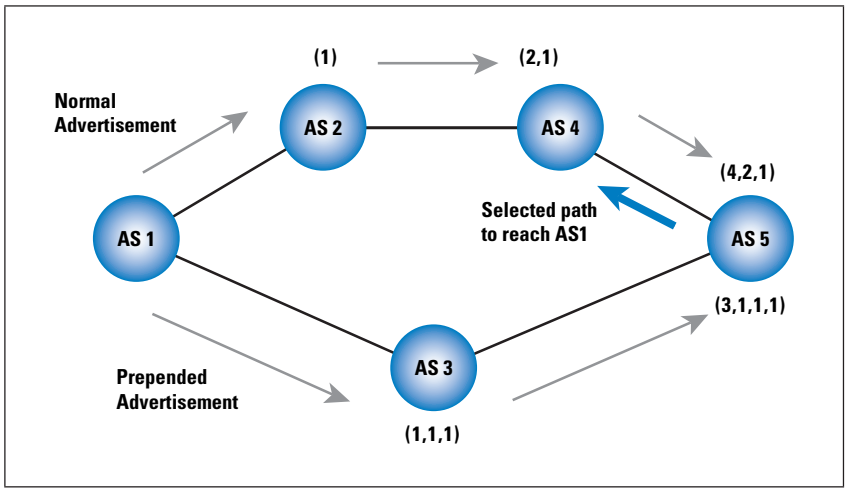
The basic mechanism of path preference in BGP is that of the AS *path length*. Where there are two advertised paths to reach a particular address prefix, the default selection algorithm in BGP is to prefer the advertisement with the *shorter* AS path length.

A multihomed domain may wish to have other domains prefer one particular path over another to reach it. This may be because the local domain wishes to optimize its traffic costs between the multiple upstream providers, balance the traffic load across multiple paths, or set up various forms of primary and backup relationships across the multiple provider upstream paths.

Although such policy preferences are often set up using BGP *communities*, BGP community signaling requires the cooperation of multiple parties in consistent interpretation of the community values. A more coarse form of expressing such policy preferences can be achieved through AS *path prepending*, a technique of deliberately extending the AS path length of a prefix advertisement by adding additional ASNs into the AS path of an advertised prefix. Normally the form of AS path prepending uses the local ASN to perform the prepending.

In the example in Figure 5, AS1 wants to express the policy to prefer incoming traffic through AS2, and use the link to AS3 only as a backup. To achieve this with AS path prepending, AS1 prepends itself twice in the AP path of the advertisement passed to AS3, in order to artificially lengthen the AS3 transit path. AS5 would have normally used the shorted AS path through AS3 to reach AS1. As a result of AS1 artificially lengthening its path to AS3, AS5 now selects the transit path through AS4 and AS2 to reach AS1.

Figure 5: AS Path Prepending



Of course AS path prepending is a very imprecise technique, and can often produce surprising results in real-world situations. A more deterministic method of traffic engineering uses additional signals attached to address prefix advertisements, through BGP communities.

A more subtle, and more controversial, prepending technique is that of so-called AS *path poisoning*, where an AS uses some other value to prepend in the AS path. In Figure 6, AS1 wants to express the policy that under no circumstances should AS5 use the transit through AS3 to reach AS1. In this case AS1 could use AS5 as the prepending value in its advertisement to AS3.

When AS5 receives this advertisement, the presence of its own ASN in the AS path means that it will not accept this advertisement, and prefers the transit path through AS4 and AS2. The difference between these two examples is that in the case where the connection between AS1 and AS2 is broken, none of AS2, AS4, or AS5 can possibly reach AS1 when this AS path poisoning technique is being used.

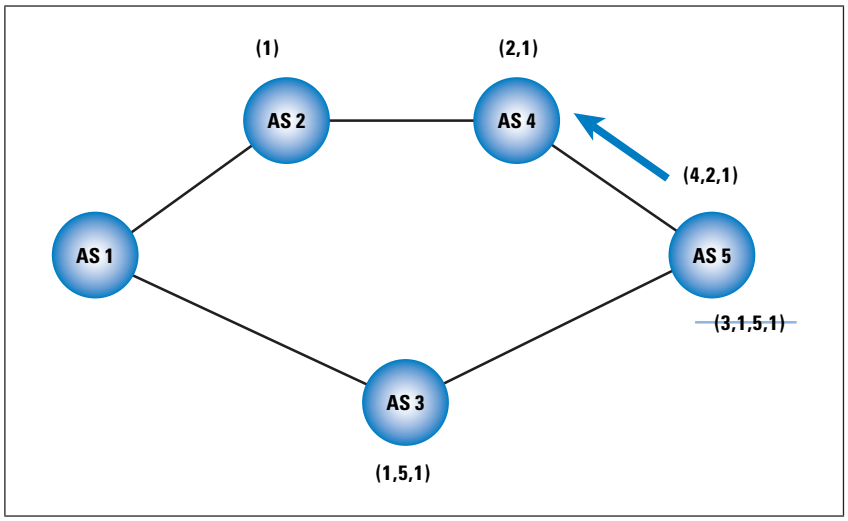


Figure 6: AS Path Prepending with AS Path Poisoning

AS Number Consumption

In this section we will look at the rate of consumption of ASNs, and estimate when they may be fully consumed. Of the 64,510 available AS numbers, as of January 2006 we have already allocated some 40,000, or well over half of the number pool. Two immediate questions arise—how long do we have before the number pool is completely exhausted, and what are our options for an expanded number pool that can encompass a larger interdomain routing environment?

The Factors for AS Number Consumption

Before looking at these two questions in further detail, it would be useful to understand the factors that affect AS number consumption.

From one perspective it is counterintuitive to assume that the Internet will evolve from tens of thousands of distinct routing domains to one of hundreds of thousands or even millions of distinct routing domains. It may appear that there is a reasonable level of correlation between the number of active *Internet Service Providers* (ISPs) in the Internet and the number of advertised ASNs. If forecasting a future demand for hundreds of thousands or even millions of ASNs, it would appear that we are forecasting continued fragmentation of the service provider industry with large numbers of small enterprises that, collectively, compose the Internet. This scenario does not appear to be likely.

The ISP industry is one with an underlying factor of economies of scale. Larger ISPs generally have access to more efficient use of resources and are more capable of sustaining a market share at competitive prices, with reasonable operating margins because of these economies of scale. Smaller providers tend to service niche markets, and in general are highly susceptible to pricing pressures in the competitive supply market. The overall result is strong pressure for continued aggregation in the service provider market, tending to aggregate to a smaller number of larger providers.

If the number of ASs in use is roughly commensurate to the number of service providers, then this view of the market dynamics would lead to a view that the service provider population is either in a state of equilibrium where the entrance of new niche-oriented players is much the same as the rate at which smaller players are aggregated into larger providers, or one of relatively small growth based on the larger dynamics of continued expansion of the Internet on a global basis.

In practice this has not been the case, and we see a continuous rate of consumption of new ASNs. This rate appears to be some 3,500 ASNs per year, and this consumption rate appears to have been steady since 2002 (see Figure 7). Accordingly, it appears that some additional factors affect AS number consumption rates.

One of these factors is the practice of *multihoming* at the edge of the network. Many end-site networks have business-critical needs for assured Internet connectivity, and a common way to achieve this connectivity is by using the services of two or more upstream providers. In such situations the end site may want to express different routing policies to each upstream provider, and it does so by using its own ASN and expressing these routing policies using BGP to each of its upstreams.

AS numbers are also used in other contexts. In *Multiprotocol Label Switching* (MPLS) Layer 3 networks, one form of generating the *Route Distinguisher* value for a VPN client network is through the use of concatenating the VPN host's AS number with a serial number. To what extent this semiprivate use of AS numbers in a VPN context contributes to the consumption rate of ASNs is difficult to assess, simply because the use of these numbers is not generally visible.

Even within the public Internet there are other contributory factors to AS number consumption. ISPs with diverse product portfolios may wish to express different routing policies for various product families, or express different routing policies in different regions of network coverage. Again this can be achieved through the use of distinct AS numbers of each routing policy set.

An associated contributory factor for AS Number consumption is that there is little incentive for AS Number return and recycling. With the current framework there is no direct cost to maintain an AS number allocation, and the overall characteristic of AS number allocation appears to be a "once and forever" allocation model. When AS numbers are no longer required, AS numbers generally do not return to the unallocated pool for subsequent reallocation.

Taken together, these factors lead to the conclusion that continued AS number consumption is based on a larger set of considerations than the dynamics of the service provider industry.

Accordingly, we can be a little more confident in making the assumption that the factors that have affected AS number consumption in the recent past will continue to be factors in the near-term future, leading to some further confidence in a predictive technique that uses recent consumption data to generate trends that can made predictive forecasts of future demands. We will apply this technique to AS number consumption data to make some forecasts of the time by which the current AS number pool will be exhausted.

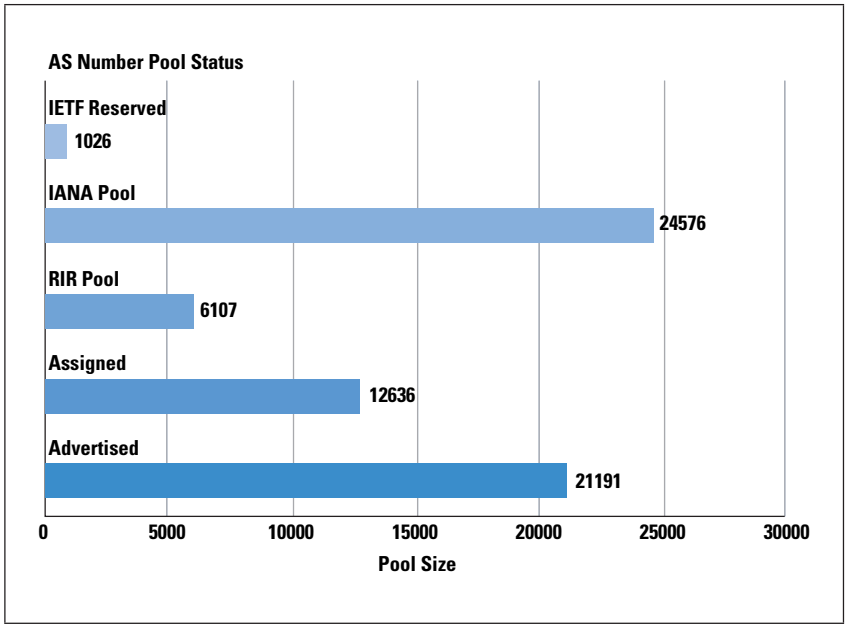
AS Number Pool Status

There are 65,536 AS numbers. As noted already, some 1,026 numbers are reserved and unable to be used in the public Internet, leaving 64,510 for use in the public Internet.

The pool of AS numbers is administered by the *Internet Assigned Numbers Authority* (IANA), and blocks of 1,024 numbers are allocated to the *Regional Internet Registries* (RIRs) periodically when the RIR's pool drops below a threshold level.

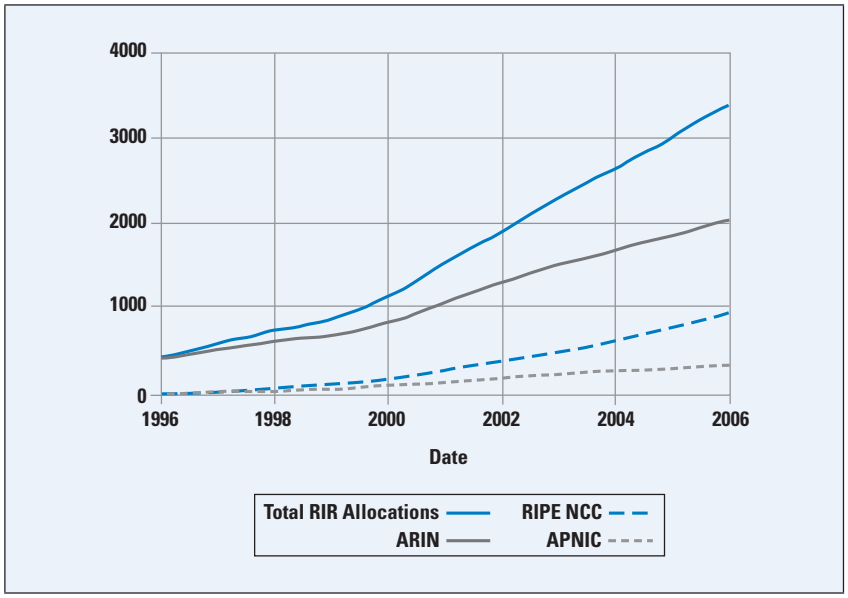
Of the 39,934 AS numbers that have been allocated by IANA by January 2006, there is a further classification of AS numbers. A working pool of numbers is held by the RIR for current assignment to ISPs. Of the assigned AS numbers, some are visibly used in the interdomain routing table of the public Internet, but others are not visible in the Internet. The breakdown of AS numbers into the RIR pool, assigned but not advertised, and assigned and advertised, as of January 2006, is shown in Figure 7. Of the 34,827 assigned AS numbers, some 21,191 are advertised; 12,636 have been allocated in the past, but are not currently advertised in the BGP routing table.

Figure 7: AS Number Status of Advertised, Unadvertised, and Unallocated Pools



The RIRs allocate ASNs to ISPs and end-user networks. A second time series can be generated, showing the cumulative sum of the RIR AS allocations (Figure 8). Not surprisingly, the time series shows the effects of the Internet boom across the period from 1999 through to late 2001 as a sharp upward trend in allocations. The subsequent market correction is also evident as a visible change in the AS allocation rate by early 2002.

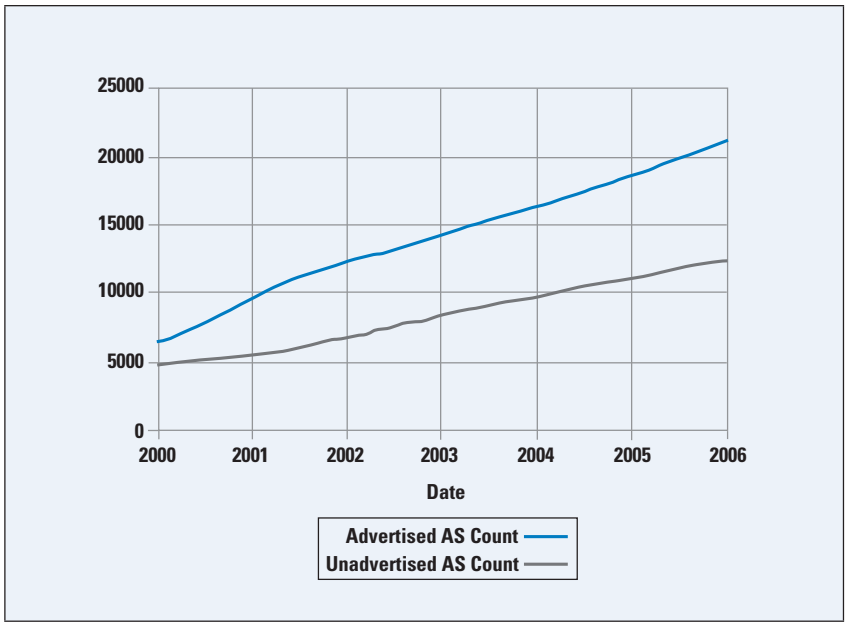
Figure 8: RIR Allocations



BGP AS Advertisements

In addition to allocation rates, a further source of ASN data is the interdomain routing table. The number of distinct ASs advertised in the interdomain routing space of the public Internet has been measured regularly since 1997. The time series of this count of advertised ASNs, and the complementary number of unadvertised ASNs, is shown in Figure 9.

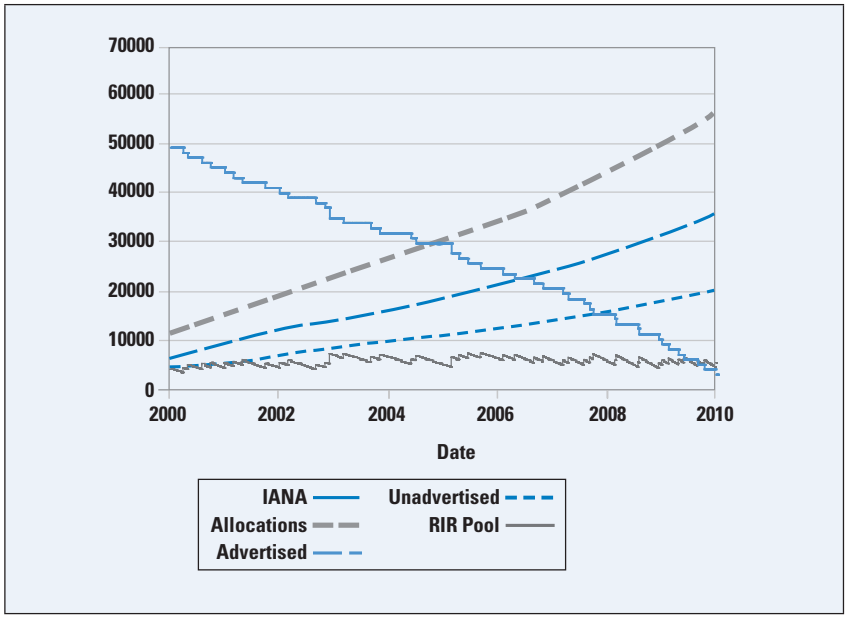
Figure 9: Advertised and Unadvertised AS Numbers



AS Number Consumption Projections

At this point, it is possible to make some projections on AS number consumption. The technique here is to use the past three years' consumption data (taking a starting point of January 2003) and derive an associated exponential function as a best fit to the 3-year data series in order to generate a trend function. This trend function is then projected forward in time to forecast the point in time when the resource reaches a certain threshold point. A considerable amount of detail is associated with this exercise, including the use of an exponential function as the best fit to the past 3 years' ASNs use rates (see **`http://www.potaroo.net/tools/asns/`**). However, for the purposes of this article it is appropriate to proceed to the outcome (Figure 10).

Figure 10: A Predictive Model of AS Number Consumption



From this model it appears that we are looking at steadily accelerating consumption of ASNs, and a projected date of late 2010 of exhaustion available AS numbers to allocate to ISPs.

The implication is that this model indicates that by late 2010 either the Internet should be using a new protocol for interdomain routing that does not rely on AS numbers at all, or, more likely, that the Internet should be using a version of BGP that supports the use of larger AS numbers that are drawn from a number pool significantly larger than 16 bits. The first option appears to be somewhat unrealistic, to say the least. And the second option, although simpler and very much the preferred path, is still going to take some time to deploy, particularly considering the growing size of the interdomain space of the Internet and the diversity of these component domains.

When contemplating a transition to a larger ASN pool, it should be remembered that every day there are more networks that will need to undertake a transition to a longer ASN field in their deployed instances of the BGP protocol.

The steps in this transition path appear to include:

- The completion of the relevant protocol standards for a larger ASN field in BGP
- The production of code in available implementations of BGP that support this protocol standard
- Various forms of testing this code, both in terms of its correct operation and interoperability and in terms of the correctness and viability of the relevant transition steps

- Developing the necessary infrastructural support system to manage the distribution of this new number pool
- A process of deployment of this protocol so that the deployment of larger ASNs can commence well before the point at which the existing AS number pool is exhausted

Even an aggressive schedule of transition across such a large and diverse network as the Internet will take many years to reach the final step. It also appears that a prudent course of action would see us reach that position not by 2010, but by 2008 at the latest, allowing us a margin of some 2 years (and some 10,000 remaining AS numbers) to complete the task.

32-Bit AS Numbers

In this part of the article we will look at the current proposal for a larger AS number pool. As of October 2005, the document defining this proposal is an IETF Internet Draft: **`draft-ietf-idr-as4bytes-12.txt`**. The proposed approach is to expand the size of the AS number pool space from 16 to 32 bits. In number terms this expands the number space from a pool of 65,536 numbers to 4,294,967,296 numbers. In terms of the current use of ASNs, the current scaling properties of the BGP routing protocol, and the use of ASs in the context of interdomain routing, a pool of some 4.3 billion numbers would easily encompass a network environment of significantly greater levels of domains, and interdomain interconnection density. Such a pool size would exceed some current guesses of the scaling capabilities of the BGP protocol by up to a further two orders of magnitude.

It is also proposed to preserve the first block of 65,536 32-bit ASNs to align with the allocations of the 16-bit numbers.

> Let's use a new form of terminology here for 32-bit ASN values, where the first 65,536 ASNs are numbers that use the form "**`0.0`**" through "**`0.65535`**." The second set of 65,536 numbers would be written as **`1.0`** through to **`1.65535`**, and so on. So here we will be using a number format of <*upper16 bits*>.<*lower 16 bits*>.

What is the inventory of concerns that need to specifically addressed in the transition to these 32-bit AS Numbers?

Obviously there is a need for some changes to the routing protocol, and an ordered interdomain transition is unrealistic to expect. More reasonable is an expectation of a piecemeal transition of domains, where individual domains transition their BGP platform to supporting 32-bit ASs in their own time. Domains that are currently using 16-bit ASs may have less reason to undergo an early transition to 32-bit AS support, whereas those domains that are assigned a nonmappable 32-bit ASN will find that they have to support 32-bit ASNs from the outset.

32-Bit Changes to BGP

BGP has two major parts within its protocol: opening up a BGP conversation with a peer BGP speaker, and then the transfrerring of protocol objects that describe reachability of address prefixes and associated attributes of these address prefixes. Both parts include AS Number components, and in considering changes to the current protocol, both parts of the protocol require some change. The message objects that need to be considered here are, therefore, the BGP OPEN message and the BGP UPDATE message.

The changes to BGP create a "NEW" BGP implementation that is capable of supporting a 32-bit ASN environment. The essential task of the changes is to define mechanisms that all NEW BGP speakers use to speak to each other and pass all ASN values in 32-bit fields. However, the Internet is way too large to set up a "flag day" at which point the entire collection of BGP speakers will undertake a switch from "OLD" BGP to NEW BGP. Accordingly, it is also necessary to define protocol interactions in NEW BGP where the transition in the Internet will be gradual and essentially uncoordinated. NEW BGP speakers will have to set up sessions with OLD BGP speakers, and of course OLD BGP speakers will also be peering with other OLD BGP speakers. The information associated with 32-bit AS paths must be passed across sections of the network that normally support only 16-bit AS paths. In other words, 32-bit AS information needs to be passed to OLD BGP speakers and between OLD BGP speakers.

The general approach adopted for transition is preserve AS path length information across the OLD and NEW BGP boundaries, while recognizing that some 32-bit AS information cannot be cleanly mapped into a 16-bit AS path. In order to preserve 32-bit information—a necessary step to prevent loop formation for 32-bit ASs—the 32-bit information is preserved across OLD transit paths and restored upon reentry into NEW BGP realms (Figure 11).

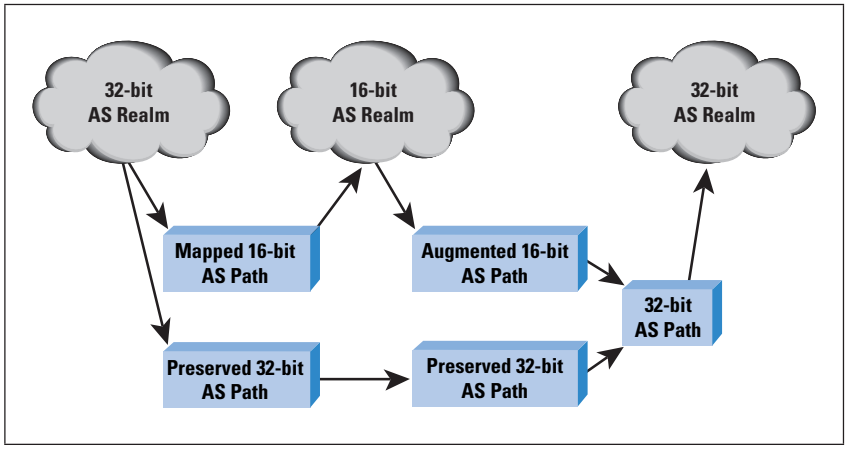


Figure 11: 16-Bit and 32-Bit AS Realms

Opening a BGP Session

The proposed approach is to initiate a NEW BGP session in a mode that is compatible with the OLD BGP protocol, and also inform the remote peer of its capability to conduct a NEW BGP conversation if the remote peer is also a NEW BGP speaker. NEW BGP speakers who open a peer session with an OLD BGP peer will ignore the NEW capability and operate their BGP peer session in OLD mode. A NEW BGP peer will respond positively to the NEW capability, and that BGP session can then operate in NEW mode.

The BGP OPEN message includes a fixed-length 16-bit *My_AS* field as well as potentially containing a capability query as part of the *Optional Parameters* section. In order to ensure that NEW and OLD speakers can communicate, this 16-bit *My_AS* field needs to be preserved in NEW BGP even when the Optional Parameters section includes the capability to undertake a NEW peering session. This may appear contradictory in the first instance, because the OPEN message then contains both a 16-bit ASN and a 32-bit AS *Capabilities Query*. The mechanism proposed for the OPEN message varies according to whether the NEW speaker is using a mappable ASN drawn from the original pool (that is, with a *My_AS* number in the range 0.0 through 0.65535), or it is using a number drawn from a higher-numbered 32-bit number block. In the first case the OPEN message would use the 16-bit mapped value in the *My_AS* field (dropping out the zero-valued high-order 16 bits of the AS value), whereas in the second case the BGP speaker would use for *My_AS* a special 16-bit value that is reserved for this purpose (AS 23456). In both cases the Optional Parameter section would include a capability code to indicate that the local BGP speaker can support 32-bit ASNs (Capability Code 65).

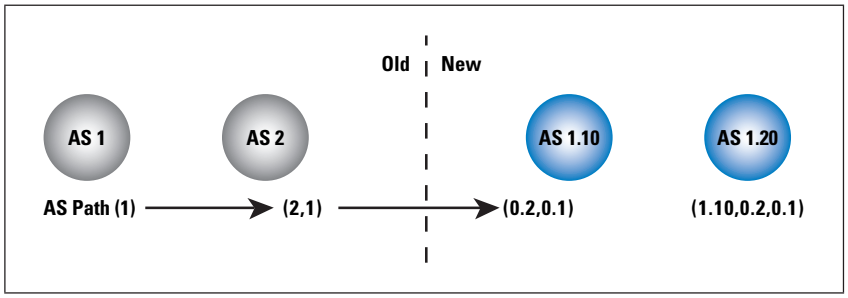
The side effect is that from the perspective of OLD BGP domains AS 23456 may appear to be connected to the interdomain network in many different locations. From the OLD BGP realm this does not present a protocol problem, although, as always, there is the potential here that this repeated use of AS 23456 as a 32-bit AS substitution token may create a somewhat confusing BGP view of the Internet from the perspective of the OLD BGP world.

The capability exchange uses a protocol described in RFC 3392. The NEW BGP speaker adds an optional capability field to the OPEN message. The 32-bit AS capability code 65 carries as its capability value the local 32-bit local ASN value. For a NEW peer this capability value is to be interpreted as the actual AS of the remote side, on the basis that the *My_AS* field in the body of the OPEN is either a truncation of the local 32-bit AS value (in the case of mappable 32-bit AS values), or the special value of AS 23456.

The BGP UPDATE Message

For a NEW BGP session (32-bit peering with 32 bits) the changes to the protocol are the use of 32-bit ASNs in the AS_PATH attribute of UPDATE messages. All 16-bit AS values are padded with a zero high-order 16 bits. If the AGGREGATOR attribute is used, it is similarly carried as a 32-bit value. So in the 32-bit peering, all 16-bit information is carried in mapped 32-bit ASNs (Figure 12).

Figure 12: OLD to NEW BGP AS Path Mapping



In this way AS path length is preserved without change when translating 16-bit AS information into the 32-bit domain.

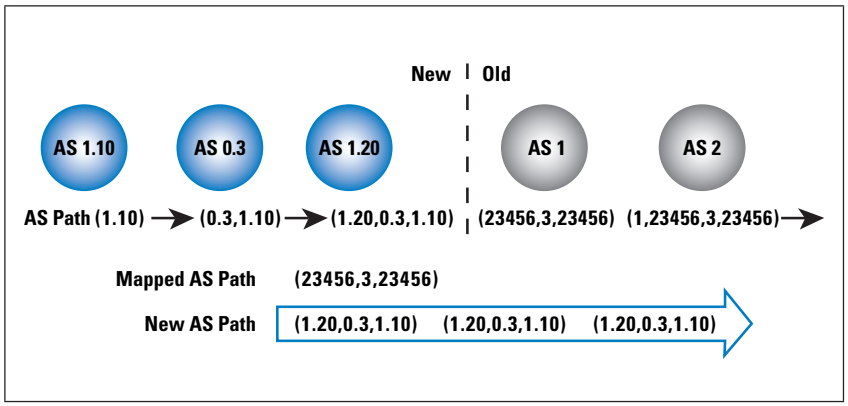
The next case is where an OLD BGP peers with a NEW BGP. We have already seen the simple case where the information is coming from a 16-bit path and there is no additional 32-bit information, and in this case the 16-bit values are simply mapped into 32-bit values, by padding the ASN values with 16 zero high-order bits. What about the reverse case where 32-bit information is being passed back into the 16-bit world?

This case has two parts: first creating an equivalent 16-bit AS path and second, packing up the 32-bit AS path information in such a way that it transits across the 16-bit domain in such a manner that that it can be reassembled in any subsequent transition into a 32-bit domain. In the first case, the equivalent path information is constructed by stripping the high-order 16 bits off the AS value, as long as this part is all zeros. Where this is not possible—and the AS path contains one or more ASNs with non-zero high-order bits—then the transition ASN, 23456, is substituted in the place of each such ASN in the AS path. In this way the AS path length metric is preserved, and the prevention of count-to-infinity loops in the 16-bit domain is avoided.

The second part to this case is packaging up the 32-bit path into the OLD BGP session in such a way that it can be unpacked at any subsequent boundary back into a 32-bit routing realm. Here the proposal calls for new transitive community attributes to be carried in OLD BGP routing realms. These attributes are defined as transitive attributes, and should be passed through the OLD BGP peering sessions without alteration. It should be noted that this is not a protocol change as such, but it does require the explicit configuration support within OLD BGP implementations of this attribute as a transitive community.

The proposed mechanism is an extended community attribute called "NEW_AS_PATH." When a NEW BGP speaker is speaking to an OLD BGP, the NEW BGP prepends its own AS value to the AS_PATH and copies this information into the NEW_AS_PATH attribute. It then translates the 32-bit AS path into a 16-bit equivalent AS path. The translation is straightforward, in that where the 32-bit AS has all zeros in the high-order 16 bits, the translation truncates the AS value to a 16-bit value, and where the high-order 16 bits are nonzero, the translation substitutes the reserved 16-bit value AS 23456 in its place (Figure 13).

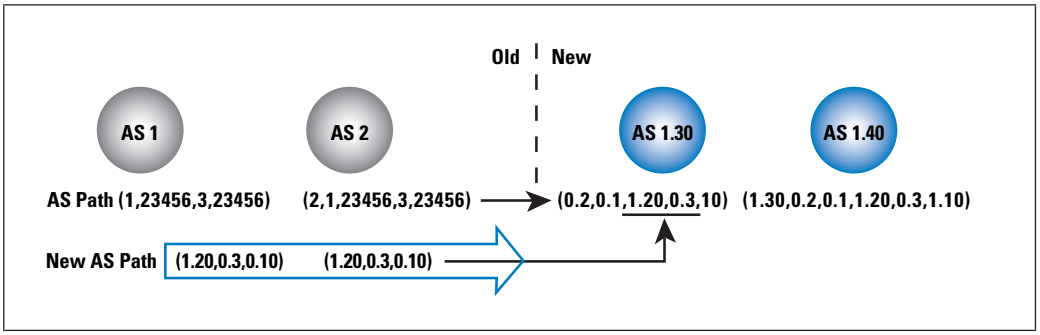
Figure 13: NEW to OLD BGP AS Path Mapping



The transit across the OLD BGP domains leaves the NEW_AS_PATH untouched, and prepends 16-bit AS values to the AS_PATH. In other words, OLD BGP behaves as it always has. The NEW_AS_PATH is passed through the OLD realm as an opaque bit block.

The next transition is one from the OLD to the NEW domain when a NEW_AS_PATH attribute is present. In this case the NEW BGP speaker takes the AS path as presented by the OLD BGP speaker and converts the 16-bit AS values to 32-bit AS values by adding 16 bits of zero padding to each entry, as before. However, in this case the NEW BGP speaker then overwrites the trailing entries with the values specified by the NEW_AS_PATH attribute. The effective result is that the 32-bit AS path that entered the 16-bit sequence is prepended with the equivalent of the 16-bit transit AS sequence. The NEW_AS_PATH attribute is then removed from the BGP Update, leaving an intact 32-bit path as the AS_PATH attribute. This scenario ensures that the resultant BGP environment can accurately detect loops in both the NEW 32-bit and OLD 16-bit realms (Figure 14).

Figure 14: OLD to NEW BGP AS Path Mapping



What if there was a routing loop that traversed a mixed sequence of NEW and OLD routing realms? The restoration of the original 32-bit AS path at the OLD-to-NEW transition ensures that the potential loop is discarded, because a 16-bit AS sees its own AS in the 16-bit AS_PATH attribute, and a 32-bit AS also sees its own value in the 32-bit AS_PATH. The transition mapping ensures that the potential routing loop is detected by BGP.

The ability to perform AS path prepending is also unaltered in this mixed NEW and OLD BGP environment. The AS simply prepends its local AS value to the AS_PATH as usual. In the case of prepending on a NEW-to-OLD boundary, the prepended AS path is mapped into the NEW_AS_PATH attribute as described previously.

Earlier in this article we noted the less common use of AS path poisoning, where the prepending uses a different ASN value in order to ensure that the particular advertisement is not learned by a remote AS. For NEW BGP speakers there is no change to this capability. For OLD BGP speakers the AS path poisoning can be directed only toward 16-bit ASs, because the OLD BGP speaker has no knowledge of the structure or content of the NEW_AS_PATH attribute.

Another part of the BGP protocol that uses ASNs is the AGGREGATOR attribute. This attribute is attached to an update message when an AS combines two or more prefixes into a single aggregate prefix (a practice that is often referred to as "proxy aggregation"). The ASN of the aggregating AS is attached to the aggregate prefix advertisement as an AGGREGATOR attribute. The same ASN translation technique applies to AGGREGATOR attribute when an advertisement is passed across a transition point. In a NEW-to-OLD transition the AGGREGATOR may be a mappable ASN, in which case the value is truncated to 16 bits and no further action is required. Otherwise the 32-bit AGGREGATOR value is rewritten into a NEW_AGGREGATOR attribute and the transition 16-bit value, AS 2356, is placed into the AGGREGATOR attribute. On an OLD-to-NEW transition the NEW_AGGREGATOR attribute is copied back into the AGGREGATOR attribute, if defined; otherwise the AGGREGATOR is padded out with leading zeros.

Transition

Transition in this scheme is relatively straightforward. NEW BGP speakers can be deployed within the network in a piecemeal fashion without any major concerns, and no changes are required for OLD BGP speakers. The size of BGP UPDATE messages is slightly longer because of the extended length of the AS PATH attribute in NEW BGP and the NEW_AS_PATH attribute that has been added in the OLD BGP environment, but it should not prove to be a major factor.

BGP loop prevention appears to be adequately addressed in all commonly encountered situations, and there appears to be no other significant transition considerations from the perspective of BGP platforms.

This scenario implies a relatively straightforward transition, in that OLD BGP speakers do not have to migrate to NEW BGP capability just because 32-bit ASNs are deployed elsewhere in the network. As long as they transmit the NEW-AS_PATH update across their domain without attempting to alter it in any way, then the 32-bit routing realm will be able to perform loop detection and shortest AS path selection in a manner that is entirely consistent with the 16-bit routing realm. Deployment of NEW BGP code is required only when the local AS is numbered from the nonmappable 32-bit ASN space.

Alternatives to AS Numbers

It is certainly a challenging task to contemplate an environment in which a 32-bit ASN space is exhausted, but one would suppose that the same consideration was in the minds of the original BGP protocol designers when they opted to use 16-bit ASNs. Of course a 32-bit number pool is not double the pool size of a 16-bit number pool—it is 65,536 times larger. That does appear to lead one to believe that this time it will be a far more challenging task to exhaust this expanded number pool.

This approach of simply extending the number space appears to offer a path of minimal disruption and minimal change in terms of operational configuration, storage, message size, and processing overheads for BGP. Nothing much has changed here except the range of the number space, and some ancillary considerations relating to transitional arrangements.

Of course, other labeling spaces remain possibilities, and a shift to a different labeling scheme could well use the same transitional approach. There is no significance in the ASN apart from its uniqueness, and any other form of name space would function equally well in terms of its role in BGP. One could use strings such as domain names, URIs, fixed-length hashes of public keys, the public keys themselves, or even IPv6 addresses as distinguishing AS identifiers.

There is no direct requirement for summarization of ASN ranges within the protocol use, no requirement within the protocol to continue to use number identifiers, and no direct requirement to stick with values that are encoded in a fixed-length field.

However, such approaches would add to the size of BGP UPDATE messages, increase the storage requirements, and, perhaps marginally, increase processing overheads for BGP. The more complex the identity space the more complex the basic task of BGP configuration and the higher the possibility of mistakes. "Borrowing" AS identifiers from another name space, such as domain names, or derived URIs, has the associated concern that the uniqueness of the space is derived from the inherent stability and uniqueness of the name space upon which the identifiers are derived. It is definitely possible that at times this trust is misplaced.

Numbers are often the simplest of identifiers. This approach represents minimal change to the installed base of BGP speakers, and there is no requirement for an existing routing domain using a 16-bit ASN and OLD BGP to make any changes to its routing environment at all. The transition appears to offer flexibility, orderly transition, and minimal disruptions to existing operational practices.

Conclusion

We are certainly running out of available 16-bit ASNs, and an industry of the size of the Internet is no longer as agile as it may have been in the past to make the necessary adjustments to alleviate this situation. At present we need to have a considerable period of advance warning of change in something as fundamental as the interdomain routing space in order to be able to integrate changes into various operational cycles of testing and transitional deployment prior to integration into production environments. The first steps that need to be taken are the completion of the technical specification of this approach in the form of an Internet standard and the production and distribution of BGP implementations that support 32-bit ASNs from the existing BGP implementation suppliers. It would be preferable to get this transition process under way in the near future, while there is still time to complete the transition well before we exhaust the current 16-bit ASN space.

Working with IP Addresses

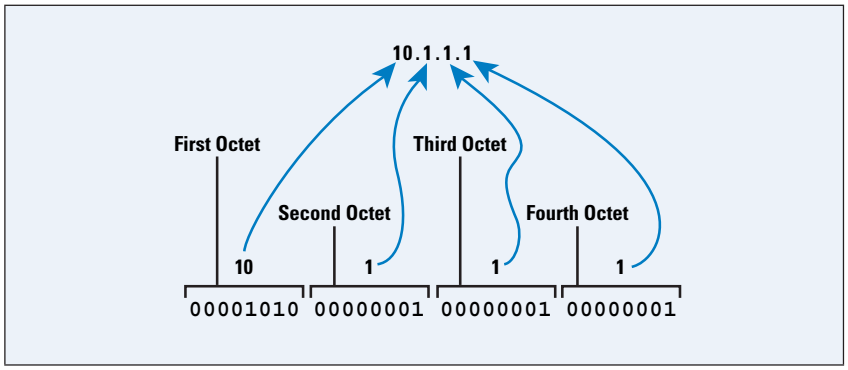
by Russ White, Cisco Systems

IP addresses, both IPv4 and IPv6, appear to be complicated when you first encounter them, but in reality they are simple constructions, and a using a few basic rules will allow you to find the important information for any situation very quickly—and with minimal math. In this article, we review some of the basics of IPv4 address layout, and then consider a technique to make working with IPv4 addresses easier. Although this is not the "conventional" method you might have been taught to work with in IP address space, you will find it is very easy and fast. We conclude with a discussion of applying those techniques to the IPv6 address space.

Basic Addressing

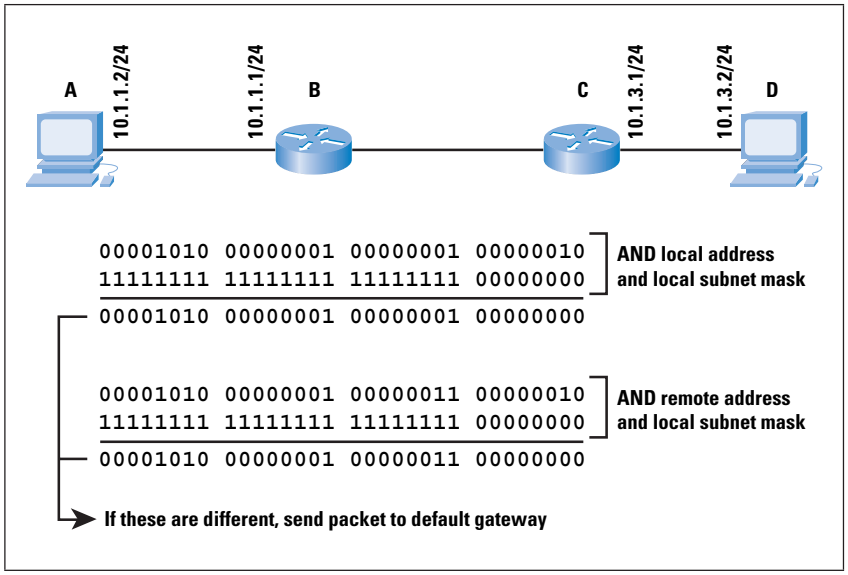
IPv4 addresses are essentially 32-bit binary numbers; computer systems and routers do not see any sorts of divisions within the IPv4 address space. To make IPv4 addresses more human-readable, however, we break them up into four sections divided by dots, or periods, commonly called "octets." An octet is a set of eight binary digits, sometimes also called a "byte." We do not use byte here, because the real definition of a byte can vary from computer to computer, whereas an octet remains the same length in all situations. Figure 1 illustrates the IPv4 address structure.

Figure 1: IPv4 Address Structure



Because each octet represents a binary (base 2) number between 0 and 2^8, each octet will be between 0 and 255. This part of IPv4 addresses is simple—but what about subnet masks? To understand a subnet mask, we need to understand how a device actually uses subnet masks to determine where to send a specific packet, as Figure 2 illustrates.

Figure 2: Subnet Masks



If host A, which has the local IP address **`10.1.1.2`** with a subnet mask of **`255.255.255.0`**, wants to send a packet to **`10.1.3.2`**, how does it know whether D is connected to the same network (broadcast domain) or not? If D is connected to the same network, then A should look for D's local Layer 2 address to transmit the packet to. If D is not connected to the same network, then A needs to send any packets destined to D to A's local default gateway.

To discover whether D is connected or not, A takes its local address and performs a logical AND between this and the subnet mask. A then takes the destination (remote) address and performs the same logical AND (using its local subnet mask). If the two resulting numbers, called the *network address* or *prefix*, match, then the destination must be on the local segment, and A can simply look up the destination in the *Address Resolution Protocol* (ARP) cache, and send the packet locally. If the two numbers do not match, then A needs to send the packet to its default gateway.

Note: ARP is a protocol used to discover the mappings between the IP addresses of devices attached to the same network as the local device and the Layer 2 address of devices attached to the same network as the local device. Essentially, a device sends an ARP broadcast containing the IP address of some other device it believes to be connected, and the device with the specified IP address replies with its Layer 2 address, providing a mapping between these two addresses.

If a subnet mask is a "dotted decimal" version of the binary subnet mask, then what is the prefix length? The prefix length is just a shorthand way of expressing the subnet mask. The prefix length is the number of bits set in the subnet mask; for instance, if the subnet mask is **`255.255.255.0`**, there are 24 1's in the binary version of the subnet mask, so the prefix length is 24 bits. Figure 3 illustrates network masks and prefix lengths.

Figure 3: Prefix Lengths

Binary Mask	Prefix Length	Subnet Mask
11111111 00000000 00000000 00000000	/8	255.0.0.0
11111111 10000000 00000000 00000000	/9	255.128.0.0
11111111 11000000 00000000 00000000	/10	255.192.0.0
11111111 11100000 00000000 00000000	/11	255.224.0.0
11111111 11110000 00000000 00000000	/12	255.240.0.0
11111111 11111000 00000000 00000000	/13	255.248.0.0
11111111 11111100 00000000 00000000	/14	255.252.0.0
11111111 11111110 00000000 00000000	/15	255.254.0.0
11111111 11111111 00000000 00000000	/16	255.255.0.0
11111111 11111111 10000000 00000000	/17	255.255.128.0
11111111 11111111 11000000 00000000	/18	255.255.192.0
11111111 11111111 11100000 00000000	/19	255.255.224.0
11111111 11111111 11110000 00000000	/20	255.255.240.0
11111111 11111111 11111000 00000000	/21	255.255.248.0
11111111 11111111 11111100 00000000	/22	255.255.252.0
11111111 11111111 11111110 00000000	/23	255.255.254.0
11111111 11111111 11111111 00000000	/24	255.255.255.0
11111111 11111111 11111111 10000000	/25	255.255.255.128
11111111 11111111 11111111 11000000	/26	255.255.255.192
11111111 11111111 11111111 11100000	/27	255.255.255.224
11111111 11111111 11111111 11110000	/28	255.255.255.240
11111111 11111111 11111111 11111000	/29	255.255.255.248
11111111 11111111 11111111 11111100	/30	255.255.255.252
11111111 11111111 11111111 11111110	/31	255.255.255.254
11111111 11111111 11111111 11111111	/32	255.255.255.255

Working with IPv4 Addresses

Now that we understand how an IPv4 address is formed and what the subnet length and prefix length are, how do we work with them? The most basic questions we face when working with an IP address follow:

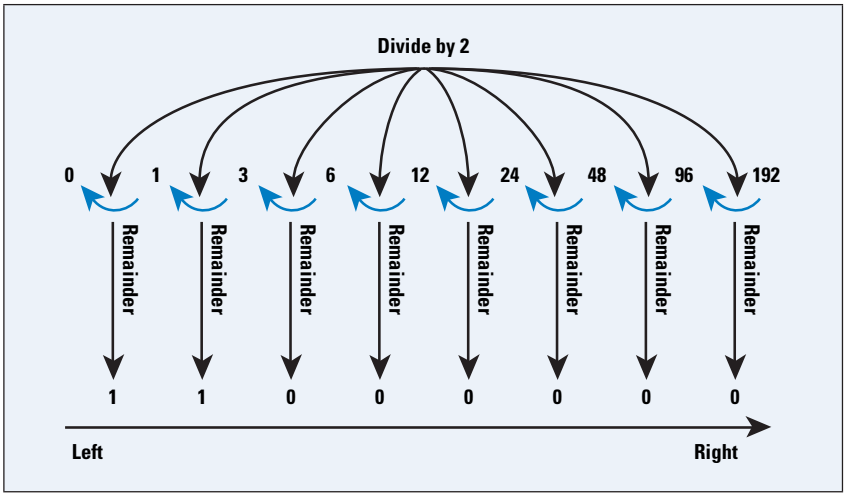
- What is the network address of the prefix?
- What is the host address?

There are two ways to find the answers to these questions: the hard way and the easy way. We cover the hard way first, and then show you the easy way.

The Hard Way

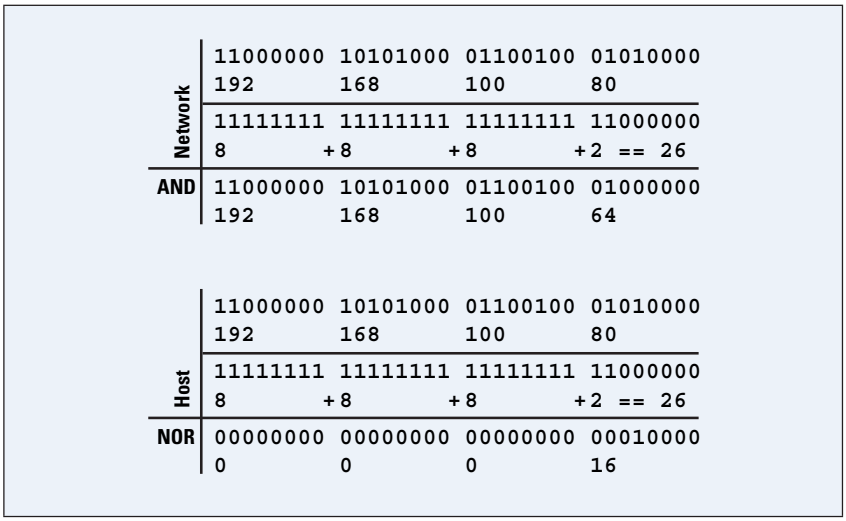
The hard way to determine the prefix and host addresses is to convert the address into binary, perform logical AND and NOR operations on the address and the subnet mask, and then convert the resulting numbers back to decimal. Figure 4 illustrates the process of converting a single octet of the IPv4 address into binary; the number converted in this case is 192.

Figure 4: Binary Conversion



The process is simple, but tedious; divide the octet value by 2, take the remainder off, and then divide by 2 again, until you reach 0. The remainders, reversed in direction, are the binary numbers representing the value of the octet. Performing this process for all four octets, we have the binary IP address, and can use logical AND and NOR operations to find the prefix (network address) and the host address, as Figure 5 shows for the address **`192.168.100.80/26`**.

Figure 5: Address Calculation



The Easy Way

All this conversion from binary to decimal and from decimal to binary is tedious— is there an easier way? Yes. First, we start with the observation that we work only with the numbers within one octet at a time, no matter what the prefix length is. We can assume all the octets before this *working octet* are part of the network address, and octets after this *working octet* are part of the host address.

The first thing we need to do, then, is to find out which octet is our *working octet*. This task is actually quite simple: just divide the prefix length by 8, discard the remainder, and add 1. The following table provides some examples.

Address	Hard Math	Working Octet
`192.158.100.80/26`	(26 ÷ 8) + 1 = 4	4
`10.1.1.48/23`	(23 ÷ 8) + 1 = 3	3
`172.31.80.10/22`	(22 ÷ 8) + 1 = 3	3

Note: Another way to look at this task is that you will ignore the octets indicated by the division. For instance, for **`192.168.100.80/26`**, *the result of dividing 26 by 8 is 3, so you will ignore the first three octets of the IP address, and work only with the fourth octet. This process has the same result.*

When we know the working octet, what do we do with it? Well, we could simply use the procedure outlined, convert the single octet to binary, perform AND and NOR operations on it with the right bits from the subnet mask, and then put it all back together to find the network and host addresses—but there is an easier way to find the network and host parts of the working octet. Start by doing the same math, only this time we want to work with the remainder rather than the result.

`192.168.100.80/26`
26 ÷ 8 = 3 with a remainder of 2

Take the remainder, and use the following table to find the corresponding *jump* within the octet; this number is the distance, in decimal form, between the network addresses within the octet.

1	2	3	4	5	6	7	8
128	64	32	16	8	4	2	1

In this chart, the first line represents the prefix length *within this octet*, the second line represents the prefix value when this bit is set to 1, the number of hosts in the subnet for this prefix length, and the *jump* between network addresses with the specified prefix length.

The number 2 corresponds to 64, so the jump is 64—there is a network at 0, 64, 128, 192, and 224 in this octet. Now all we need to do is figure out which one of those networks this address is in. This task is fairly simple: just take the largest network number that fits into the number in the working octet. In this case, the largest number that fits into 80 is 64, so our network address is **`192.168.100.64/26`**.

Now, what about the host address? That is easy when we have the network address—just subtract the network address from the IP address, and you have the host address within the network: 80 – 64 = 16. This process takes a little practice, but it is not hard when you become accustomed to the steps.

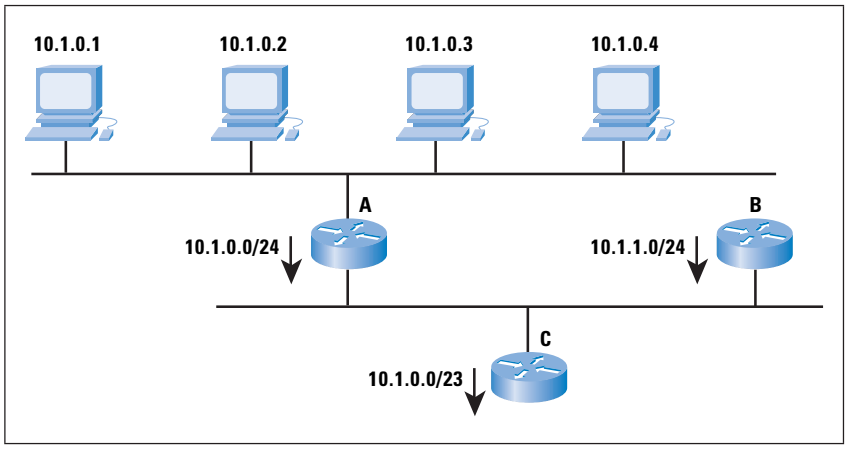
Address	Hard Math	Working Octet	Remainder	Jump	Network	Host
192.158.100.80/26	26 ÷ 8 = 3	3 + 1 = 4	2	64	192.168.100.64/26	80 – 64 = 16
10.1.1.48/23	23 ÷ 8 = 2	2 + 1 = 3	7	2	10.1.0.0/23	1 – 0 = 1.48
172.31.80.10/22	22 ÷ 8 = 2	2 + 1 = 3	6	4	172.31.80.0/22	80 – 80 = 0.10

In the second and third examples, you see that the working octet is actually the third, rather than the fourth, octet. To find the host address in these examples, you simply find the host address in the third octet, and then "tack on" the fourth octet as part of the host address as well, because part of the third octet—and all of the fourth octet—are actually part of the host address.

Summarization and Subnets

Subnets and supernets are probably the hardest part of IP addressing for most people to understand and handle quickly, but they are both based on a very simple concept—*aggregation*. Figure 6 shows how aggregation works.

Figure 6: Address Aggregation



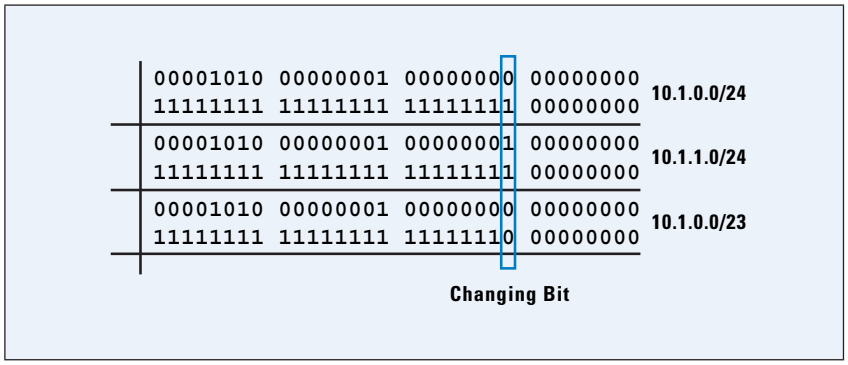
The figure shows four hosts with the addresses **10.1.0.1**, **10.1.0.2**, **10.1.0.3**, and **10.1.0.4**. Router A advertises **10.1.1.0/24**, meaning: "Any host within the address range **10.1.0.0** through **10.1.0.255** is reachable through me." Note that not all the hosts within this range exist, and that is okay—if a host within that range of addresses is reachable, it is reachable through Router A. In IP, the address that A is advertising is called a *network address*, and you can conveniently think of it as an address for the wire the hosts and router are attached to, rather than a specific device.

For many people, the confusing part comes next. Router B is also advertising **10.1.1.0/24**, which is another network address. Router C can combine—or aggregate—these two advertisements into a single advertisement. Although we have just removed the correspondence between the wire and the network address, we have not changed the fundamental meaning of the advertisement itself. In other words, Router C is saying: "Any host within the range of addresses from **10.1.0.0** through **10.1.1.255** is reachable through me." There is no wire with this address space, but devices beyond Router C do not know this, so it does not matter.

To better handle aggregated address space, we define two new terms, *subnets* and *supernets*. A subnet is a network that is contained entirely within another network; a supernet is a network that entirely contains another network. For instance, **10.1.0.0/24** and **10.1.1.0/24** are both subnets of **10.1.0.0/23**, whereas **10.1.0.0/23** is a supernet of **10.1.0.0/24** and **10.1.1.0/24**.

Now we consider a binary representation of these three addresses, and try to make more sense out of the concept of aggregation from an addressing perspective; Figure 7 illustrates.

Figure 7: Aggregation Details



By looking at the binary form of **10.1.0.0/24** and **10.1.1.0/24**, we can see that only the 24th bit in the network address changes. If we change the prefix length to 23, we have effectively "masked out" this single bit, making the **10.1.0.0/23** address cover the same address range as the **10.1.0.0/24** and **10.1.1.0/24** addresses combined.

The Hardest Subnetting Problem

The hardest subnetting problem most people face is that of trying to decide what the smallest subnet is that will provide a given number of hosts on a specific segment, and yet not waste any address space. The way this sort of problem is normally phrased is something like the following:

You have 5 subnets with the following numbers of hosts on them: 58, 14, 29, 49, and 3, and you are given the address space **10.1.1.0/24**. Determine how you could divide the address space given into subnets so these hosts fit into it.

This appears to be a very difficult problem to solve, but the chart we used previously to find the jump within a single octet actually makes this task quite easy. First, we run through the steps, and then we solve the example problem to see how it actually works.

- Order the networks from the largest to the smallest.
- Find the smallest number in the chart that fits the number of the largest number of hosts + 2 (*you cannot, except on point-to-point links, use the address with all 0's or all 1's in the host address; for point-to-point links, you can use a /31, which has no broadcast addresses*).
- Continue through each space needed until you either run out of space or you finish.

This process seems pretty simple, but does it work? Let's try it with our example.

- Reorder the numbers 58, 14, 29, 49, 3 to 58, 49, 29, 14, 3.
- Start with 58.
  - The smallest number larger than (58 + 2) is 64, and 64 is 2 bits.
  - There are 24 bits of prefix length in the address space given; add 2 for 26.
  - The first network is **10.1.1.0/26**.
  - The next network is **10.1.1.0** + 64, so we start the next "round" at **10.1.1.64**.
- The next block is 49 hosts.
  - The smallest number larger than (49 + 2) is 64, and 64 is 2 bits.
  - There are 24 bits of prefix length in the address space given; add 2 for 26.
  - We start this block at **10.1.1.64**, so the network is **10.1.1.64/26**.
  - The next network is **10.1.1.64** + 64, so we start the next "round" at **10.1.1.128**.
- The next block is 29 hosts.
  - The smallest number larger than (29 + 2) is 32, and 32 is 3 bits.
  - There are 24 bits of prefix length in the address space given; add 3 for 27.
  - We start this block at **10.1.1.128**, so the network is **10.1.1.128/27**.

  - The next network is **10.1.1.128** + 32, so we start the next "round" at **10.1.1.160**.

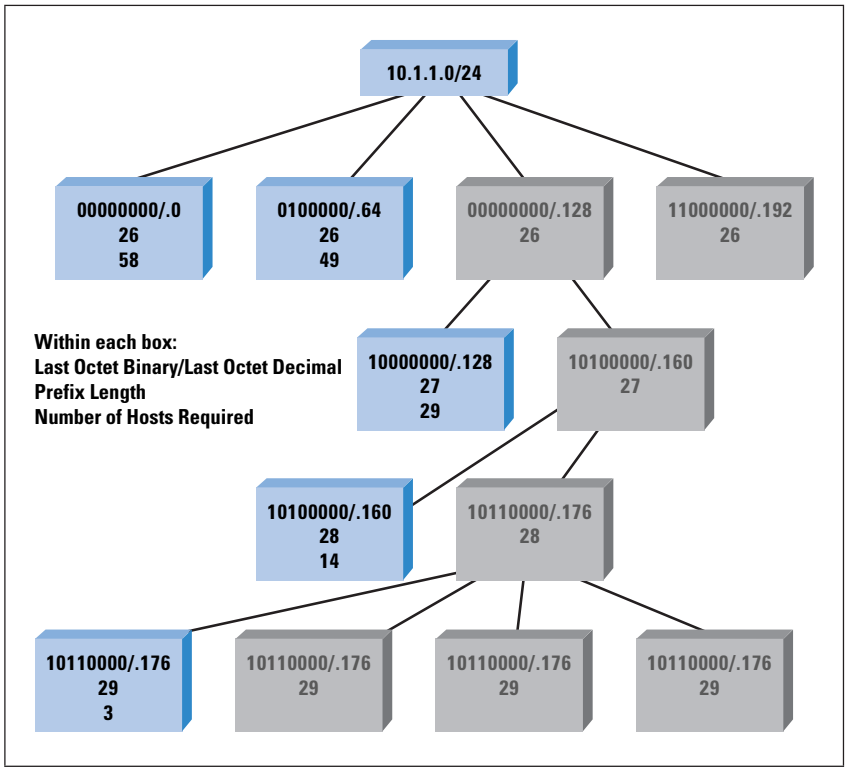
- The next block is 14 hosts.
  - The smallest number larger than (14 + 2) is 16, and 16 is 4 bits (actually equal, but it still works).
  - There are 24 bits of prefix length in the address space given; add 4 for 28.
  - We start this block at **10.1.1.160**, so the network is **10.1.1.160/28**.
  - The next network is **10.1.1.160** + 16, so we start the next "round" at **10.1.1.176**.

The last block is 3 hosts.

  - The smallest number larger than (3 + 2) is 8, and 8 is 5 bits.
  - There are 24 bits of prefix length in the address space given; add 5 for 29.
  - We start this block at **10.1.1.176**, so the network is **10.1.1.176/29**.
  - This is the last block of hosts, so we are finished.

It is a simple matter of iterating from the largest to the smallest block, and using the simple chart we used before to determine how large of a *jump* we need to cover the host addresses we need to fit onto the subnet. Figure 8 illustrates the resulting hierarchy of subnets.

Figure 8: Subnet Chart



In this illustration:

- The first line in each box contains the final octet of the network address in binary and decimal forms.
- The second line in each box contains the prefix length.
- The third line indicates the number of hosts the original problem required on that subnet.
- Gray boxes indicate blocks of address space that are unused at that level.

Working with IPv6 Addresses

IPv6 addresses appear to be much more difficult to work with—but they really are not. Although they are larger, they are still made up of the same fundamental components, and hosts and routers still use the addresses the same way. All we really need to do is realize that each pair of hexadecimal numbers in the IPv6 address is actually an octet of binary address space. The chart, the mechanisms used to find the network and host addresses, and the concepts of super and subnets remain the same.

For example, suppose we have the IPv6 address **`2002:FF10:9876:DD0A:9090:4896:AC56:0E01/63`** and we want to know what the network number is (host numbers are less useful in IPv6 networks, because they are often the MAC address of the system itself).

- 63 ÷ 8 = 7, remainder 7.
- The working octet is the 8th, which is 0A.
- Remainder 7 on the chart says the jump is 2, so the networks are **`00`**, **`02`**, **`04`**, **`06`**, **`08`**, **`0A`**, **`0C`**, and **`0E`**.
- The network is **`2002:FF10:9876:DD0A::/63`**.

The numbers are longer, but the principle is the same, as long as you remember that every *pair* of digits in the IPv6 address is a single octet.

Summary

IP addresses appear to be very complex on first approach, but their inbuilt structure actually provides easy ways to divide the problems into pieces and approach one piece of the problem at a time—the same way we design and build networks on a large scale. If you learn to use some simple techniques and understand how IP addresses are structured, they are relatively easy to work with.

Letter to the Editor

Dear Editor,

I read with interest the article by Dave Crocker in the December 2005 issue of IPJ (Volume 8, No. 4) titled "Challenges in Anti-Spam Efforts." However, I was surprised not to find any mention of *graylisting*, an effective anti-spam technique. The technique is not a programmatic or analytical approach to the spam problem but rather relies on exploiting the general behavioral weakness of spam delivery (that spammers typically want to try an address just once for their delivery of spam contents). The technique provides a pragmatic solution to the contemporary bulk commercial e-mail problem to a large extent.

If you are planning for a sequel of this article, I would strongly advocate mentioning the technique for the general benefit of the community.

I administrate a national ISP of considerable size in Pakistan, and the extent to which graylisting has helped us in fighting against spam is amazing.

Successful spam-fighting techniques (especially those that are still far from being widely adopted and worked upon) of today make good candidates for future efforts. My enthusiasm for graylisting is chiefly a result of the benefits our company has derived from its use, but I also want to champion its use because I think it is not widely adopted among peer ISPs because of ignorance. Hence my enthusiastic advocacy of this unsung hero in the fight against spam.

—*Tee Emm, Supernet, Pakistan*
tm@super.net.pk

The Author responds:

Dear Editor,

I appreciate Tee Emm's concern that graylisting was not explicitly cited in my article.

I must use the cliché of "limited space" as my primary excuse for omitting graylistng. The tight constraints for a brief article required some difficult choices. As I mentioned at the end of the article, the people reviewing it before publication were particularly helpful (and vigorous). The question of what detail to include was a major focus. My decision was to have only a basic review of existing techniques, because the focus of the article was on future activities.

I believe the work on detection and reaction mechanisms against "bad actors" is reasonably mature. I also believe that the creation of a trust overlay for e-mail, to permit better handling of messages from "good actors," is very early and in need of much more focus.

With that said, I think I can also generate a plausible claim that graylisting is a form of "traffic shaping," which is cited in the article.

I primarily meant the traffic shaping reference to be about the technique of tracking aggregate (statistical) flow from a specific address. However, I think that graylisting constitutes a simple—albeit quite useful—mechanism that is designed to slow down the senders, to limit their impact. As Tee Emm notes, graylisting is based on the spammers' pattern of giving up, after a single failure to send the message. That is the ultimate "shaping," I think.

Certainly a summary of existing techniques is a worthy topic. It has become quite a rich topic, and matured to a level of qualifying as an area of administration and operations specialization.

As for a follow-up article, I do not have one planned, currently. If I do another one, I hope it will be about open mechanisms for achieving authentication and assessment (vetting) of good actors.

Perhaps next year.

For reference, I should note that there has been some public follow-up on the article, when CircleID reprinted a posting I made about it: **http://www.circleid.com/posts/challenges_in_anti_spam_efforts/**

Again, I appreciate Tee Emm's interest and comment.

IETF @ 20

The *Internet Engineering Task Force* (IETF) and the *Internet Society* (ISOC) celebrate the 20th anniversary of the IETF, the world's leading Internet standards development body. The IETF is a large open international community of network designers, operators, vendors, and researchers concerned with the evolution of the Internet architecture and the smooth operation of the Internet. Its principal task today is the development and publication of technical specifications and standards for basic Internet protocols. It is open to any interested individual.

The first IETF meeting was held on the afternoon of January 16, 1986, in San Diego, California. As a community-driven activity the IETF went on to pioneer a unique, open process for standards development. Open to all, and based on principles such as "rough consensus and running code," the IETF has enabled the development of standards that have supported every aspect of the Internet's phenomenal growth.

"The IETF is unique," said Brian Carpenter, IETF Chair. "Unlike other standards bodies, there is very little in the way of formal hierarchy and there are no membership requirements or fees. The IETF welcomes broad participation by anyone interested in the future technical evolution and stability of the Internet—and IETF standards are available to all, without charge."

"There is global recognition of the achievements of the IETF in its support of the development of Internet technology. As the demands on the Internet increase, the IETF clearly has a vital role to play in ensuring that Internet technologies continue to evolve in a coherent and coordinated manner," said Leslie Daigle, chair of the *Internet Architecture Board* (IAB) which provides architectural oversight of IETF activities."

"The success of the IETF has largely been due to a pragmatic, consensus-based approach to technology standards development," noted Lynn St. Amour, President and CEO of ISOC. "Many of the principles of co-operation and collaboration that were developed in the IETF are now being successfully applied in other global forums. ISOC is proud to be associated with the IETF—we value its members' accomplishments over the last 20 years and look forward to celebrating these achievements over the course of 2006."

ISOC has declared 2006 "The Year of the IETF" and will be running several activities during the year in celebration of the IETF's 20th anniversary. For more information, see: **`http://ietf20.isoc.org`**

The Internet Society is a not-for-profit membership organization founded in 1992 to provide leadership in Internet related standards, education, and policy. With offices in Washington, DC, and Geneva, Switzerland, it is dedicated to ensuring the open development, evolution and use of the Internet for the benefit of people throughout the world. ISOC is the organizational home of the IETF and other Internet-related bodies who together play a critical role in ensuring that the Internet develops in a stable and open manner. For over 13 years ISOC has run international network training programs for developing countries and these have played a vital role in setting up the Internet connections and networks in virtually every country connecting to the Internet during this time.

ISOC Welcomes WSIS Proposal

Delegates meeting at the *World Summit on the Information Society* (WSIS) in Tunis have affirmed their commitment to build on the governance mechanisms that have enabled the Internet's incredibly successful growth.

ISOC welcomes the recognition by WSIS of how the effectiveness of the existing arrangements for Internet governance has helped make the Internet the highly robust, dynamic and geographically diverse medium that it is today.

"We are delighted that there is now much broader recognition of the achievements of the organisations that support the Internet community," said Lynn St. Amour, President and CEO of the ISOC. "These organizations, along with their open, consensus-based processes clearly have a vital role to play in the further development of the Internet. It is also significant that the WSIS debate has moved beyond the details of technical administration and on to broader issues that require increased coordination by stakeholders in order to ensure the continued stability of the Internet."

The WSIS recommendation includes a proposal for a new forum for multi-stakeholder policy dialogue—the *Internet Governance Forum*. ISOC, together with partner organizations from the Internet community, has always worked to encourage full engagement in such dialogues by all those with an interest in the Internet's future. ISOC believes that the forum's success depends upon the fullest participation by all stakeholders. At the same time, ISOC is pleased to note that the proposed forum would have no oversight function and would have no involvement in the day-to-day operations of the Internet.

"ISOC will facilitate increased cooperation and information sharing amongst all parties interested in Internet governance and we look forward to playing an active role in the new forum as is expected of us by the global community," said Lynn St. Amour. "We very much hope that the Tunis summit will lead to some real and positive outcomes that will help bring the benefits of the Internet to people everywhere—especially to those who are yet to be connected."

ISOC, along with some of its partner organisations—the *Number Resource Organisation* (NRO), the IETF, *London Internet Exchange* (LINX), the *Internet Corporation for Assigned Names and Numbers* (ICANN) and the *Council of European National Top level domain Registries* (CENTR)—were present at the *ICT 4 All* exhibition held in conjunction with WSIS.

Upcoming Events

The *Internet Engineering Task Force* (IETF) will meet in Montreal, Canada, July 9–14, 2006. For more information, visit:
http://ietf.org

ACM's *SIGCOMM 2006* will be held in Pisa, Italy, September 11–15, 2006. For more information, visit:
http://www.acm.org/sigs/sigcomm/sigcomm2006

The *North American Network Operators Group* (NANOG) will meet in St. Louis, MO October 8–10, 2006. For more information, see: **http://nanog.org**

The *American Registry for Internet Numbers* (ARIN) will meet (jointly with NANOG) in St. Louis, October 11–13, 2006. For more information, see: **http://arin.net**

From The Editor

In our June 2000 issue we wrote: "Two protocols used in the Internet are so important that they deserve special attention: the *Internet Protocol* (IP) from which this journal takes its name, and the *Transmission Control Protocol* (TCP). IP is fundamental to Internet addressing and routing, while TCP provides a reliable transport service that is used by most Internet applications, including interactive Telnet, file transfer, electronic mail, and Web page access via HTTP. Because of the critical importance of TCP to the operation of the Internet, it has received much attention in the research community over the years. As a result, numerous improvements to implementations of TCP have been developed and deployed." We return to TCP in this issue with a look at its performance at gigabit speeds. Geoff Huston describes numerous research proposals related to TCP and discusses lessons learned by operators and researchers involved with this protocol.

My first encounter with the Internet (then called the ARPANET) took place in 1976 when I visited the *Norwegian Defence Research Establishment* (NDRE) at Kjeller, about 20 kilometers from Oslo, Norway. At NDRE, one of the researchers, named Pål, showed me a teletype terminal that was connected through the ARPANET to a host computer at SRI International in Menlo Park, California. After a few minutes, the teletype started printing messages from someone called "Geoff" on the other end of the line. Pål typed back, passing on questions from myself about the weather in California and so on. I later learned that the host computer was a PDP-10 model KA10 running the TENEX operating system. TENEX could "link" two terminals together so that anything typed on one terminal would appear on the other, and conversely. This primitive "chat" system is the forerunner of today's *Instant Messaging* (IM) environment. David Strom gives an overview of the current state of IM solutions in our second article.

The article "Working with IP Addresses" in our last issue sparked several comments, some of which are included in our Letters to the Editor section. A few readers also noticed some errors in the article, so we have included the corrections in this issue. We very much appreciate your feedback. Please send your comments to: **ipj@cisco.com**

Gigabit TCP

by Geoff Huston, APNIC

In looking back over some 30 years of experience with the Internet, the critical component of the Internet Protocol Suite that has been the foundation of its success as the technology of choice for the global communications system is the *Internet Protocol* (IP) itself, working an overlay protocol that can span almost any form of communications media. But I would also like to nominate another contender for a critical role within IP, namely the reliable transport protocol that sits on top of IP, the *Transmission Control Protocol* (TCP), and its evolution over time. In support of this nomination is the fact that the end-to-end rate-adaptive control algorithm that was adopted by TCP represented a truly radical shift from the reliable gateway-to-gateway virtual circuit flow control systems used by other protocols of similar vintage. It is also interesting to note that TCP is not designed to operate at any particular speed, but it attempts to operate at a speed that uses its fair share of all available network capacity along the network path. The fundamental property of the TCP flow control algorithm is that it attempts to be maximally efficient while also attempting to be maximally fair.

Previous articles on this topic, "TCP Performance"[12] and "The Future for TCP"[13] looked at the design assumptions behind TCP and its performance characteristics. The essential characteristic of TCP is that it attempts to establish a dynamic equilibrium with other concurrent sessions and opportunistically use all available network capacity. It achieves this by constantly altering its flow characteristics, continually probing the network to see if higher speeds are supportable, while also being prepared to immediately decrease the current sending rate in the face of received signals of network congestion.

In a world where network infrastructure capacity and complexity are related to network cost and delivered data is related to network revenue, TCP fits in well. The minimal assumptions that TCP makes about the capability of network components permit networks to be constructed using simple transmission capabilities and simple switching systems. "Simple" often is synonymous with cheap and scalable, and there is no exception here. TCP also attempts to maximize data delivery through adaptive end-to-end flow rate control and careful management of retransmission events. In other words, TCP is an enabler for cheaper networking for both the provider and consumer. For the consumer the offer of fast cheap communications has been a big motivation in the increase in demand for Internet-based services, and this—more than any other factor—has been the major enabling factor for the increased use of the Internet itself. "Cheap" is often enough in this world, and TCP certainly helps to make data communications efficient and therefore cheap.

Although TCP is highly effective in many networking environments, that does not mean it is highly effective in every environment. For example:

- In those wireless environments where there is significant wireless noise, TCP may confuse the outcome of radio-based signal corruption and the corresponding packet drop with the outcome of network congestion, and consequently the TCP session may back off its sending rate too early and back off for too long.
- TCP also backs off too early when the network routers have insufficient buffer space. This effect is more subtle, but it is related to the coarseness of the TCP algorithm and the consequent burstiness of TCP packet sequences. These bursts, which occur at up to twice the bottleneck capacity rate, are smoothed out by network buffers. Buffer exhaustion in the interior of the network causes packet drop, which causes the generation of a loss signal to the active TCP session, which, in turn, either halves its sending rate or—in the worst case—resets the session state and restarts with a single packet exchange. Particularly in wide-area networks, where the end-to-end delay-bandwidth product becomes a significant factor, TCP uses the network buffers to sustain a steady-state throughput that matches the available network capacity. Where the interior buffers are underconfigured in memory it is not possible to even out the TCP bursts to continuously flow through the constrained point at the available data rate.
- TCP also asks its end hosts to have local capacity equal to the available network capacity on the forward and reverse paths. The reason is that TCP does not discard data until the remote end has reliably acknowledged it, so the sending host has to retain a copy of the data for the time it takes to send the data plus the time for the remote end to send the matching acknowledgement.

Even accounting for these limitations, it is true to say that TCP works amazingly well in most environments. Nevertheless, one area is proving to be quite a fundamental challenge to TCP as we know it, and that is the domain of wide-area, very-high-speed data transfer.

Very-High-Speed TCP

End host computers, even laptop computers these days, are typically equipped with Gigabit Ethernet interfaces, and have gigabytes of memory and internal data channels that can move gigabits of data per second between memory and the network interface. Current IP networks are constructed using multigigabit circuits and high-capacity switches and routers (assuming there is still a quantitative difference between these two forms of packet switching equipment). If the end hosts and the network both can support gigabit transmissions then a TCP session should be able to operate end to end at gigabits per second, and achieve the same efficiency at gigabit speeds as it does today at megabit speeds—right?

Well, no, not exactly!

This conclusion is not obvious, particularly when the TCP Land Speed Record is now at some 7Gbps across a distance that spans 30,000 km of network. What is going on?

Let's return to the basics of TCP to understand some of the variables with very-high-speed TCP. TCP operates in one of two states, that of *slow start* and *congestion avoidance*.

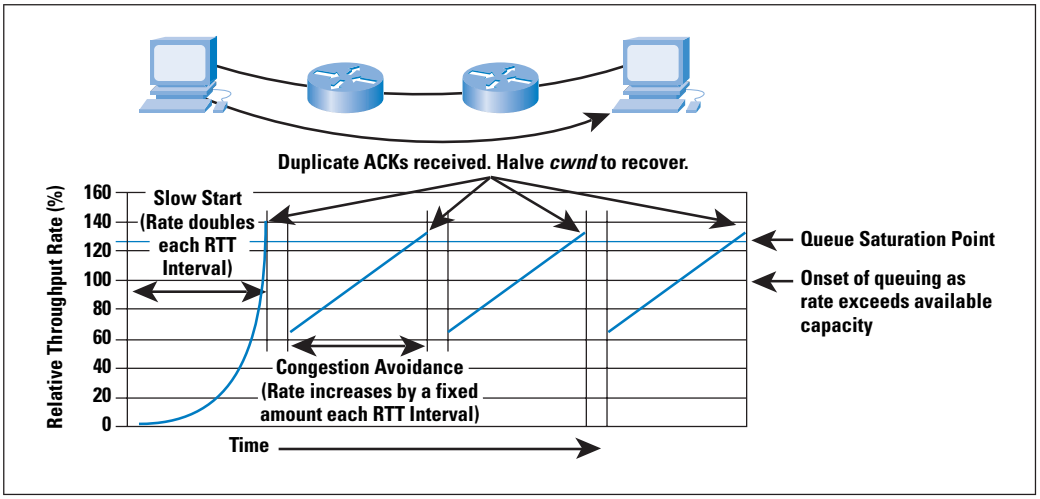
- *Slow start* mode is the initial mode of operation of TCP in any session, as well as its "reset" mode. In this mode, TCP sends two packets in response to each ACK packet that advances the sender's window. In approximate terms (*delayed* ACKs notwithstanding), this mode allows TCP to double its sending rate in each successive lossless *round-trip-time* (RTT) interval. The rate increase is exponential, effectively doubling each RTT interval, and the rate increase is bursty, effectively sending data into the network at twice the bottleneck capacity during this phase.

  Sending data into the network at twice the bottleneck data speed is possible because of the "ACK clocking" property of TCP. Disregarding the complications of the TCP delayed ACK mechanism for a second, a TCP receiver generates a new ACK packet each time a packet arrives at the receiver. The sending rate of the ACKs is, in effect, the same as the receiving rate for the data packets. Assuming a one-way data transfer, so that ACK packets in the reverse direction are of minimal size, and assuming minimal jitter on the reverse path from the receiver back to the sender, the arrival rate of ACKs at the sender is comparable to the arrival rate of data packets at the receiver. In other words, the return ACK rate is comparable to the bottleneck capacity of the forward network path from sender to receiver. Sending two packets per received ACK is effectively sending packets into the network at twice the bottleneck capacity. At the bottleneck point the switching unit receives twice the amount of data than it can transmit to the output device over a period that corresponds to the delay-bandwidth product of the bottleneck link. Hence the comment that TCP is a *bursty* protocol, particularly at startup. For this reason TCP tends to operate more effectively across network switching elements that are generously endowed with memory, or have for each output port a buffer capacity roughly equal to the delay-bandwidth product of the link that is attached to that port.

- In the other operating mode, that of *congestion avoidance,* TCP sends an additional segment of data for each loss-free round-trip time interval. This increase is additive rather than exponential, increasing the sender's speed at the constant rate of one segment per RTT interval.

TCP undertakes a state transition upon the detection of packet loss. Small-scale packet loss (of the order of 1 or 2 packets per loss event) causes TCP to halve its sending rate and enter congestion avoidance mode, irrespective of whether it was in this mode already. Repetition of this cycle gives the classic sawtooth pattern of TCP behavior, and the related derivation of TCP performance as a function of packet loss rate. Longer sustained packet loss events cause TCP to stop using the current session parameters, recommence the congestion control session using the restart window size, and enter the slow start control mode once again. (See Figure 1).

Figure 1: TCP Behavior



But what happens when two systems are at opposite sides of a continent with a high-speed path between them? How long does it take for a single TCP session to get up to a data transfer rate of 10 Gbps? Can a single session operate at a sustained rate of 10 Gbps?

Let's look at a situation such as the network path from Brisbane, on the eastern side of the Australian continent, to Perth on the western side. The cable path is essentially along the southern coast of the continent, so the RTT delay is 70 ms, implying that there are 14.3 round-trip intervals per second. Let's also assume that the packet size being used is 1500 octets, or 12,000 bits, and the TCP initial window size is a single packet. And let's also assume that the bottleneck capacity of the host-to-host path between Brisbane and Perth is 10 Gbps.

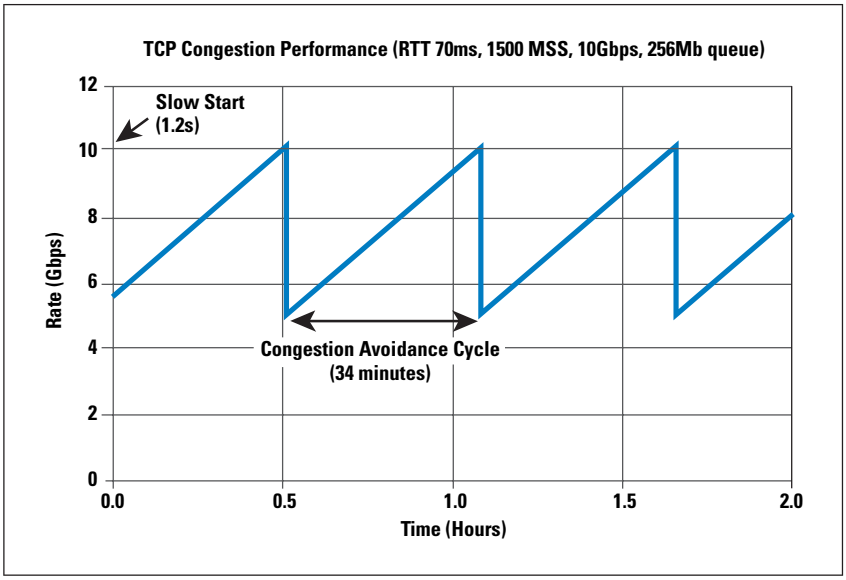
In a simple slow start model the sending speed doubles every 70 ms, so after 17 RTT intervals where the sending rate has doubled for each interval, or after some 1.2 seconds have elapsed, the transfer speed reaches 11.2 Gbps (assuming a theoretical host with sufficiently fast hardware components, sufficiently fast internal data paths, and adequate memory). At this stage let's assume that the sending rate exceeded the buffer capacity at the bottleneck point in the network path. Packet drop will occur, because the critical point buffers in the network path are now saturated.

At the point of reception of an ACK sequence that signals packet loss, the TCP sender's congestion window will halve, as will the TCP sending rate, and TCP will switch to congestion avoidance mode. In congestion avoidance mode the rate increase is 1 segment per RTT, equivalent to sending an additional 12 kilobits per RTT, or, given the session parameters as specified previously, equivalent to a rate increase of 171 kbps each RTT. So how long will it take TCP to recover and get back to a sending rate of 10 Gbps?

If this were a T1 circuit where the available path bandwidth is 1.544 Mbps, and congestion loss occurred at a sending rate of 2 Mbps (higher than the bottleneck transmission capacity due to the effect of queuing buffers within the network), then TCP would rate halve to 1 Mbps and then use congestion avoidance to increase the sending rate back to 2 Mbps. Within the selected parameters of a 70-ms RTT and 1500-byte segment size, this process involves using congestion avoidance to inflate the congestion window from 6 segments to 12. This process takes 0.42 seconds. So as long as the network can operate without packet loss for the session over an order of 1-second intervals, then TCP can comfortably operate at maximal speed in a megabit-per-second network.

What about our 10-Gbps connection? The first estimate is the amount of usable buffer space in the switching elements. Assuming a total of 256 MB of usable queue space on the network path prior to the onset of queue saturation, the TCP session operating in congestion avoidance mode will experience packet loss some 590 RTT intervals after reaching the peak transmission speed of 10 Gbps, or some further 41 seconds, at which point the TCP sending rate in congestion avoidance mode is 10.1 Gbps. For all practical purposes the TCP congestion avoidance mode causes the sawtooth oscillation of this ideal TCP session between 5.0 Gbps and 10.1 Gbps. A single iteration of this sawtooth cycle takes 2062 seconds, or 34 minutes and 22 seconds. The implication here is that the network has to be stable in terms of no packet loss along the path for time scales of the order of tens of minutes (or some billions of packets), and corresponding transmission bit error rates that are less than 10^{-14}. It also implies massive data sets to be transferred, because the amount of data passed in just one TCP congestion avoidance cycle is 1.95 terabytes (1.95×10^{12} bytes). It is also the case that the TCP session cannot make full use of the available network bandwidth, because the average data transfer rate is 7.55 Gbps under these conditions, not 10 Gbps. (See Figure 2).

Figure 2: TCP Behavior at High Speed



Clearly something is unexpected with this scenario, because it certainly looks like it is a difficult and lengthy task to fill a long-haul, high-capacity cable with data, and TCP is not behaving as expected. Although experimenting with the boundaries of TCP is in itself an interesting area of research, some practical problems here could well benefit from this type of high-speed transport.

A commonly quoted example, and certainly one of the more impressive ones is the Large Hadron Collider at CERN:

"The CERN Particle Physics lab in Geneva, Switzerland, successfully transmitted a data stream averaging 600Mbytes per second for 10 days to seven countries in Europe and the US. It was a crucial test of the computing infrastructure for the Large Hadron Collider being built at CERN. The LHC will be the most data intensive physics instrument ever built, generating 1500 Megabytes every second for a decade or more."

—*New Scientist,* 30 April 2005

TCP and the Land Speed Record

The TCP Land Speed Record was originally an informal effort to achieve record-breaking TCP transfer speeds across IP networks. The late 1980s and early 1990s saw some noted milestones, particularly with Van Jacobson's efforts in achieving sustained 10-Mbps and 45-Mbps TCP transfer speeds.

This activity has been incorporated into the Internet2 program, with the introduction of some formal rules about what constitutes a TCP Land Speed effort. In particular, the rules now have times, distances, and TCP constraints, and they call for the use of operational networks. Updates to the record have been posted frequently in recent years, and as of May 2006 the IPv4 single stream record is a TCP session operating at 7.21 Gbps for 30 minutes over 30,000 km of fibre path.

It is certainly possible to have TCP perform for sustained intervals at very high speed, as the land speed records for TCP show, but something else is happening here, and a set of preconditions need to be met before attempting to set a new record:

- First, it is good—indeed essential—to have the network path all to yourself. Any form of packet drop is a major problem here, so the best way to ensure no packets are lost is to keep the network path all to yourself.
- Secondly, it is good—indeed essential—to have a fixed latency. If the objective of the exercise is to reach a steady-state data transmission, then any change in latency, particularly a reduction in latency, has the risk of a period of oversending, which in turn has a risk of packet loss. So keep the network as stable as possible.
- Thirdly, it is good—indeed essential—to have extremely low bit error rates from the underlying transmission media. Data corruption causes checksum failure, which causes packet drop.
- Lastly, it is essential to know in advance both the round-trip latency and the available bandwidth.

You can then multiply these two numbers together (RTT and bandwidth), divide by the packet size, round down, and be sure to configure the sending TCP session to have precisely this buffer size, and the receiver to have a slightly larger size. And then start up the session.

The intention here is for TCP to use slow start to the point where the sender runs out of buffer space, at which point it will continue to sit at this buffer speed for as long as the sender, receiver and network path all remain in a stable state. For the example configuration of a 10-Gbps system with 70 ms RTT, setting a buffer limit of 116,000 packets will cause the TCP session to operate at 9.94 Gbps. As long as the latency remains steady (no jitter), with no bit errors, and as long as there is no other cross traffic, in theory this sending rate can be sustained indefinitely, with a steady stream of data packets being matched by a steady stream of ACK packets.

Of course, this situation is artificially constrained. The real concerns here with the protocol are in the manner in which it shares a network path with other concurrent sessions as well as its ability to fill the available network capacity. In other words, what would be good to see is a high-speed, high-volume version of TCP that could coexist on a network with all other forms of traffic, and, perhaps more ambitiously, that this high-speed form of TCP could share the network fairly with other traffic sessions while at the same time making maximal use of the network. The problem with TCP in its current incarnation is that it takes way too long in its additive increase mode (congestion avoidance) to recover its sustainable operating speed when operating at high speed across transcontinental-size network paths. If we want very-high-speed TCP to be effective and efficient, then we need to look at changes to TCP for high-speed operation.

High-Speed TCP

There are two basic approaches to high-speed TCP: parallelism of existing TCP, or changes to TCP to allow faster acceleration rates in a single TCP stream.

Using parallel TCP streams as a means of increasing TCP performance is an approach that has existed for some time. The original HTTP specification, for example, allowed the use of parallel TCP sessions to download each component of a Webpage (although HTTP 1.1 reverted to a sequential download model because the overheads of session startup appeared to exceed the benefits of parallel TCP sessions in this case). Another approach to high-speed file transfer through parallelism is that of GRID FTP. The basic approach is to split up the communications payload into numerous discrete components, and send each of these components simultaneously. Each component of the transfer can be between the same two endpoints (such as GRID FTP), or can be spread across multiple endpoints (as with BitTorrent).

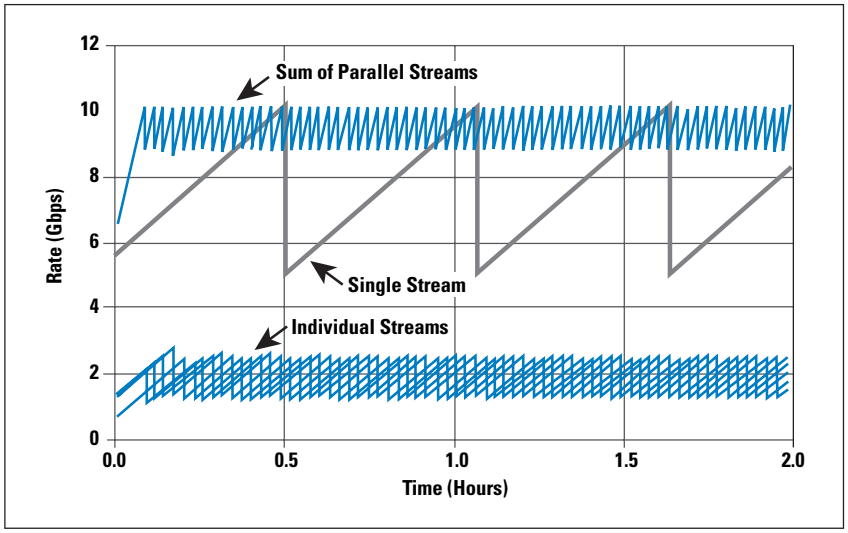
But for parallel TCP to operate correctly, we need to have already assembled all the data (or at a minimum know where all the data components are located). Where the data is being generated in real time (such as observatories or particle colliders) in massive quantities, there may be no choice but to treat the data set as a serial stream and use a high-speed transport protocol to dispatch it. In this case the task is to adjust the basic control algorithms for TCP to allow it to operate at high speed, but also to operate "fairly" on a mixed-traffic high-speed network.

Parallel TCP

Using parallelism as a key to higher speed is a common computing technique, and lies behind many supercomputer architectures. The same can apply to data transfer, where a data set is divided into numerous smaller chunks, and each component chunk is transmitted using its own TCP session. The underlying expectation here is that when using some number, *N*, of parallel TCP sessions, a single packet drop event will most probably cause the fastest of the *N* sessions to rate halve, because the fastest session will have more packets in flight in the network, and is therefore the most likely session to be impacted by a packet drop event. This session will then use congestion avoidance rate increase to recover, implying that the response to a single packet drop is reduction of the sending rate by at most $1/(2N)$. For example, using five parallel TCP sessions, the response to a single packet drop event is to reduce the total sending rate by $1/(2 \times 5)$, or 1/10, as compared to the response from a single TCP session, where a single packet drop event would reduce the sending rate by ½.

A simulated version of five parallel sessions in a 10 Gbps session is shown in Figure 3.

Figure 3: Parallel TCP Simulation: Single vs Parallel Streams



The essential characteristic of the aggregate flow is that under lossless conditions the data flow of N parallel sessions increases at a rate N times faster than a single session in congestion avoidance mode. Also the response to an isolated loss event is that of rate halving of a single flow, so that the total flow rate under ideal conditions is between R and $R \times (2N - 1)/2N$, or a long-term average throughput of $R \times (4N - 1)/4N$. For $N = 100$ our theoretical 10-Gbps connection could now operate at 9.9 Gbps.

Of course practice is different from theory, and a considerable amount of work has looked at the performance of parallel TCP under various conditions, in terms of both maximizing throughput and choosing the most efficient number of parallel active streams to use. Part of the problem is that although simple simulations, such as that used to generate Figure 4, tend to evenly distribute each of the parallel sessions to maximize the throughput, there is the more practical potential that the individual sessions self-synchronize. Because the parallel sessions have a similar range of window sizes, it is possible that at a given point in time a similar number of packets will be in the network path from each stream. If the packet drop event is a multiple packet drop event, such as a tail-drop queue, then it is entirely feasible that numerous parallel streams will experience packet loss simultaneously, and there is the consequential potential for the streams to fall into synchronization.

The two extremes, evenly distributed and tightly synchronized multiple streams, are indicated in Figure 4 The average throughput of parallel synchronized streams is the same as a single stream over extended periods in this simulation, and both are certainly far worse than an evenly distributed set of parallel streams.

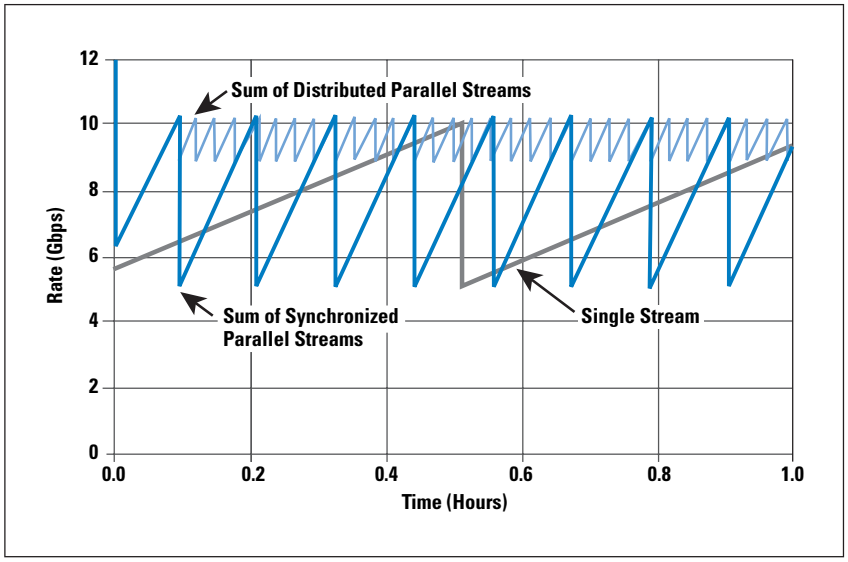


Figure 4: Comparison of Parallel TCP: Synchronized and Distributed Streams

One way to address this problem is to reunite these parallel streams into a single controlled stream that exhibits the same characteristics as evenly spread parallel streams. This approach, MulTCP, is considered in the next section.

If all this analysis of parallel TCP streams sounds a little academic and unrelated to networking today, it is useful to note that many *Internet Service Providers* (ISPs) currently see *BitTorrent* traffic as their highest-volume application. BitTorrent is a peer-to-peer protocol that undertakes transfer of datasets using a highly parallel transfer technique. Under BitTorrent the original dataset is split into blocks, each of which can be downloaded in parallel. The subtle twist here is that the individual sessions do not have the same source points, and the host may take feeds from many different sources simultaneously, as well as offering itself as a feed point for the already downloaded blocks. This behavior exploits the peer-to-peer nature of these networks to a very high extent, potentially not only exploiting parallel TCP sessions for speed gains, but also exploiting diverse network paths and diverse data sources to avoid single path congestion. Considering its effectiveness in terms of maximizing transfer speeds for high-volume datasets and its relative success in truly exploiting the potential of peer-to-peer networks—and of course the dramatic acceptance of BitTorrent and its extensive use—BitTorrent probably merits closer examination, but perhaps that is for another time and an article of its own.

Very High Speed Serial TCP

The other general form of approach is to reexamine the current TCP control algorithm to see if there are parameter or algorithm changes that could allow TCP to undertake a better form of rate adaptation to these high-capacity, long-delay network paths. The aim here is to achieve a good congestion response algorithm that does not amplify transient congestion conditions into sustained disaster areas, while at the same time being able to support high-speed data transfers, thereby making effective use of all available network capacity.

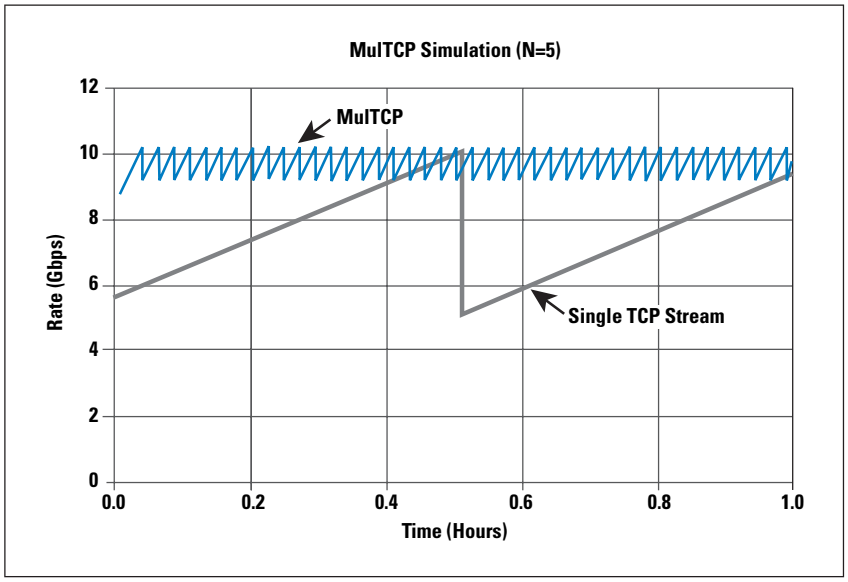
We also want TCP to behave sensibly in the face of other TCP sessions, so that it can share the network with other TCP sessions fairly.

MulTCP

The first of these approaches is *MulTCP*[1], which is a single TCP stream that behaves in a manner equivalent to *N* parallel TCP sessions, where the virtual sessions are evenly distributed in order to achieve the optimal outcome in terms of throughput. The essential changes to TCP are in congestion avoidance mode and the reaction of packet loss. In congestion avoidance mode MulTCP increases its congestion window by *N* segments per RTT, rather than the default of a single segment. Upon packet loss, MulTCP reduces its window by W/(2*N*), rather than the default of W/2. MulTCP uses a slightly different version of slow start, increasing its window by 3 segments per received ACK, rather than the default value of 2.

MulTCP represents a simple change to TCP that does not depart radically from the TCP congestion control algorithm. Of course when choosing an optimal value for *N*, some understanding of the network characteristics would help. If the value for *N* is too high, the MulTCP session has a tendency to claim an unfair amount of network capacity, but if the value is too low, it does not necessarily take full advantage of available network capacity. Figure 5 shows MulTCP compared to a simulation of an equivalent number of parallel TCP streams and a single TCP stream (*N* = 5 in this particular simulation).

Figure 5: MulTCP



Good as this is, there is the lingering impression that we can do better. It would be better not to have to configure the number of virtual parallel sessions; it would be better to support fair outcomes when competing with other concurrent TCP sessions over a range of bandwidths; and it would be better to have a wide range of scaling properties.

There is no shortage of options here for fine-tuning various aspects of TCP to meet some of these preferences, ranging from adaptations applied to the TCP rate control equation to approaches that view the loading onto the network as a power spectrum problem.

HighSpeed TCP

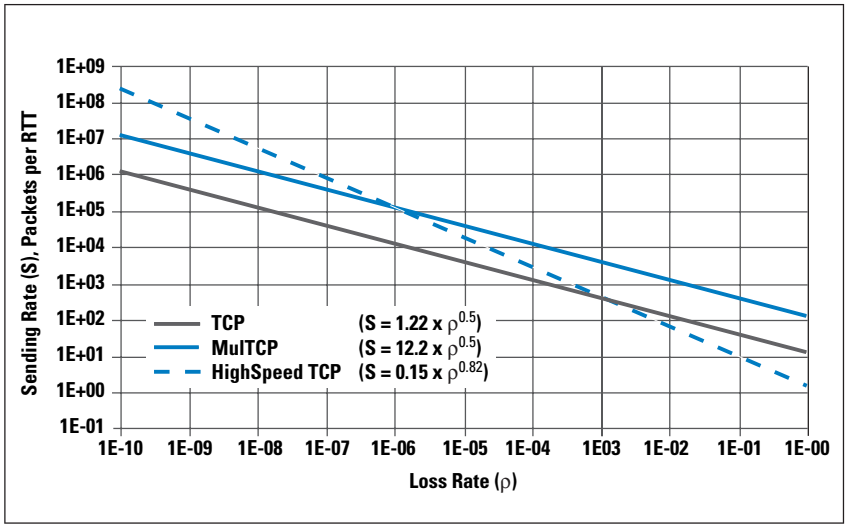
Another approach, described in [2], "HighSpeed TCP for Large Congestion Windows" looks at this from the perspective of the TCP rate equations, developed by Sally Floyd at ICIR.

When TCP operates in congestion avoidance mode at an average speed of W packets per RTT, then the number of packets per RTT varies between $(2/3)W$ and $(4/3)W$. Each cycle takes $(2/3)W$ RTT intervals, and the number of packets per cycle is therefore $(2/3)W^2$ packets. This result implies that the rate can be sustained at W packets per RTT as long as the packet loss rate is 1 packet loss per cycle, or a loss rate, ρ, where $\rho = 1/((2/3)W^2)$. Solving this equation for W gives the average packet rate per RTT of $W = \sqrt{(1.5)}/\sqrt{(\rho)}$. The general rate function for TCP, R, is therefore: $R = (\text{MSS/RTT}) \times (\sqrt{(1.5)}/\sqrt{(\rho)})$, where MSS is the TCP packet size.

Taking this same rate equation approach, what happens for N multiple streams? The ideal answer is that the parallel streams operate N times faster at the same loss rate, or, as a rate equation the number of packets per RTT, W_N, can be expressed as $W_N = N((\sqrt{(1.5)}/\sqrt{(\rho)})$, and each TCP cycle is compressed to an interval of $(2/3)$ (W_N^2/N^2).

But perhaps the desired response is not to shift the TCP rate response by a fixed factor of N—as is the intent with MulTCP—but to adaptively increase the sending rate through increasing values of N as the loss rate falls. The proposition made by HighSpeed TCP is to use a TCP response function that preserves the fixed relationship between the logarithm of the sending rate and the logarithm of the packet loss rate, but alters the slope of the function, such that TCP increases its congestion avoidance increment as the packet loss rate falls. This relationship is shown in Figure 6 where the log of the sending rate is compared to the log of the packet loss rate. MulTCP preserves the same relationship between the log of the sending rate and the log of the packet loss rate, but alters the offset, whereas changing the value of the exponent of the packet loss rate causes a different slope in the rate equation.

Figure 6: TCP Response Functions



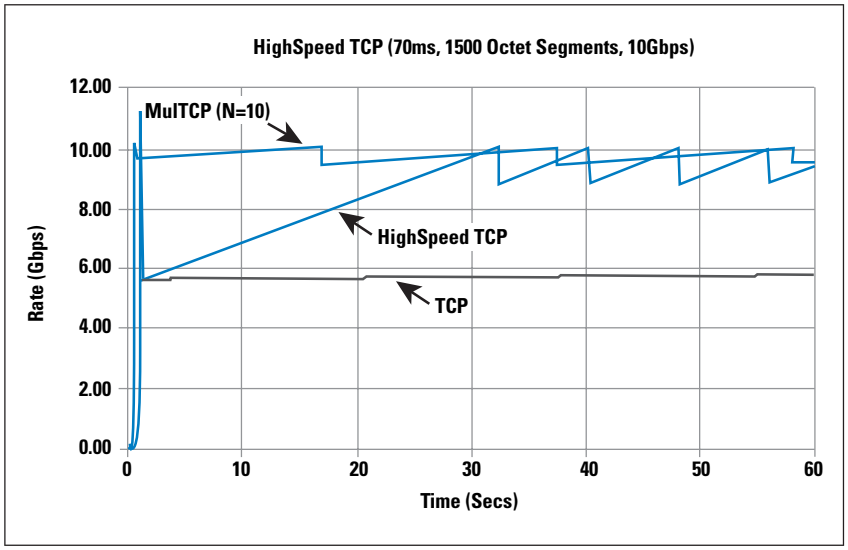
One way to look at the HighSpeed TCP proposal is that it operates in the same fashion as a turbocharger on an engine; the faster the engine is running, the higher the turbo-charged boost to the normal performance of the engine. Below a certain threshold value the TCP congestion avoidance function is unaltered, but when the packet loss rate falls below a certain threshold value then the higher speed congestion avoidance algorithm is invoked. The higher-speed rate equation proposed by HighSpeed TCP is based on achieving a transfer rate of 10 Gbps over a 100-ms latency path with a packet loss rate of 1 in 10 million packets. Working backward from these parameters gives us a rate equation for *W*, the number of packets per RTT interval of $W = 0.12/\rho^{0.835}$, approximately equivalent to a MulTCP session where the number of parallel sessions, *N*, is raised as the TCP rate increases.

This result can be translated into two critical parameters for a modified TCP: the number of segments to be added to the current window size for each lossless RTT time interval, and the number of segments to reduce the window size in response to a packet loss event. Conventional TCP uses values of 1 and (½)*W*, respectively. The HighSpeed TCP approach increases the congestion window by 1 segment for TCP transfer rates up to 10 Mbps, but then uses an increase of some 6 segments per RTT for 100 Mbps, 26 segments at 1 Gbps and 70 segments at 10 Gbps. In other words the faster the TCP rate that has already been achieved, then the greater the rate acceleration. Highspeed TCP also advocates a smaller multiplicative decrease in response to a single packet drop, so that at 10 Mbps the multiplier would be ½, at 100 Mbps the multiplier is 1/3, at 1 Gbps it is 1/5, and at 10 Gbps it is set to 1/10.

What does this process look like? Figure 7 shows a HighSpeed TCP simulation. What is not easy to discern is that during congestion avoidance HighSpeed TCP opens its sending window in increments of 53 through 64 segments each RTT interval, making the rate curve slightly upward during this window expansion phase.

HighSpeed TCP manages to recover from the initial rate halving from slow start in about 30 seconds, and operates at an 8-second cycle, as compared to the 38-minute cycle of a single TCP stream, or a 10-stream MulTCP session that operates at a 21-second cycle.

Figure 7: HighSpeed TCP Simulation



One other aspect of this work concerns the so-called slow start algorithm, which at these speeds is not really slow at all. The final RTT interval in our scenario has TCP attempting to send an additional 50 MB of data in just 70 ms, meaning an additional 33,333 packets are pushed into the network queues. Unless the network path is completely idle at this point, it is likely that hundreds—if not thousands—of these packets will be dropped in this step, pushing TCP back into a restart cycle. HighSpeed TCP has proposed a limited slow start to accompany HighSpeed TCP that limits the inflation of the sending window to a fixed upper rate per RTT to avoid this problem of slow start overwhelming the network and causing the TCP session to continually restart. Other changes for HighSpeed TCP are to extend the limit of three duplicate ACKs before retransmitting to a higher value, and a smoother recovery when a retransmitted packet is itself dropped.

Scalable TCP

Of course HighSpeed TCP is not the only offering in the high-performance TCP stakes.

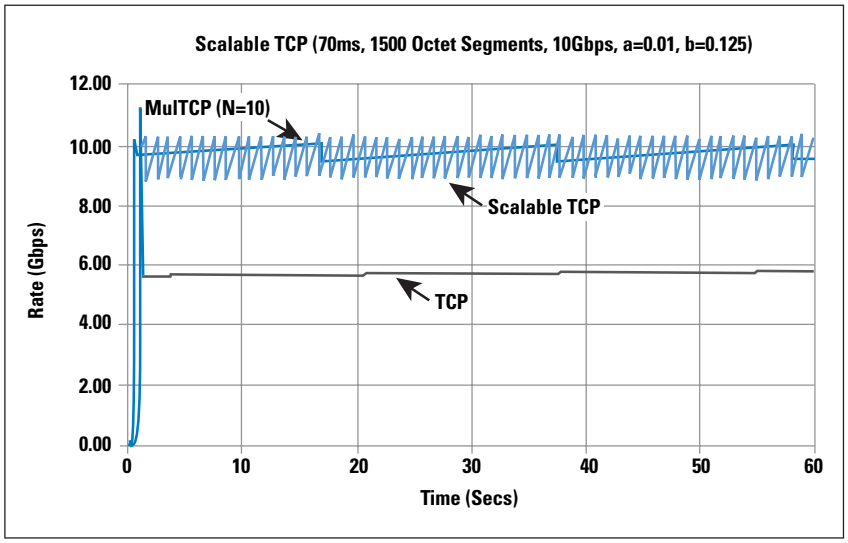
Scalable TCP[3], developed by Tom Kelly at Cambridge University, attempts to break the relationship between TCP window management and the RTT time interval. It does this by noting that in "conventional" TCP, the response to each ACK in congestion avoidance mode is to inflate the sender's congestion window size *(cwnd)* by *(1/cwnd)*, thereby ensuring that the window is inflated by 1 segment each RTT interval. Similarly the window halving on packet loss can be expressed as a reduction in size by *(cwnd/2)*. Scalable TCP replaces the additive function of the window size by the constant value *a*.

The multiplicative decrease is expressed as a fraction *b*, which is applied to the current congestion window size.

In Scalable TCP, for each ACK the congestion window is inflated by the constant value *a*, and upon packet loss the window is reduced by the fraction *b*. The relative performance of Scalable TCP as compared to conventional TCP and MulTCP is shown in Figure 8.

The essential characteristic of Scalable TCP is the use of a multiplicative increase in the congestion window, rather than a linear increase, effectively creating a higher frequency of oscillation of the TCP session, probing upward at a higher rate and more frequently than HighSpeed TCP or MulTCP. The frequency of oscillation of Scalable TCP is independent of the RTT interval, and the frequency can be expressed as $f = log(1 - b) / log(1 + a)$. In this respect, longer networks paths exhibit similar behavior to shorter paths at the bottleneck point. Scalable TCP also has a linear relationship between the log of the packet loss rate and the log of the sending rate, with a greater slope of HighSpeed TCP.

Figure 8: Scalable TCP



BIC and CUBIC

The common concern here is that TCP underperforms in those areas of application where there is a high bandwidth-delay product. The common problem observed here is that the additive window inflation algorithm used by TCP can be very inefficient in long-delay, high-speed environments. As can be seen in Figure 10, the ACK response for TCP is a congestion window inflation operation where the amount of inflation of the window is a function of the current window size and some additional scaling factor.

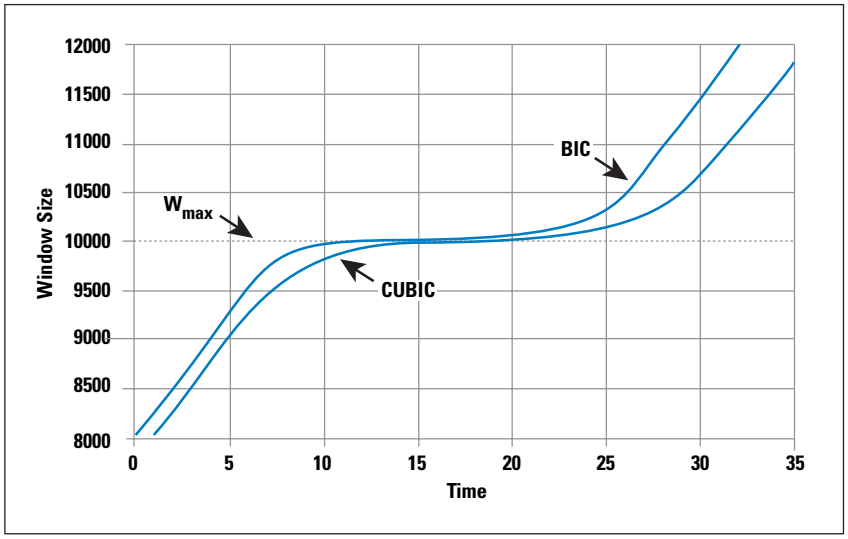
Binary Increase Congestion Control (BIC)[4] takes a different view, by assuming that TCP is actively searching for a packet sending rate that is on the threshold of triggering packet loss, and uses a binary chop search algorithm to achieve this efficiently.

When BIC performs a window reduction in response to packet drop, it remembers the previous maximum window size, as well as the current window setting. With each lossless RTT interval BIC attempts to inflate the congestion window by one half of the difference between the current window size and the previous maximum window size. In this way BIC quickly attempts to recover from the previous window reduction, and, as BIC approaches the old maximum value, it slows down its window inflation rate, halving its rate of window inflation each RTT. This process is not quite as drastic as it may sound, because BIC also uses a maximum inflation constant to limit the amount of rate change in any single RTT interval. The resultant behaviour is a hybrid of a linear and a non-linear response, where the initial window inflation after a window reduction is a linear increase, but as the window approaches the previous point where packet loss occurred the rate of window increase slows down. BIC uses the complementary approach to window inflation when the current window size passes the previous loss point. Initially further window inflation is small, and the size of the window inflation value doubles for each RTT, up to a limit value, beyond which the window inflation is once more linear.

BIC can be too aggressive in low RTT networks and in slower speed situations, leading to a refinement of BIC, namely CUBIC[5]. CUBIC uses a third-order polynomial function to govern the window inflation algorithm, rather than the exponential function used by BIC. The cubic function is a function of the elapsed time since the previous window reduction, rather than the implicit use by BIC of an RTT counter, so that CUBIC can produce fairer outcomes in a situation of multiple flows with different RTTs. CUBIC also limits the window adjustment in any single RTT interval to a maximum value, so the initial window adjustments after a reduction are linear. Here the new window size, W, is calculated as $W = C(t - K)^3 + W_{max}$, where C is a constant scaling factor, t is the elapsed time since the last window reduction event, W_{max} is the size of the window prior to the most recent reduction and K is a calculated value: $K = (W_{max} \beta / C)1/3$. This function is more stable when the window size approaches the previous window size W_{max}. The use of a time interval rather than an RTT counter in the window size adjustment is intended to make CUBIC more sensitive to concurrent TCP sessions, particularly in short RTT environments.

Figure 9 shows the relative adjustments for BIC and CUBIC, using a single time base. The essential difference between the two algorithms is evident in that the CUBIC algorithm attempts to reduce the amount of change in the window size when near the value where packet drop was previously encountered.

Figure 9: Window Adjustment for BIC and CUBIC



Westwood

The "steady state" mode of TCP operation is one that is characterized by the "sawtooth" pattern of rate oscillation. The additive increase is the means of exploring for viable sending rates while not causing transient congestion events by accelerating the sending rate too quickly. The multiplicative decrease is the means by which TCP reacts to a packet loss event that is interpreted as being symptomatic of network congestion along the sending path.

BIC and CUBIC concentrate on the rate increase function, attempting to provide for greater stability for TCP sessions as they converge to a long-term available sending rate. The other perspective is to examine the multiplicative decrease function, to see if there is further information that a TCP session can use to modify this rate decrease function.

The approach taken by Westwood[6], and a subsequent refinement, Westwood+[7], is to concentrate on the halving by TCP of its congestion window in response to packet loss (as signaled by three duplicate ACK packets). The conventional TCP algorithm of halving the congestion window can be refined by the observation that the stream of return ACK packets actually provides an indication of the current bottleneck capacity of the network path, as well as an ongoing refinement of the minimum RTT of the network path. The Westwood algorithm maintains a bandwidth estimate by tracking the TCP acknowledgement value and the inter-arrival time between ACK packets in order to estimate the current network path bottleneck bandwidth. This technique is similar to the "Packet Pair" approach, and that used in the TCP Vegas. In the case of the Westwood approach the bandwidth estimate is based on the receiving ACK rate, and is used to set the congestion window, rather than the TCP send window. The Westwood sender keeps track of the minimum RTT interval, as well as a bandwidth estimate based on the return ACK stream. In response to a packet loss event, Westwood does not halve the congestion window, but instead sets it to the bandwidth estimate times the minimum RTT value.

If the current RTT equals the minimum RTT, implying that there are no queue delays over the entire network path, then the sending rate is set to the bandwidth of the network path. If the current RTT is greater than the minimum RTT, the sending rate is set to a value that is lower than the bandwidth estimate, and allows for additive increase to once again probe for the threshold sending rate when packet loss occurs.

The major concern here is the potential variation in inter-ACK timing, and although Westwood uses every available data and ACK pairing to refine the current bandwidth estimate, the approach also uses a low pass filter to ensure that the bandwidth estimate remains relatively stable over time. The practical result here is that the receiver may be performing some form of ACK distortion, such as a delayed ACK response, and the network path contains jitter components in both the forward and reverse direction, so that ACK sequences can arrive back at the sender with a high variance of inter-ACK arrival times. Westwood+ further refines this technique to account for a false high reading of the bandwidth estimate due to ACK compression, using a minimum measurement interval of the greater of the RTT or 50 ms.

The intention here is to ensure that TCP does not over-correct when it reduces its congestion window, so that the problems relating to the slow inflation rate of the window are less critical for overall TCP performance. The critical part of this work lies in the filtering technique that takes a noisy sequence of measurement samples and applies an anti-aliasing filter followed by a low-pass discrete-time filter to the data stream in order to generate a reasonably accurate available bandwidth estimate. This estimate is coupled with the minimum RTT measurement to provide a lower bound for the TCP congestion window setting following detection of packet loss and subsequent fast retransmit repair of the data stream. If the packet loss is caused by network congestion the new setting will be lower than the threshold bandwidth (lower by the ratio RTT_{min} / $RTT_{current}$), so that the new sending rate will also allow the queued backlog of traffic along the path to clear. If the packet loss is caused by media corruption, the RTT value will be closer to the minimum RTT value, in which case the TCP session-rate backoff is smaller, allowing for a faster recovery of the previous data rate.

Although this approach has direct application in environments where the probability of bit-level corruption is intermittently high, such as often encountered with wireless systems, it also has some application to the long-delay, high-speed TCP environment. The rate backoff of TCP Westwood is one that is based on the RTT_{min} / $RTT_{current}$ ratio, rather than rate halving in conventional TCP, or a constant ratio, such as used in MulTCP, allowing the TCP session to oscillate its sending rate closer to the achievable bandwidth rather than performing a relatively high-impact rate backoff in response to every packet loss event.

H-TCP

The observation made by the proponents of H-TCP[9] is that better TCP outcomes on high-speed networks is achieved by modifying TCP behavior to make the time interval between congestion events smaller. The signal that TCP has taken up its available bandwidth is a congestion event, and by increasing the frequency of these events TCP will track this resource metric with greater accuracy. To achieve this tracking, the H-TCP proponents argue that both the window increase and decrease functions may be altered, but in deciding whether to alter these functions, and in what way, they argue that a critical factor lies in the level of sensitivity to other concurrent network flows, and the ability to converge to stable resource allocations to various concurrent flows.

> "While such modifications might appear straightforward, it has been shown that they often negatively impact the behaviour of networks of TCP flows. High-speed TCP and BIC-TCP can exhibit extremely slow convergence following network disturbances such as the start-up of new flows; Scalable-TCP is a multiplicative-increase multiplicative-decrease strategy and as such it is known that it may fail to converge to fairness in drop-tail networks."
>
> Work-in-progress: **`draft-leith-tcp-htcp-01.txt`**

H-TCP argues for minimal changes to the window control functions, observing that in terms of fairness a flow with a large congestion window should, in absolute terms, reduce the size of their window by a larger amount that smaller-sized flows, as a means of readily establishing a dynamic equilibrium between established TCP flows and new flows entering the same network path.

H-TCP proposes a timer-based response function to window inflation, where for an initial period, the existing value of one segment per RTT is maintained, but after this period the inflation function is a function of the time since the last congestion event, using an order-2 polynomial function where the window increment in each RTT interval, $\alpha = (\frac{1}{2}T2 + 10T + 1)$, where T is the elapsed time since the last packet loss event. This equation is further modified by the current window reduction factor β where $\alpha' = 2 \times (1 - \beta) \times \alpha$.

The window reduction multiplicative factor, β, is based on the variance of the RTT interval , and β is set to RTT_{min} / RTT_{max} for the previous congestion interval, unless the RTT has a variance of more than 20 percent, in which case the value of ½ is used.

H-TCP appears to represent a further step along the evolutionary path for TCP, taking the adaptive window inflation function of HighSpeed TCP, using an elapsed timer as a control parameter as was done in Scalable TCP, and using the RTT ratio as the basis for the moderation of the window reduction value from Westwood.

FAST

FAST[10] is another approach to high-speed TCP. FAST is probably best viewed in context in terms of the per packet response of the various high speed TCP approaches, as indicated in the following Control and Response table:

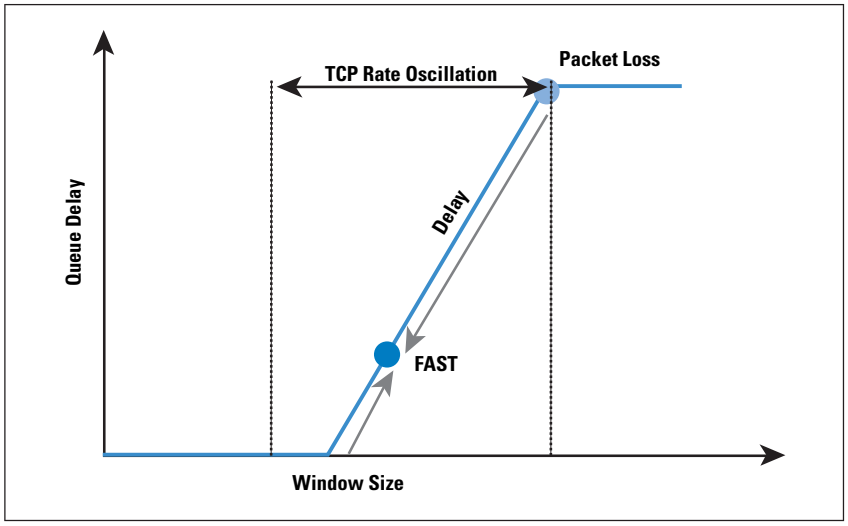
Type	Control Method	Trigger	Response
TCP	AIMD(1,0.5)	ACK response Loss response	W = W + 1/W W = W – W × 0.5
MulTCP	AIMD(N,1/2N)	ACK response Loss response	W = W + N/W W = W – W × 1/2N
HighSpeed TCP	AIMD(a(w), b(w))	ACK response Loss response	W = W + a(W)/W W = W – W × b(W)
Scalable TCP	MIMD(1/100, 1/8)	ACK response Loss response	W = W + 1/100 W = W – W × 1/8
FAST	RTT Variation	RTT	W = W × (base RTT/RTT) + α

All these approaches share a common structure of window adjustment, where the sender's window is adjusted according to a control function and a flow gain. TCP, MulTCP, HighSpeed TCP, Scalable TCP, BIC, CUBIC, Westwood, and H-TCP all operate according to a congestion measure that is based on ACK clocking and a packet loss trigger. What is happening in these models is that a bottleneck point on the network path has reached a level of saturation such that the bottleneck queue is full and packet loss is occurring. It is noted that the build up of the queue prior to packet loss would have caused a deterioration of the RTT.

This fact leads to the observation made by FAST, that another form of congestion signalling is one that is based on RTT variance, or cumulative queuing delay variance. FAST is based on this latter form of congestion signalling.

FAST attempts to stabilize the packet flow at a rate that also stabilizes queue delay, by basing its window adjustment, and therefore its sending rate, such that the RTT interval is stabilized. The window response function is based on adjusting the window size by the proportionate amount that the current RTT varies from the average RTT measurement. If the current RTT is lower than the average, then window size is increased, and if the current RTT is higher then window size is decreased. The amount of window adjustment is based on the proportionate difference between the two values, leading to the observation that FAST exponentially converges to a base RTT flow state. By comparison, conventional TCP has no converged state, but instead oscillates between the rate at which packet loss occurs and some lower rate (Figure 10).

Figure 10: TCP Response Function vs. FAST



FAST maintains an exponential weighted average RTT measurement and adjusts its window in proportion to the amount by which the current RTT measurement differs from the weighted average RTT measurement. It is harder to provide a graph of a simulation of FAST as compared to the other TCP methods, and the more instructive material has been gathered from various experiments using FAST.

XCP — End-to-End and Network Signalling

It is possible to also call in the assistance of the routers on the path and call on them to mark packets with signaling information relating to current congestion levels. This approach was first explored with the concept of ECN, or *Explicit Congestion Notification*, and has been generalized into a transport flow control protocol, called XCP,[11] where feedback relating to network load is based on explicit signals provided by routers relating to their relative sustainable load levels. Interestingly this digresses from the original design approach of TCP, where the TCP signaling is set up as effectively a heartbeat signal being exchanged by the end systems, and the TCP flow control process is based upon interpretation of the distortions of this heartbeat signal by the network.

XCP appears to be leading into a design approach where the network switching elements play an active role in end-to-end flow control, by effectively signalling to the end systems the current available capacity along the network path. This setup allows the end systems to respond rapidly to available capacity by increasing the packet rate to the point where the routers along the path signal that no further capacity is available, or to back off the sending rate when the routers along the path signal transient congestion conditions.

Whether such an approach of using explicit router-to-end host signals leads to more efficient very high-speed transport protocols remains to be determined, however.

Where Next?

The basic question here is whether we have reached some form of fundamental limitation of the TCP window-based congestion control protocol, or whether it is a case that the window-based control system remains robust at these speeds and distances, but that the manner of control signalling will evolve to adapt to an ever-widening range of speed extremes in this environment.

Rate-based pacing, as used in FAST can certainly help with the problem of the problem of guessing what are "safe" window inflation and reduction increments, and it is an open question as to whether it is even necessary to use a window inflation and deflation algorithm or whether it would be more effective to head in other directions, such as rate control, RTT stability control or adding additional network-generated information into the high-speed control loop. Explicit router-based signaling, such as described in XCP, allows for quite precise controls over the TCP session, although what is lost there is the adaptive ability to deploy the control system over any existing IP network.

However, across all these approaches, the basic TCP objectives remain the same: what we want is a transport protocol that can use the available network capacity as efficiently as possible—and as quickly as possible—minimizing the number of retransmissions and maximizing the effective data throughput.

We also want a protocol that can adapt to other users of the network, and attempt to fairly balance its use with competing claims for network resources.

The various approaches that have been studied to date all represent engineering compromises in one form or another. In attempting to optimize the instantaneous transfer rate the congestion control algorithm may not be responsive to other concurrent transport sessions along the same path. Or in attempting to optimize fairness with other concurrent sessions, the control algorithm may be unresponsive to available network path capacity. The control algorithm may be very unresponsive to dynamic changes in the RTT that may occur during the session because of routing changes in the network path. Which particular metrics of TCP performance are critical in a heterogeneous networking environment is a topic where we have yet to see a clear consensus emerging from the various research efforts.

However, we have learned a few things about TCP that form part of this consideration of where to take TCP in this very-high-speed world:

- The first lesson is that TCP has been so effective in terms of overall network efficiency and mutual fairness because everyone uses much the same form of TCP, with very similar response characteristics. If we all elected to use radically different control functions in each of our TCP implementations then it appears likely that we would have a poorly performing chaotic network subject to extended conditions of complete overload and inefficient network use.

- The second lesson is that a transport protocol does not need to solve media level or application problems. The most general form of transport protocol should not rely on characteristics of specific media, but should use specific responses from the lower layers of the protocol stack in order to function correctly as a transport system.
- The third lesson from TCP is that a transport protocol can become remarkably persistent and be used in contexts that were simply not considered in the original protocol design, so any design should be careful to allow generous margins of use conditions.
- The final lesson is one of fair robustness under competition. Does the protocol negotiate a fair share of the underlying network resource in the face of competing resource claims from concurrent transport flows?

Of all these lessons, the first appears to be the most valuable and probably the most difficult to put into practice. The Internet works as well as it does today largely because we all use the much same transport control protocol. If we want to consider some changes to this control protocol to support higher-speed flows over extended latency, then it would be perhaps reasonable to see if there is a single control structure and a single protocol that we can all use.

So deciding on a single approach for high-speed flows in the high-speed Internet is perhaps the most critical part of this entire agenda of activity. It is one thing to have a collection of differently controlled packet flows each operating at megabits-per-second flow rates on a multi-gigabit network, but it is quite a frightening prospect to have all kinds of different forms of flows each operating at gigabits per second on the same multigigabit network. If we cannot make some progress in reaching a common view of a single high-speed TCP control algorithm then it may indeed be the case that none of these approaches will operate efficiently in a highly diverse high-speed network environment.

Acknowledgment

I must acknowledge the patient efforts of Larry Dunn in reading through numerous iterations of this article, correcting the text and questioning some of my wilder assertions. Thanks Larry.

However, whatever errors may remain are, undoubtedly, all mine.

Further Reading

There is a wealth of reading on this topic, and here any decent search engine can assist. However if you are interested in this topic and want a starting reference that describes it in a very careful and structured manner, then I can recommend the following two sources as a good way to start exploring this topic to gain an overview of the current state of the art in this area:

- "HighSpeed TCP for Large Congestion Windows," S. Floyd, RFC 3649, December 2003.

  Floyd's treatment of this topic is precise, encompassing, and wonderfully presented. If only all RFCs were of this quality.

- Proceedings of the Workshops on Protocols for Fast Long-Distance Networks.

  These workshops have been held in:

How Instant Messaging Is Transforming the Enterprise Network

by David Strom

Instant Messaging (IM) has come of age and is close to becoming one of those protocols that offers something for everyone. Once the province of chatty teens looking to replace phone conversations with electronic ones, IM is now a corporate mainstay and part of a new breed of applications that are built around "presence detection," the ability to determine when someone—or something—is online and available to communicate.

Indeed, IM is rapidly spreading across the corporate world and becoming an able replacement for overflowing voicemail and e-mail inboxes that are clogged with spam and buried in irrelevant and non-time-sensitive postings. If you must get through to a busy corporate executive, IM is becoming the fastest and most effective method of communicating. Move over CrackBerry.

IM offers several benefits today, having taken some lessons learned by other Internet protocols of the past. First, it has a solid user and developer base. Second, it has a relatively simple building-block structure like the best of Internet protocols, with well-defined clients and servers. Third, interoperability efforts are beginning to pay off among the leading independent and private IM systems. Fourth, open-source rules are making inroads in all the right places. Fifth, Microsoft is a friend (for once) of IM and helping matters—rather than playing its usual monopolist role in this space, the company is actually encouraging future developments and interoperability. Finally, a new collection of advanced applications is taking hold that will take advantage of the existing Internet and IM infrastructure and create some very sophisticated IM applications.

Let's examine more closely where IM originated, where it is going, and what the specific implications are for each of these developments and for networking professionals. As a warning, this article by its very nature takes some positions on products and vendors. These opinions are solely those of the author, and they represent nothing wider or more inclusive.

User Base

The IM servers are operated by either public network or private entities. The major difference between the two is that the public systems operate across the Internet and can be accessed by any users who download the appropriate client software and create their own identity. Message traffic is usually transmitted in plaintext and without any encryption whatsoever.

The private IM systems are usually maintained by a corporate IT department and operate behind firewalls; they offer message encryption, message retention, and archiving; prepopulated buddy lists that are integrated into the corporate authentication and directory servers; and better security and privacy that are specific to a particular set of corporate users. These private systems are not available to the public and are designed strictly for employee communications or communications among particular trading partners of the corporation

The four most popular public IM systems are currently all in corporate hands: Microsoft, Yahoo, eBay/Skype, and AOL. Actually, we should make that five systems because AOL owns two separate networks, *AOL Instant Messenger* (AIM) and *I seek you* (ICQ). Introduced in November 1996, ICQ was actually the first general-purpose IM system combining presence or a list of contacts with the ability to send messages. Other popular systems include the open-source Jabber and Tencent QQ, the latter very popular in China. Estimates vary widely as to the total number of nonduplicated users—because many people have multiple accounts and use multiple systems—but it is safe to say that more than 150 million users are active across all these systems at any moment. The most recent estimates of active users are as follows:[1]

IM System	Estimate of Active Users
AIM	53 million active users
ICQ	15 million active users
Skype	10 million active users
MSN Messenger	29 million active users
Yahoo Messenger	21 million active users
Jabber	13.5 million enterprise users
Tencent QQ	10 million active users

Why IM Is So Popular for Businesses

But these numbers are more about individuals using IM. They hide the real story over the past several years, the rise of IM as a solid enterprise communications tool. Corporate IM usage has skyrocked the last several years, and one survey has found IM users in more than 50 percent of American corporations[2]. As mentioned earlier, there are public and private IM systems. The vast majority of the private IM systems are for institutional use for communications inside a company or among several suppliers, customers, and other trading partners.

The largest players in the private IM space are Microsoft Office Live Communications Server and IBM/Lotus' Sametime, although Jabber Corporation (not to be confused with the Jabber Software Foundation) is also gaining a strong following. We will discuss more about the role of open source in a moment, but first let's examine the reasons why IM has become so popular among so many business users.

First, workers have become more mobile and more difficult to track down. As secretarial support disappears and voicemail becomes more the norm, you want to know when people are actually at their desk—or laptop—these days. Staffs are more far-flung, and the global village becomes a lot smaller when you use IM to "talk" to someone halfway across the planet and get an immediate response. Finding someone who is available requires more than just making a phone call or exchanging e-mail messages. IM automatically tells you who is available—and who is not—at any given hour of the day.

Second, e-mail is no longer the productivity tool it once was because pipes are clogged with spam, viruses, and phishing attacks. Getting a quick response—that is, within minutes—through e-mail now seems so quaint, so "last year."

Third, IM enables better collaboration and a tighter sense of community. With IM, you can educate an entire team, give the team feedback in real time, develop relationships, and cement the team together. It is a nice antidote and countermeasure to connect all these home-based and remote workers.

Fourth, the next generation of IM is not just about text chats; it also offers solid integration with voice and video. Voice and video calling is now part of Microsoft, Yahoo, Apple, and AOL IM software as well as part of the Skype network, which pioneered the feature. These audio and video extensions are becoming more popular with the private Lotus and Microsoft systems as well.

Finally, the real-time features of IM and its ability to track someone down no matter where they are located are attractive to customers, partners, and suppliers that need a guaranteed method of communication. IM is becoming the critical technology ingredient for corporations that are looking for faster response times, tying their customers closer together, and enabling teleworkers to communicate across the globe.

Components

Following are some definitions and explanations for those unfamiliar with the world of IM. Every IM network is composed of clients, servers, and protocols to connect them.

Each IM client has three major pieces:

A buddy list or roster of friends with whom you wish to communicate—The list is organized by groups that you specify, such as "friends," "work colleagues," "family," and so forth. The list indicates who is online, who is available to talk to, and who is offline or blocked by the user from communicating. Users organize their buddies in different ways and have complete control over the categories, naming conventions, and the like.

A separate window that shows the text chats in process—Users type in this window and view the responses of their correspondents.

Any additional features for video and audio chats and for file transfers between users

The last item bears some further discussion. All major IM products are moving beyond their roots of simple text chats toward more integrated and sophisticated communications, including real-time voice and video calls. Indeed, the mixture of *Voice over IP* (VoIP) and IM is a potent and popular one, accounting for the rapid uptake in Skype's adoption around the world. To use Skype as an example (although Yahoo has begun offering similar phone calling features in its IM client, and the others are soon to follow), users can make phone calls to the land-line phone numbers for a few pennies per minute—even calls to numbers in other countries. This is part of its attraction, along with voice mailboxes that are attached to a particular IM username.

The IM server maintains the directory of user accounts and keeps track of who is online, and in most cases routes messages among users. The major difference between an IM server and a *Simple Mail Transfer Protocol* (SMTP) e-mail server is that the IM server operates in real time, sending messages back and forth between two users as they finish typing a line of text. The servers also pass information in real time as to the availability of various users in the directory, when they come online and change their "status" message.

Users can typically set their availability in one of many different modes:

Online and ready to receive messages

Away from the computer, in which case correspondents receive a message saying so (or whatever the user wishes to be displayed)

Unavailable or offline

Blocked from anyone's view for privacy reasons

This status message can be changed at the user's discretion and is one of the main attractions for teens and other hypercommunicators. You can actually track what people are doing (or at least, saying that they are doing), by monitoring their status messages. (I am at the beach, I am taking a nap, I am at lunch, I am having coffee, and so forth.) For my teenaged daughter, this is one way she documents her life and one way that her friends can keep track of her—having a cell phone is not enough! There are numerous third-party add-ins to enhance your away message with clever graphics, hyperlinks to various Websites, and other effluvia as well.

The combination of instant access and persistent status indicator is at the core of why IM is such a powerful application. In a single window on your computer, you have a list of all your correspondents and can quickly determine who is online and who is not.

The blocking ability for some systems works universally, meaning that your presence is cloaked for everyone, as well as for specific users that you do not wish to communicate with or know your particular status, such as ex-spouses or ex-colleagues.

In most IM networks, you can be signed on from only one computer at any given moment. If you attempt to sign on from a second machine, you get an error message or your first computer is automatically logged out of the system. This is one way for the network to keep track of where you are located, because you can be in only one place at any given time.

Each server uses the TCP/IP Internet infrastructure and communicates with its clients over an assigned port number across the Internet. These ports can be blocked or proxied to different numbers, depending on the network administrator's policies toward IM traffic. Typical port numbers follow:

IM System	Port Numbers
ICQ	4000
AIM	5190–3
XMPP	5222–3
MSNP (Microsoft)	1863
YMSG (Yahoo)	5050
Skype	80, 443, and others

Notice an interesting thing about Skype's protocol: there is no single assigned port number. Users can set one of the ports in its configuration settings, but Skype uses a series of ports to communicate.[3] This setup suggests several concerns, which we address next.

The Dark Side

Although these are all compelling reasons for the rise of IM across the corporate network, all is not constructive with IM. This section discusses problems specifically germane to Skype and problems with all IM products in general.

When the Skype client is installed on a computer, it picks a random port to communicate with other Skype computers, using what is believed to be a form of *Request for Comments* (RFC) 3489[4]. This process is similar to many network-based games and peer-to-peer file-sharing products—no surprise because the developers of Skype worked on the Kazaa music file-sharing software. Because of its programming model, Skype is adept at traversing *Network Address Translation* (NAT) routers and can usually find a communications path to the outside world. Skype also encrypts all its message traffic, and this fact coupled with random port usage and its peer-to-peer programming model makes it look very similar to some malicious code that is unleashed across your network.

This is part of its charm and its challenge: network administrators who want to block Skype usage usually have a very difficult time figuring out how to do so[5], and may have to resort to third-party blocking products or clever configurations. One of the papers listed in [3] shows a way to block Skype using the popular open-source Squid caching proxy: not only do you have to prevent outbound *User Datagram Protocol* (UDP) connections over port 443, but you also must prevent connections to numeric IP addresses.

Although Skype has its own problems because of the way it is designed, there are several significant drawbacks to widespread adoption and deployment of any IM application. IM is not immune to infections, and just as its popularity is on the increase, so are ways to send malicious payloads and attacks too. What makes matters worse with IM versus say, e-mail, is its very instant nature: an infection can easily spread across a network in a matter of seconds, given that users are logged in, have long lists of users, and tend to think that any message coming from their respondents is more trusted than the average e-mail. In addition, Internet chat has long been a mechanism for controlling large-scale bot-nets of zombie computers, whose owners are unaware of such usage. Numerous virus authors have used exploits in Internet Relay Chat, for example, to control their villains across the Internet.

To avoid these problems, many corporations have either designed their own or are using one of several commercial IM protection products to screen incoming messages for particular patterns and methods of attack. The IM protection products work just like antivirus products work with e-mail messages: they download pattern files on a regular basis from a central server, and perform deep packet inspection across a perimeter to determine what is malicious and what is not.

Interoperability

Each public IM system is an island unto itself: users on one cannot easily communicate with users of another, unless one of two things happens:

A user runs one of the multisystem client programs that allows them to sign in to multiple systems concurrently. Still, using these types of products means that just the user can communicate with his or her "buddies" across systems. Many mostly free products that enable this are available[6].

A private IM operator can combine more than one protocol inside the IM server application. This approach means that clients need not know or care about other IM protocols, such as using Microsoft's Live Communications Server 2005[7].

But variables are changing on the interoperability scene to make life better for IM users. First, efforts are under way among the major operators to form better relationships with each other:

In October 2005, Yahoo and Microsoft announced plans to introduce interoperability between MSN and Yahoo Messenger by mid-2006, using *Session Initiation Protocols* (SIPs). In December 2005, AOL and Google announced a strategic partnership deal where Google Talk users can talk with AIM and ICQ users provided they have an identity at AOL.

Second, both Microsoft and Apple have made efforts to include multi-protocol IM clients as part of their desktop operating systems. Apple's iChat in its latest Mac OS 10.4 Tiger, as an example, now supports AIM, Google Talk, and Jabber. Microsoft has announced plans to support other networks in its next release of Windows Vista, expected later this year.

Finally, the private IM systems of Microsoft and Lotus both support multiple IM protocols, and are widening their support for others, making them more useful for corporations.

Still, with all this activity, the IM interoperability scene is pretty poor: think where e-mail was in the early 1990s with custom-crafted gateways and the like so that an MCIMail user could send messages to a CompuServe user.

Setting up two systems to talk to each other is neither simple nor obvious, and each pair of systems must be done separately. So to add Google Talk to Trillian, a user would need to provide the server host name (`talk.google.com`) and port number (5222). (By the way, GoogleTalk has the most helpful instructions on how to set up a variety of third-party applications to connect to its servers.)

But that is not all—even if a user follows these instructions to set up cross-system connections, most systems can exchange only plaintext messages. Video and voice chats between disparate systems are not generally supported, although Apple's iChat has done the best job so far in this arena. And even if users take the multiple-client approach, the structure of their buddy lists is not always maintained and sometimes is presented in a single group of buddies, rather than separated into the groups that were specified when initially setting up the IM account.

The other concern for cross-systems interoperability is a lack of support for privacy or online status. All of the IM systems have the ability to create blacklists, or lists of users that cannot view your online status. These blacklists are not necessarily preserved when running the multiple client systems.

The Rise of Open Source

There is hope on the interoperability scene, however, and that hope is spelled *open source*. The Jabber group of programmers is growing, and the community is aggressively establishing a more pluralistic IM society. These steps revolve around software using the protocol called the *Extensible Messaging and Presence Protocol* (XMPP), the IETF's formalization of the core protocols created by the Jabber open-source community in 1999, and contained in four RFCs[8, 9, 10, and 11].

Jeremie Miller developed the original Jabber server in 1998. Now the project has reached critical mass. Notable is the wide number of different server and client formulations that support XMPP. Jabber.com sells a commercial license, along with a combination of *General Public License* (GPL)-based licensed servers and other commercial versions. The project has supported the efforts of dozens of client implementations[12]. Last year, support reached a new milestone with Google Talk and more recently the Gizmo Project using these protocols.

Numerous efforts are under way with these clients to extend basic IM functions into new areas, including providing more sophisticated and secure communications, the ability to have multiple identities presented (`david@strom.com` for work colleagues, `dstrom@gmail.com` for personal communications) from the same IM client, and support for more interoperable communications between Jabber and private IM systems.

At the heart of XMPP is the *Extensible Markup Language* (XML) constructs and basic protocols. The core "transport" layer for XMPP is an XML streaming protocol that makes it possible to exchange fragments of XML between any two network endpoints. Authentication and channel encryption happen at the XML streaming layer using other IETF-standard protocols for *Simple Authentication and Security Layer*[13] and *Transport Layer Security*[14].

Servers can connect to each other for interdomain communications, using the form of address for each user as `<user@domain>`—similar to SMTP e-mail, and in many cases, the IM address is the same as one's Internet e-mail address to simplify things.

What is notable about using XMPP is that RFC 3921 also makes it possible to separate the messaging and presence functions if desired (although most deployments offer both). This feature is helpful when building applications-to-applications messaging that does not involve users typing text messages to each other, such as a server sending a network operator an alert when it detects a problem.

The Jabber Software Foundation develops extensions to XMPP through a standards process centered on *Jabber Enhancement Proposals* (JEPs), similar to the RFC process[15]. Currently, more than 30 active proposals have been developed, extending IM into bookmarks, delayed messaging, and other areas.

What Microsoft Is Doing

Microsoft is heavily involved in the IM scene in three important areas. The company operates one of the larger public IM networks, it includes an IM client as part of its Windows operating system, and it sells a private IM server that has some powerful interoperability features called *Live Communications Server* (LCS). What does this mean for the IM community? All good things. Microsoft's MSN and Skype are the more popular IM services outside of North America, and having Skype now a part of eBay is making Microsoft add competitive features such as voice and video chats to its public IM service. Microsoft has actually led the way on IM interoperability with LCS, a fact that can only motivate its competitors to include more pluralist IM offerings of their own. Finally, building in more support for IM in future versions of Windows will help popularize these applications even further.

It was not always this way. Earlier versions of Windows included something called Windows Messenger that was woefully underfeatured and had many bugs. But like so many early Microsoft efforts, technology has improved over time, and now the built-in software that comes with Windows is actually quite competitive with the public IM clients from AOL, Yahoo, and Skype.

Certainly, having Microsoft on one side and open-source efforts on the other is a nice way to encourage development and innovation in the IM arena, and we should expect more here in the future.

Building IM Applications

For most of this article we have addressed the one-to-one aspect of IM. However, IM is evolving into a much more important role, and that is one-to-many communications, and communications between applications instead of actual people. Many vendors have begun selling products in this space, and it is more interesting for several reasons:

First, IM is replacing other means for applications communications. It used to be the case that many network management applications used the *Simple Network Management Protocol* (SNMP) or SMTP protocols to send out their alerts. Now, many applications are using IM messages and taking advantage of the real-time nature of the protocol.

Second, the origins of IM go back to group chat sessions, so group collaboration tools make sense for new IM applications.

Third, even the closed public IM vendors have begun to open their programming interfaces, making it is easier for corporations to build new and sophisticated applications that are presence-aware, in some cases between two computer programs to communicate their status. AOL this year is one such example of opening its IM *application programming interface* (API) kimono, and of course Jabber has always been an open system that has helped lead more of these innovations.

One illustration is with the automotive giant Reynolds and Reynolds, which is using Jabber servers to monitor its own software status at the numerous automotive dealerships around the world. The IT department at Reynolds can quickly see if the company's software is down and take steps to get it working again.

Accredited Home Lenders is using IM to provide its loan brokers a secure and reliable means of communicating in real time with loan specialists to resolve problems with loan applications. And Ecreation built a virtual disk jockey for a Dutch radio station that also broadcasts over the Internet, allowing the station to take requests from listeners around the world through Microsoft's IM network.

Even traders have embraced IM. NetEnergy has been using IM for the past three years, and now negotiates trades between buyers and sellers of oil contracts using IM, decreasing errors and enabling faster communications.

Finally, IM figures prominently helping deaf and hard-of-hearing users communicate. In the era before IM, deaf users required a telephone relay operator to type the message to them and speak to the hearing callers. Go America has built a gateway to IM for its `i711.com` Website, so that deaf users can send messages directly to the operator.

Summary

We have tried to paint a comprehensive a picture of what IM is and where it is going. Certainly, the amount of messaging traffic using the various IM protocols is impressive, and will continue to grow as these new applications are created and as more people discover the advantages of using IM. In several instances IM has replaced voicemail for most internal communications, particularly at high-tech companies and places where real-time communications is important. Although IM is not without its problems, there are ways to protect networks from infection and abuse.

Letters to the Editor

Dear Editor,

In Russ White's "Working with IP Addresses" article (IPJ Volume 9, Number 1), he presents an example subnetting problem ("The Hardest Subnetting Problem") together with a worked solution. While useful as a reinforcement exercise for the rest of the article, care should be exercised before using the steps in the solution "as-is" in a real-world network configuration.

The main problem is that by packing subnets tightly together as shown, growth is restricted in order to guarantee that no address space is wasted. Worse, growth of host numbers on all but the smallest subnet requires renumbering of the subnet or all the smaller subnets allocated after it.

For example, the /26 subnet with 58 hosts will not accommodate more than another four hosts, less than 10-percent growth, without being renumbered.

Since renumbering a network is a nontrivial task even with the tools at our disposal, it is desirable to make it as infrequent as possible.[1]

Allowing for growth will likely but not necessarily waste some address space, but it is preferable to frequent renumbering. It turns out that this example has alternative arrangements of subnets that would permit growth of some subnets without the need to renumber and would lessen the amount of renumbering when it is required.

Using realistic estimates of future hosts rather than current numbers isa simple measure to decrease the frequency of renumbering required. This would also make it obvious that the entire allocation is close to exhaustion and can be exhausted by the need to accommodate as little as six hosts on two subnets that are near full capacity.

Constraints on the supply of IPv4 address space limits how much growth can be accommodated and requires taking a shorter-term rather than longer-term view of growth. For private RFC 1918[2] IP allocations (such as the one used in the example), this applies in only very large organisations, allowing a long-term view to be accommodated.

Unfortunately, the future is hard to predict with any degree of accuracy. In most cases needs for subnet allocation become gradually known over time rather than all at once. The consequences of incorrect estimation can be minimised by using an allocation scheme that allows for as much growth as possible in existing subnets while leaving as much room as possible for future allocations.

This scenario can be achieved by distributing the subnets evenly, weighted by size, across the available address space. The larger the subnet, the more room that needs to be left between it and other large networks. This is particularly important for subnets that are near to capacity. At least the sum of the sizes of neighbouring networks should be allowed. Space close to a network should be reserved for it to grow into, and the remaining space between can be allocated to smaller networks in a recursive fashion. Any allocations in the areas of likely growth should be reclaimable, and preferably these networks should be sparsely populated in order to limit the impact of renumbering on these networks. Working with a diagram of the address space, for example, a linear graph or a binary tree of the address space is a helpful aid.

A more systematic way of distributing the subnets evenly is to use *mirror-image* (MI) counting for allocating subnet numbers. This process is described in RFC 1219[3], but note that some aspects of subnet addressing have altered since this RFC was written (see RFC 1878[4]), so the description of mirror-image counting there and procedure text exclude subnet numbers that are now valid.

Using mirror-image counting is like normal counting starting from zero, except that the binary digits of the number are reversed. These numbers can be allocated as subnet numbers, starting from the most significant bit. Contrary to the example in RFC 1219, leading zeros (including the solitary zero in zero itself) should always be removed before the number is reversed.

Simplifying greatly, new subnets are allocated by incrementing the subnet number until a number is reached where a subnet of the required size can be accommodated or the subnet prefix becomes so long no subnets of the required size remain. If the prefix matches a common but shorter prefix, the subnet may be able to be allocated if we can lengthen the mask of the matching subnet prefix, freeing space from a previous allocation by reducing its maximum possible size. If the longest mask is always used when allocating subnets it is sufficient to just to skip matching prefixes. Note that the null prefix is common with all subsequent prefixes until its subnet mask is made smaller, extending the prefix.

The mask chosen is preferably the longest for the required subnet size—but can be as short as the length of the subnet prefix, because it can be adjusted later: made shorter if the subnetwork grows beyond its mask (if no later allocation has been made) or longer if a subnet sharing its prefix is allocated or increases size. The host number ignoring the subnet part must be allocated from 1.

As the number is incremented it grows from right to left, progressively enumerating subnets in smaller sizes. Since subnet numbers grow from right to left and host numbers from left to right, collision is delayed between the two. Allocating subnets in descending order of size is preferable in this procedure because it tends to reduce fragmentation of the address space.

The following table shows an example allocation using the sorted number of hosts in the example:

MI Number	Subnet Prefix	Network Size	Network Number	Prefix	Last Host Number	Max Host Number
(null)	00	64	0	/26	58	62
1	10	64	128	/26	177	190
01	010	32	64	/27	93	94
11	1100	16	192	/28	206	206
001 matches subnet prefix 00						
101 matches subnet prefix 10						
011	01100	8	96	/29	99	102

Note that the /28 and the /29 can grow simply by changing their netmask. A better allocation is possible if the third and fourth hosts in the sorted list are interchanged. In this case the three smallest networks would be able to grow without renumbering. Shortening a netmask is a much simpler operation than renumbering.

Of course in the real world, needs for subnet allocation do not conveniently arrive sorted in ascending order. If it happened that one of the two largest subnets was the fifth requiring allocation, fragmentation of the address space would require renumbering one of the three smallest networks to recover an address block of the necessary size.

Another point that may be worth mentioning is that most modern hosts and routers allow for multiple subnets to share the same physical subnet, allowing two smaller subnets to cover a range of addresses that would otherwise receive a single larger allocation. For example, a 40-host subnet can be allocated a /27 and a /28 rather than a /26.

The author responds:

Andrew is correct in stating that it is often better to try to account for future growth when assigning address space. There are many viable ways to allow for growth when allocating address spaces; hopefully, this topic will be covered more fully in a future article. I used the method in the article to illustrate how to employ the technique for working with IP addresses, rather than as an absolute best practice for allocating addresses.

—Russ White, Cisco Systems
riw@cisco.com

Dear Editor,

Russ White's article titled "Working with IP Addresses" was a nice refresher on how complicated working with IPv4 addresses has become. It should remind us all how we have gotten used to dealing with the operational expense of IPv4 address scarcity. The story about putting a frog in a pot of cold water comes to mind.

In any case, at the end of the article in the section titled "Working with IPv6 Addresses," I think the author tries too hard to fit the IPv6 address structure into the model for IPv4. Actually, it is a lot simpler.

The IPv6 address structure and textual representation was designed to avoid most of the complexities encountered in IPv4. The big differences follow:

- Addresses are represented in groups of hexadecimal digits instead of decimal digits. Hexadecimal avoids the need to convert the decimal digits to octal to find subnet boundaries. In hexadecimal there are four bits per character. This makes it easy to find the subnet boundary in an address; in many cases it is at a character boundary.
- Subnet prefix lengths are listed directly in decimal. There are no decimal subnet masks. This eliminates the need to convert decimal addresses to octets, convert the subnet masks to octets, apply the mask, and convert the result back to decimal—or to use the table and division methods described in the article.

The combination of these changes makes it much easier to work with IPv6 addresses. They are, of course, longer. The length has a few advantages besides a much larger Internet.

A byproduct of the larger address space is that most of the common subnet boundaries fall on hexadecimal digit boundaries; for example, using the example address in the article:

```
2002:FF10:9876:DD0A:9090:4896:AC56:0E01
```

The most common subnet boundary is 64 bits. The address and prefix is represented as:

```
2002:FF10:9876:DD0A:9090:4896:AC56:0E01/64
```

The subnet itself then follows:

```
2002:FF10:9876:DD0A::/64
```

The current common prefix allocated to a site is a /48. The site prefix is then:

```
2002:FF10:9876::/48
```

The current default allocation to an ISP is a /32. The ISP prefix is then:

```
2002:FF10::/32
```

These common prefix lengths can be derived directly without any need for decimal-to-octal conversions, table lookups, divisions, etc.

One of the other benefits of the larger addresses and a byproduct of IPv6 autoconfiguration is that the low-order 64 bits of an IPv6 address are reserved for the host address (called Interface Identifier in IPv6 terminology). This means that "The Hardest Subnetting Problem" described in the article is avoided completely. You can have as many hosts on a specific segment as you want in IPv6. There is no need to do this kind of calculation. This makes an initial network design trivial and, more importantly, makes later changes very easy. There is no need to redesign a subnet architecture because a few hosts need to be added to a subnet.

—Bob Hinden, Nokia
bob.hinden@nokia.com

The author responds:

Bob brings up many interesting points about IPv6, and the use of the IPv6 address space. While most IPv6 address spaces have prefix lengths that break on even octet boundaries today, we can't always count on this, for all time, so it is always good to have techniques to work with situations where the prefix length is not on an octet boundary when they do occur. As for the last problem, it is true that in all cases the subnet is the set of octets excluding the last 64 bits. But if we move the problem up one level, and ask: "What is the most efficient way to allocate out an existing /48 so customer A can get 10 subnets, customer B can get 20 subnets, etc. ?" we can see the same problem could occur at the next higher level.

Corrections

A few of our eagle-eyed readers have pointed us to some errors in IPJ, Volume 9, Number 1. The text below Figure 6 on page 29 and continuing at the top of page 30 should read as follows:

The figure shows four hosts with the addresses `10.1.0.1`, `10.1.0.2`, `10.1.0.3`, and `10.1.0.4`. Router A advertises `10.1.0.0/24`, meaning: "Any host within the address range `10.1.0.0` through `10.1.0.255` is reachable through me." Note that not all the hosts within this range exist, and that is okay—if a host within that range of addresses is reachable, it is reachable through Router A. In IP, the address that A is advertising is called a *network address*, and you can conveniently think of it as an address for the wire to which the hosts and router are attached, rather than a specific device.

For many people, the confusing part comes next. Router B is advertising `10.1.1.0/24`, which is another network address. Router C can combine—or *aggregate*—these two advertisements into a single advertisement. Although we have just removed the correspondence between the wire and the network address, we have not changed the fundamental meaning of the advertisement itself. In other words, Router C is saying: "Any host within the range of addresses from `10.1.0.0` through `10.1.1.255` is reachable through me." There is no wire with this address space, but devices beyond Router C do not know this, so it does not matter.

Also, Figure 8 on page 32 is reproduced here in its corrected form:

Book Review

Wireless Networking

Wireless Networking in the Developing World: A practical guide to planning and building low-cost telecommunications infrastructure, by Rob Flickenger et al., ISBN 1-4116-7837-0, 234 pages, Limehouse Book Sprint Team, January 2006. `http://wndw.net`

To quote from the book's Website:

"This book was created by a team of individuals who each, in their own field, are actively participating in the ever-expanding Internet by pushing its reach farther than ever before. Over a period of a few months, we have produced a complete book that documents our efforts to build wireless networks in the developing world."

Even though I don't live and work in what is commonly regarded as part of the developing world, I found this to be a unique and informative book, as its practical descriptions of wireless networking have application in many environments.

Given the widespread availability of the raw materials of computers, open-source software, Wi-Fi equipment, various pieces of recycled kitchenware, scrap metal, and plastic, and a wealth of online information resources, it is possible to construct inexpensive high-speed wireless network systems almost anywhere these days. However, perhaps the most visible missing component of the overall picture, but also the most valuable, is a practical path through this wealth of information on how to construct wireless networks, and a path that is based on the recent experiences of others who have constructed cost-effective and practical wireless networks in communities in the developing world. This book sets out to meet that goal.

Organization

The book starts with a description of radio physics covering the basics of the topic. It builds upon this a description of the typical radio design trade-offs between information capacity and radio penetration, and describes the commonly encountered factors of absorption, reflection, diffraction, and interference. I found the practical approach to Fresnel zone calculation and the description of the relationship between distance and antenna height so well done that I was tempted to embark on the design of a neighborhood Wi-Fi straightaway!

The chapter on network design is somewhat of a hybrid section, covering a mix of physical layout of a wireless network and TCP/IP considerations. There were the usual summaries of IP address structure and an introduction to routing.

Study of the deployment of the *Optimized Link State Routing* (OLSR) protocol is, however, more detailed. This is a link state routing protocol that is open-source, supportable by Linux-based access points, and accommodates link quality metrics into the routing protocol metric. I found the consideration of the link budget in this section a useful practical description of the considerations that are unique to the wireless world, and the worked examples are excellent, together with some useful references to online tools. This chapter is relatively dense, and many topics are covered in a relatively short space. I suspect that an interested reader would want to drill down further before feeling confident enough to manage a service network, but some carefully chosen references to further reading are there, so that the reader can follow up this introductory material with more specialized references.

The section on antennas and transmission lines was also well-structured. I had heard of using cylindrical cans as Wi-Fi antennas, but knew little of the detail of how to actually do it. This book not only explains their design, but provides a step-by-step illustrated guide to their construction. It also provides a good description of what is involved in outdoor installation of wireless equipment. The consideration of commercial solutions as compared to the do-it-yourself approach was carefully presented, as was the section devoted to security considerations.

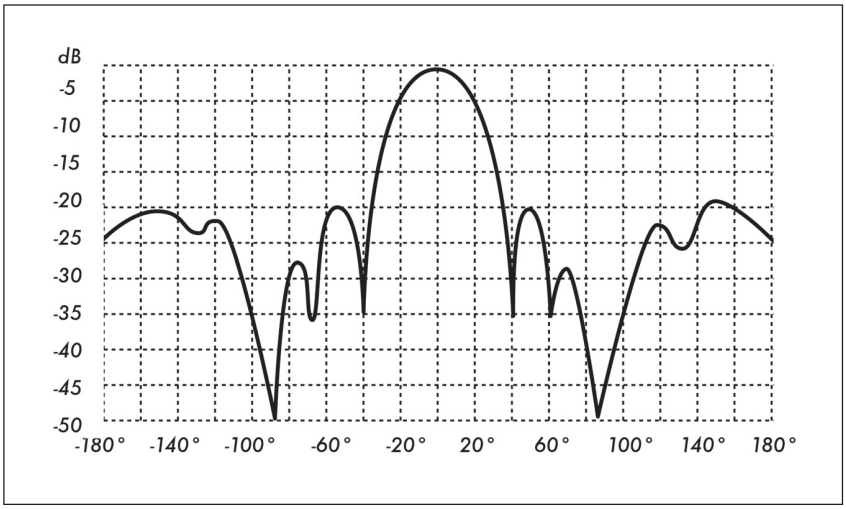
Aside from the technical considerations, the book also has some very interesting case studies of wireless networking projects, and was careful to include both success and failure stories. The issues in the developing world about combining technical capability with practical business solutions for communities that can be financially self-sustaining are indeed challenging, as the case studies show. They provide not only useful information about related experiences in setting up such network services, but also show how such projects can be assessed in a constructive manner.

Thoughtfully Written

Having spent some time working in this area myself as part of the ISOC *Developing Countries Workshop* training team, I have developed an appreciation of what constitutes truly useful and valuable training material, and this book is perhaps the best example I've seen yet. It is practical, helpful, technically accurate, and relatively complete in terms of coverage of material. Where the book does not dive into fine detail it provides useful references for further reading. The book is thoughtfully written in a simple non-nonsense style and does not hide behind technical jargon. Above all, it is material that can instill confidence that these networks can readily be built and operated by people like you and me.

I certainly would not call myself an expert after reading this book, but the next time a radio technician arrives in the office and starts talking about radiation patterns, front-to-back ratios, and the relative merits of omnis and yagis, at least I'll have an idea of what he is talking about. Even better, I might even be able to show him my own modest efforts in do-it-yourself Wi-Fi networking by then!

Rectangular plot of a Yagi Radiation Pattern from Chapter 4 of the book



Publishing Model

This is not a conventional technical book in the sense that it does not come with a conventional technical book price tag. The book is published in a manner as to be readily available in the developing world, so an online publication model has been used here. The PDF is freely available under a *Creative Commons* Attribution-Share-Alike 2.5 license at **http://wndw.net**, and they have managed to squeeze all 254 pages into an impressively small 1.92-MB file. You can find related resources and ways that you can assist in this project at **http://wndw.net**.

Then why not share your thoughts with the readers of IPJ? We accept reviews of new titles, as well as some of the "networking classics." In some cases, we may be able to get a publisher to send you a book for review if you don't have access to it. Contact us at **ipj@cisco.com** for more information.

Fragments

Internet Governance

The *World Summit on the Information Society* (WSIS) was held in two phases. The first phase took place in Geneva in December 2003, and the second phase took place in Tunis in November 2005. The so-called "WSIS Outcome Documents" are now available at:

`http://www.itu.int/wsis/promotional/outcome.pdf`

The follow-on to WSIS is called the *Internet Governance Forum* (IGF). The forum will hold its first meeting in Athens, Greece October 30th to November 2nd, 2006. For more information visit:

`http://www.intgovforum.org/`

The *Internet Society* (ISOC) played an active part in the WSIS process. You will find background information here:

`http://www.isoc.org/isoc/conferences/wsis/index.shtml`

DNS Root Name Servers Explained

Daniel Karrenberg of RIPE NCC has written two "Member Briefings" on the subject of DNS root servers that can be found on the ISOC Website:

`http://www.isoc.org/briefings/019/`
`http://www.isoc.org/briefings/020/`

Internationalized Domain Names

Internationalized Domain Names (IDNs) are, according to the ICANN Website, "...domain names represented by local language characters. Such domain names could contain letters or characters from non-ASCII scripts (for example, Arabic or Chinese). Many efforts are ongoing in the Internet community to make domain names available in character sets other than ASCII." ICANN has established an information area on its Website with links to more information about IDNs. See:

`http://icann.org/topics/idn/`

From The Editor

One of the most successful networking technologies of recent years has been IEEE 802.11 or, as it is commonly known, "Wi-Fi." Wireless networks have seen widespread deployment within organizations as well as in public "hotspots" all over the world. As a frequent traveler, I am very pleased with this development. It has been a long time since I had to resort to a modem and phone line in order to access e-mail or use the Web. Wireless networks have truly changed the way we use the Internet. Our first article, by T. Sridhar, explores the emerging use of *Wireless LAN Switches* in wireless access networks.

IPv6 is a technology that perhaps should have been widely deployed by now, but wide deployment has not happened yet, for numerous reasons. This journal has covered many aspects of IPv6. This time, Iljitsch van Beijnum looks at some of the details you need to be aware of when considering a move to IPv6. The article is adapted from his book *Running IPv6,* which was reviewed in our December 2005 issue.

In previous editions of IPJ we have pointed you to other sources of information, such as *The IETF Journal,* Geoff Huston's *ISP Column,* and other documents available from the Internet Society Website at **http://www.isoc.org**. This time I want to make you aware of an article that originally appeared in *Apster*, the newsletter of the *Asia Pacific Network Information Centre* (APNIC), one of the five *Regional Internet Registries* (RIRs). The article is entitled "IP Addressing in China and the Myth of Address Shortage," and you will find the URL for it in our "Fragments" section. If you want to further explore the work of the RIRs, you can start by visiting the *Number Resource Organization* (NRO) at **http://nro.net**.

You may have read that both of our sister publications, *Packet* and *IQ Magazine,* are publishing their final issues this September. Naturally, this has led to some of our readers asking what is in store for IPJ. We want to reassure you that we intend to continue publishing IPJ in both its paper and online forms. Plans are also under way to enhance our Website to provide you with more tools and resources. If you have suggestions for the Website, please send us a note at **ipj@cisco.com**.

Wireless LAN Switches — Functions and Deployment

by T. Sridhar, Flextronics

Deployment of *Wireless LAN* (WLAN) switches is increasing in enterprise networks. These devices, which can be standalone switches or integrated into a blade on an enterprise class switch, are useful for the management and control of WLAN access points. Although their deployment is a relatively new phenomenon, such control and configuration functions have existed before in WLAN controller devices.

WLAN switches connect to the WLAN *access points* (APs) through wired connections (through a switch port). They also connect to the enterprise network through their other switch ports. The switches are the "gateway" to the wired enterprise—all frames from WLAN clients have to pass through the WLAN switches to the enterprise network.

To understand the motivation for WLAN switches and their operation in the network, it is useful to view the WLAN network architecture and the functions of the access points. We can view the WLAN switch as the control function and the APs as the wireless termination function.

This article presents the function of WLAN switches and controllers by detailing WLAN network architectures along with functions of the AP and controller. It also presents the various functions on the controller to AP interface. Subsequently, it outlines variables related to Layer 2/3 mobility in the centralized architecture and concludes by presenting some common myths and reality about these architectures.

This article uses the term *Wireless Termination Point* (WTP) to refer generically to APs and the term *Access Controller* (AC) to refer generically to the WLAN control function (whether implemented on a WLAN switch or standalone controller).

WLAN Network Architectures

Three types of WLAN network architectures are commonly deployed:

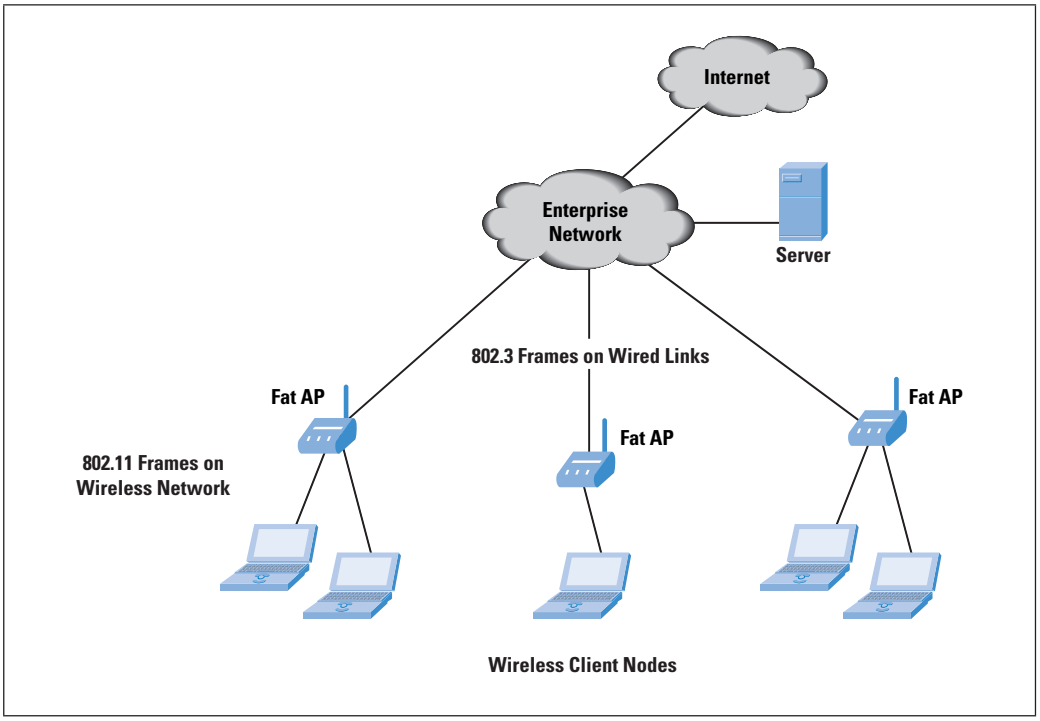
1. Autonomous Architecture
2. Centralized Architecture
3. Distributed Architecture

The following sections describe these architectures in greater detail.

Autonomous Architecture

In the autonomous architecture, the WTPs completely implement and terminate the 802.11 function so that frames on the wired LAN are 802.3 frames. Each WTP can be independently managed as a separate network entity on the network. The access point in such a network is often called a "Fat AP" (see Figure 1).

Figure 1: FAT APs in Autonomous WLAN Network Architecture

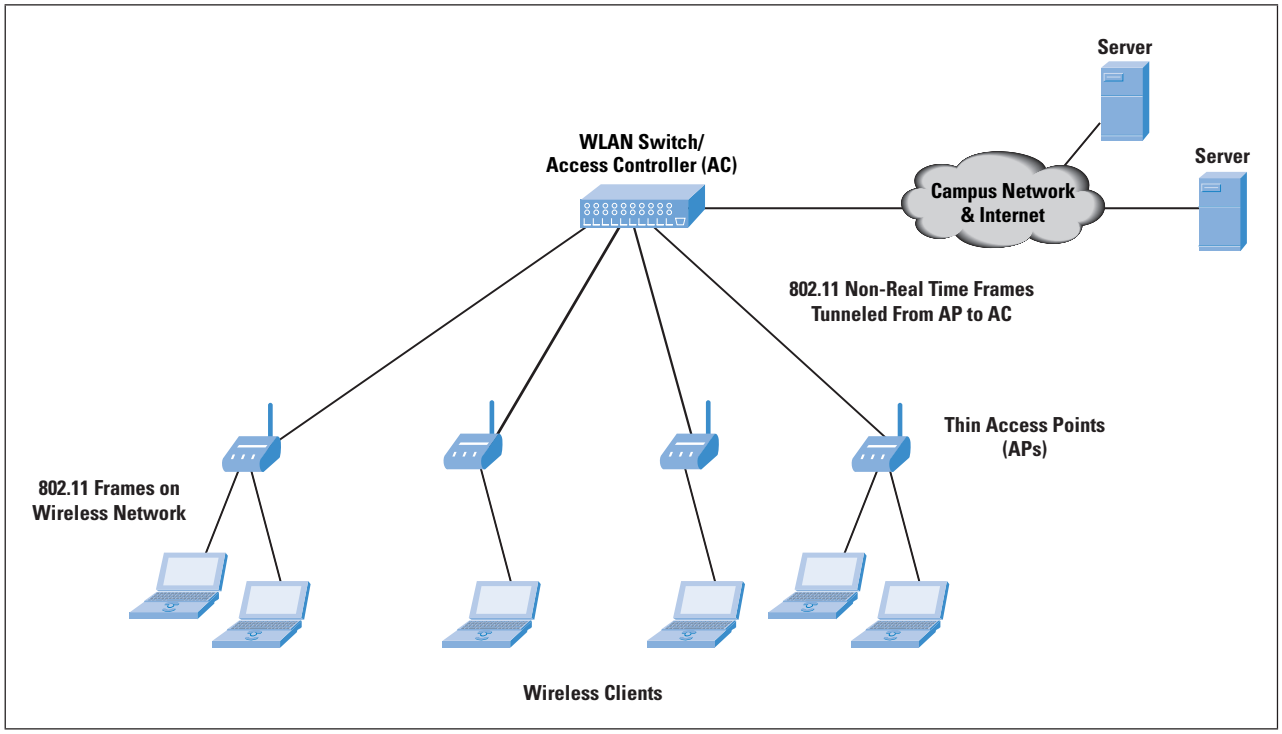


During the initial stages of WLAN deployment, most APs were autonomous APs, and manageable as independent entities in the network. During the past few years, centralized architectures (discussed next) with ACs and WTPs have gained popularity. The primary advantage of the centralized architecture is that it provides network administrators with a structured and hierarchical mode of control for multiple WTPs in the enterprise.

Centralized Architecture

The centralized architecture is a hierarchical architecture that involves a WLAN controller that is responsible for configuration, control, and management of several WTPs. The WLAN controller is also known as the *Access Controller* (AC). The 802.11 function is split between the WTP and the AC. Because the WTPs in this model have a reduced function as compared to the autonomous architecture, they are also known as "Thin APs." Some of the functions on the APs are variable, as discussed in the following section (see Figure 2).

Figure 2: Thin APs in Centralized WLAN Network Architecture



Distributed Architecture

In the distributed architecture, the various WTPs can form distributed networks with other WTPs through wired or wireless connections. A mesh network of WTPs is one example of such an architecture. The WTPs in the mesh can be linked with 802.11 links or wired 802.3 links. This architecture is often used in municipal networks and other deployments where an "outdoor" component is involved. This article does not address the distributed architecture.

WTP Functions – Fat, Thin, and Fit APs

To understand the autonomous and centralized architecture, it is useful to look at the functions performed by the APs. We start with the Fat APs, which form the core of the autonomous architecture, followed by the Thin APs, which were specified as part of the WLAN switch- or controller-based centralized architecture. The article will then outline the functions of a new variant called the "Fit AP," an optimized version of the AP for centralized architectures.

Fat Access Points

Figure 1 shows an example of an autonomous network with a fat access point. The AP is an addressable node in the network with its own IP address on its interfaces. It can forward traffic between the wired and wireless interfaces. It can also have more than one wired interface and can forward traffic between the wired interfaces—similar to a Layer 2 or Layer 3 switch. Connectivity to the wired enterprise can be through a Layer 2 or Layer 3 network.

It is important to understand that there is no "backhauling" of traffic from the Fat AP to another device through tunnels. This aspect is important and is addressed when discussing the other AP types. In addition, Fat APs can provide "router-like" functions such as the *Dynamic Host Configuration Protocol* (DHCP) server capabilities.

Management of the AP is done through a protocol such as the *Simple Network Management Protocol* (SNMP) or the *Hypertext Transfer Protocol* (HTTP) for Web-based management and a *Command-Line Interface* (CLI). To manage multiple APs, the network manager has to connect to each AP through one of these management schemes. Each AP shows up on the network map as a separate node. Any aggregation of the nodes for management and control has to be done at the *Network Management System* (NMS) level, which involves development of an NMS application.

Fat APs also have enhanced capabilities such as *Access Control Lists* (ACLs), which permit filtering of traffic for specific WLAN clients. Another significant capability of these devices is configuration and enforcement of *Quality of Service* (QoS)-related functions. For example, traffic from specific mobile stations might need to have a higher priority than others. Or, you might need to insert and enforce IEEE 802.1p priority or *Differentiated Services Code Point* (DSCP) for traffic from mobile stations. In summary, these APs act like a switch or router in that they provide many of the functions of such devices.

The downside of such APs is complexity. Fat APs tend to be built on powerful hardware and require complex software. These devices are expensive to install and maintain because of the complexity. Nevertheless, the devices have uses in smaller network installations.

Some Fat AP installations still use a controller at the back end for control and management functions. These controllers lead to a slightly scaled-down version of the Fat AP, called, not surprisingly, a Fit AP, discussed later.

Thin Access Points

As their name indicates, Thin APs are intended to reduce the complexity of APs. An important motivation for this reduction is the location of APs. In several enterprises, APs are plenum-mounted (and thus in hard-to-reach areas) so that they can provide optimum radio connectivity for end stations. In environments like warehouses, this is even more evident. For such reasons, network managers prefer to install APs just once and not have to perform complex maintenance on them.

Thin APs are often known as "intelligent antennas," in that their primary function is to receive and transmit wireless traffic. They backhaul the wireless frames to a controller where the frames are processed before being switched to the wired LAN (see Figure 2).

The APs use a (typically secure) tunnel to backhaul the wireless traffic to the controller. In their most basic form, Thin APs do not even perform WLAN encryption such as *Wired Equivalence Privacy* (WEP) or *WiFi Protected Access* (WPA/WPA2). This encryption is done at the controller—the APs just transmit or receive the encrypted wireless frames, thereby keeping the APs simple and avoiding the necessity to upgrade their hardware or software.

The introduction of WPA2 necessitated encryption on the controller. Although WPA was hardware-compatible with WEP and required only a firmware upgrade, WPA2 was not backward-compatible. Instead of replacing APs across the enterprise, network managers could just backhaul the wireless traffic to the controller where the WPA2 decryption was done, and the frames were sent on the wired LAN.

The protocol between the AP and the controller for carrying the control and data traffic was proprietary. Also, there is no capability to manage the AP as a single entity on the Layer 2/3 network—it can be managed only through the controller, to which the NMS can communicate through HTTP, SNMP, or CLI/Telnet. A controller can manage and control multiple APs, implying that the controller should be based on powerful hardware and often be able to perform switching and routing functions. Another important requirement is that the connectivity and tunnel between the AP and the AC should ensure low delay for packets between those two entities.

With Thin APs, QoS enforcement and ACL-based filtering are handled at the controller—not a problem because all the frames from the AP have to pass through the controller anyway. Centralized control functions for ACLs and QoS are not new—they were implemented in networks with Fat APs too. Such installations have controllers that act as the gateway for managing traffic from APs to the wired network. However, the controller function takes on a new dimension with Thin APs, especially with respect to the data plane and forwarding functions. The controller function subsequently was integrated into Ethernet switches that connected the wireless and wired LANs—the motivation for the family of devices known as WLAN switches.

The Wireless MAC architecture in this scenario is known as the *Remote MAC* architecture. The entire set of 802.11 MAC functions is offloaded to the WLAN controller, including the delay-sensitive MAC functions.

Fit Access Points

Fit APs are gaining in popularity in that they try to take advantage of the best of both worlds—that is, the Fat APs and the Thin APs. A Fit AP provides the wireless encryption while using the AC for the actual key exchange. This approach is used for newer APs that use the latest wireless chipsets supporting WPA2. The management and policy functions reside on the controller that connects to multiple APs through tunnels.

Also, Fit APs provide additional functions such as DHCP relay for the station to obtain an IP address through DHCP. In addition, Fit APs can perform functions such as VLAN tagging based on the *Service Set Identifier* (SSID) that the client uses to associate with the AP (when the AP supports multiple SSIDs).

Two types of MAC implementations are possible with Fit APs, known as the *Local MAC* and the *Split MAC* architectures. Local MAC is where all the wireless MAC functions are performed at the AP. The complete 802.11 MAC functions, including management and control frame processing, are resident on the APs. These functions include time-sensitive functions (also known as *Real Time MAC* functions).

The Split MAC architecture divides the implementation of the MAC functions between the AP and the controller. The real-time MAC functions include functions such as beacon generation, probe transmission and response, control frame processing (for example *Request to Send* and *Clear to Send*—RTS and CTS), retransmission, and so on. The non-real time functions include authentication and deauthentication; association and reassociation; bridging between Ethernet and Wireless LAN; fragmentation; and so on.

Vendors differ in the type of functions that are split between the AP and the controller, and in some cases, even about what constitutes real time. One common implementation of a Fit AP involves local MAC at the AP and control and management functions at the AP.

Access Controller and Control Functions

The next critical component of the Centralized WLAN Architecture is the *Access Controller* (AC). For the following discussion, we consider the controller function to be implemented on a WLAN switch and call the function an AC. We also use the term "WTP" to refer to APs (fat, thin, or fit).

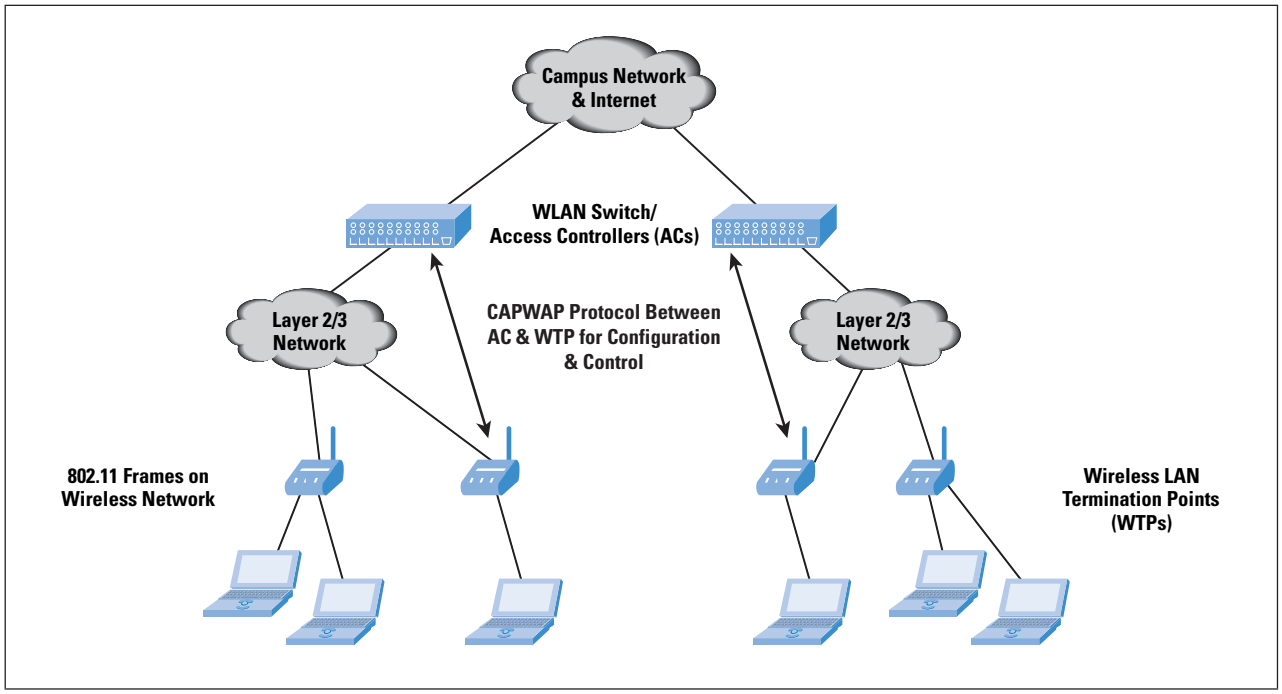
The *Control and Provisioning of Wireless Access Points* (CAPWAP) Working Group in the IETF is working on defining the interface and protocol between an AP and its controlled WTP. This section uses the CAPWAP framework to detail the interface between the AC and the WTP. [3,4,5]

Figure 3 shows an enterprise network with multiple ACs and WTPs. The WTPs can be connected to the ACs through a Layer 2 (switched) or Layer 3 (routed) network. The interface between the WTP and the AC is responsible for the following:

- Discovery and selection of an AC by WTP
- Firmware download to the WTP by the AC—upon startup and upon triggering by the WTP
- Capabilities negotiation between the WTP and the AC

- Mutual authentication between the WTP and the AC
- Configuration, status, and statistics exchange between the WTP and the AC
- QoS mapping across the wired and wireless segments

Figure 3: Centralized WLAN Architecture with Multiple ACs, WTPs and CAPWAP Protocol Context



In addition, although CAPWAP does not explicitly define all the details, the AC performs functions such as *Radio Resource Management* (RRM) and rogue AP detection based on configuration and monitoring of the various access points in its domain of control. The extent of these functions varies according to the vendor implementation. Another important function provided by ACs is mobility management. The following sections provide more detail about these functions, with specific reference to CAPWAP. Note that the CAPWAP protocol, which is based on the Cisco *Lightweight Access Point Protocol* (LWAPP), is still under development in the IETF, as of the writing this article (March 2006).

Discovery and AC Selection

A WTP discovers an AC to connect to through discovery request messages, to which one or more ACs can respond (depending on the network topology). Communication between the AC and the WTP is through the *User Datagram Protocol* (UDP). The WTP determines which AC to connect to and then tries to establish a secure session with the AC. Subsequent CAWAP packets are sent over the secure session.

Subsequently a configuration exchange takes place between the AC and WTP. This exchange includes:

- IEEE SSID
- Security parameters (for WEP, WPA, and WPA2)
- Data rate that is to be advertised (11 or 54 Mbps)
- Radio channels to be used

CAPWAP Functions

CAPWAP control messages include the following message types:

- Discovery
- WTP configuration—used to push a specific configuration to the WTP and also to retrieve statistics from a WTP; statistics includes information such as:
  - Number of fragmented frames, multicast frames transmitted and received
  - Number of transmit retries, excessive retries (failed count)
  - Number of successfully transmitted and failed *Requests to Sends* (RTS)
  - Number of errored frames: duplicate frames, failed acks, decryption errors, *frame-check-sequence* (FCS) error count, etc.

Configuration includes information such as beacon period, maximum transmit power level, *Orthogonal Frequency Division Multiplexing* (OFDM) control, antenna control, supported rates, QoS, encryption, and so on.

- *Mobile session management*—to push specific mobile policies to the WTP

  ACs can add policy information about specific mobile devices that can include security parameters that the WTP should apply for that mobile device. It can indicate whether the WTP should forward or discard traffic for that mobile device.

- *Firmware management*—used to push a specific firmware image to the WTP

AC and WTP Interaction

The WTP provides information such as hardware, software, or boot version; maximum number of radios; radios in use; encryption capabilities; type of radio (802.11b/g/a/n); type of MAC (local, split, or both); tunneling modes; and frame type between AC and WTP (for example, local bridging or native bridging—that is, encapsulating all user payloads as native wireless frames).

The AC information includes hardware or software version, number of mobile stations currently associated with the AC, number of WTPs currently attached to the AC, maximum numbers for each of these, security parameters (authentication credentials) between AC and WTP, control IPv4 or IPv6 address, and so on.

Because the WTPs fall under the category of "Fit APs," they can also be configured with an IP address from the AC. Another parameter that can be configured is ACLs at the MAC address level.

Rebooting (reset) of the WTP can be done by the AC at any time. Independently, the WTP can request a new image through an *Image Data Request*, which is followed by an *Image Data Response* and the image data itself.

Events are sent by the WTP when it determines that it has important information to send to the AC. Such information can include data transfer messages that can be used to deliver debug information from the WTP to the AC.

Radio Resource Management

Radio resource management is a generic term used to describe the control and configuration of radios on the AP. The type of control includes reducing and increasing the strength automatically or on user input—for example, if two WTPs controlled by an AC are interfering with each other, the AC can send a signal to one of the APs to reduce its strength. It can also do this based on user configuration.

Several WTPs are designed to also be used as "Air Monitors;" that is, they can monitor channels when not transmitting. Opinion is still divided on whether this mode of using WTPs is efficient—some vendors use dedicated air monitors instead of having their WTPs do double duty. With dedicated air monitors, it is much easier to scan and monitor all channels without having to worry about degrading the service for client stations.

Air monitors can forward information about other access points to the AC. The AC can determine if the information is for a valid WTP (that is, one that is supposed to be on the network and has, in fact, registered with the AC) or for a "rogue" access point. If it is for a rogue access point, the AC can perform multiple steps to prevent clients from attaching to this AP—for example, it can instruct the air monitor to "jam" this rogue AP by increasing the transmit power on the same channel.

Mobility Management

Mobility management can take two forms—Layer 2 and Layer 3 mobility. Consider a client moving from one WTP to another, a scenario that can happen when a user with a laptop moves between two conference rooms within the same building. The client station reassociates with the new WTP, after which authentication is performed. Note that the association with the previous AP is "broken" before the association with the new AP is "made;" thus handoff in WLANs is known as "break before make." Although this approach can lead to potential traffic disruption (and retransmissions), it is chosen over "make before break" (used in cellular telecommunications) to keep the client radio simple and less expensive.

One way to envision Layer 2 and Layer 3 mobility is to treat Layer 2 mobility as movement between APs under the control of the same AC (that is, Layer 3 network), whereas Layer 3 mobility is movement between APs under the control of different ACs.

Layer 2 Mobility

Layer 2 mobility means that when the station moves from one WTP to another, there is no impact on the IP addressability, effectively meaning that all the APs are on the same Layer 2 network and implying that they are connected to the same AC (see Figure 4). To prevent loss of data destined to the Layer 2 client, the WLAN switch must now forward client data to the new WTP. After the client association, the new WTP sends out an Ethernet frame to the AC with the client's MAC address as the source address. The switch now associates the client's MAC address to the port on which the new WTP is connected.

Although this process works well with Layer 2 (switched network) connectivity between the APs and the AC, it requires a slightly different approach when tunnels are used between them. The AC moves the mapping of the client to a different tunnel (that is, a virtual port) when it receives the MAC frame from the new WTP.

Another concern to be addressed with Layer 2 handoff is the buffering of data at the WTP. In normal circumstances, the switch or AC is not aware of the handoff until it hears from the new WTP. However, with enhanced statistics available at the WTP, it can determine that the specific client has moved away from the old WTP and stop forwarding data to the old WTP. These statistics can include maximum retry attempts on the *Carrier Sense Multiple Access/Collision Avoidance* (CSMA/CA) MAC layer protocol on the wireless link. The switch does not need to buffer the data because it is not clear when the handoff to the new WTP will occur. This approach helps avoid wasteful traffic on the link between the old WTP and the AC.

Some vendors have approached this problem differently with Fat APs. There, the APs might buffer the traffic until they see a frame from the switch indicating that the client is now on a different switch port. These APs then send the buffered traffic to the switch, which forwards that to the new WTP. Because our intent is to lower the complexity of the WTPs, this approach is not a preferred one in the Centralized AC + WTP architecture.

Another important feature of Layer 2 roaming is preauthentication that needs to be done on the new WTP. Through 802.11i, clients can preauthenticate with neighboring WTPs so that roaming to a different WTP does not involve the lengthy authentication process of *Pairwise Master Keys* (PMKs) being sent to the new WTP. (The *Pairwise Transient Keys* (PTKs) still need to be derived.)

When the AC maintains the PMK for a specific client (through interaction with a RADIUS server), this process is automatic—that is, the AC can send the client-specific PMK to the new WTP. The encryption of 802.11 frames is still done by the old and new WTPs with the new PTKs.

Layer 3 Mobility

Layer 3 mobility involves the client retaining the same IP address while moving across multiple APs. This often happens when the client has published its IP address to multiple nodes. Such a scenario is likely in peer-to-peer communications and when the mobile station needs to act as a server for some function. It is desirable that the correspondent nodes communicating with the mobile node not have to change their configuration whenever the mobile node moves to a new Layer 3 network.

This problem of Layer 3 mobility is solved by *Mobile IP*[6]. We do not discuss the details of Mobile IP here except to indicate that it has three distinct components. The *Home Agent* (HA) on the client's home network is responsible for the address of the client. All packets destined to the client's (invariant) IP address are sent to the Home Agent. If the client is on the home network, the HA forwards the packets directly to the client. If it is on a foreign or visited network, the HA forwards the packets to a *Foreign Agent* (FA) that is on the visited network.

To do this, it has to set up a tunnel to the FA—which is usually a *Generic Routing Encapsulation* (GRE) or IP-in-IP tunnel.

After stripping out the original packet from the tunnel, the FA is responsible for forwarding the packet to the client. This description is a simplification—numerous other steps are involved here. The important factor in a wireless LAN scenario for Layer 3 client mobility is where the Mobile IP endpoint resides. Some client stations include a software stack for a MIP client.

This *Client MIP* (CMIP) software:

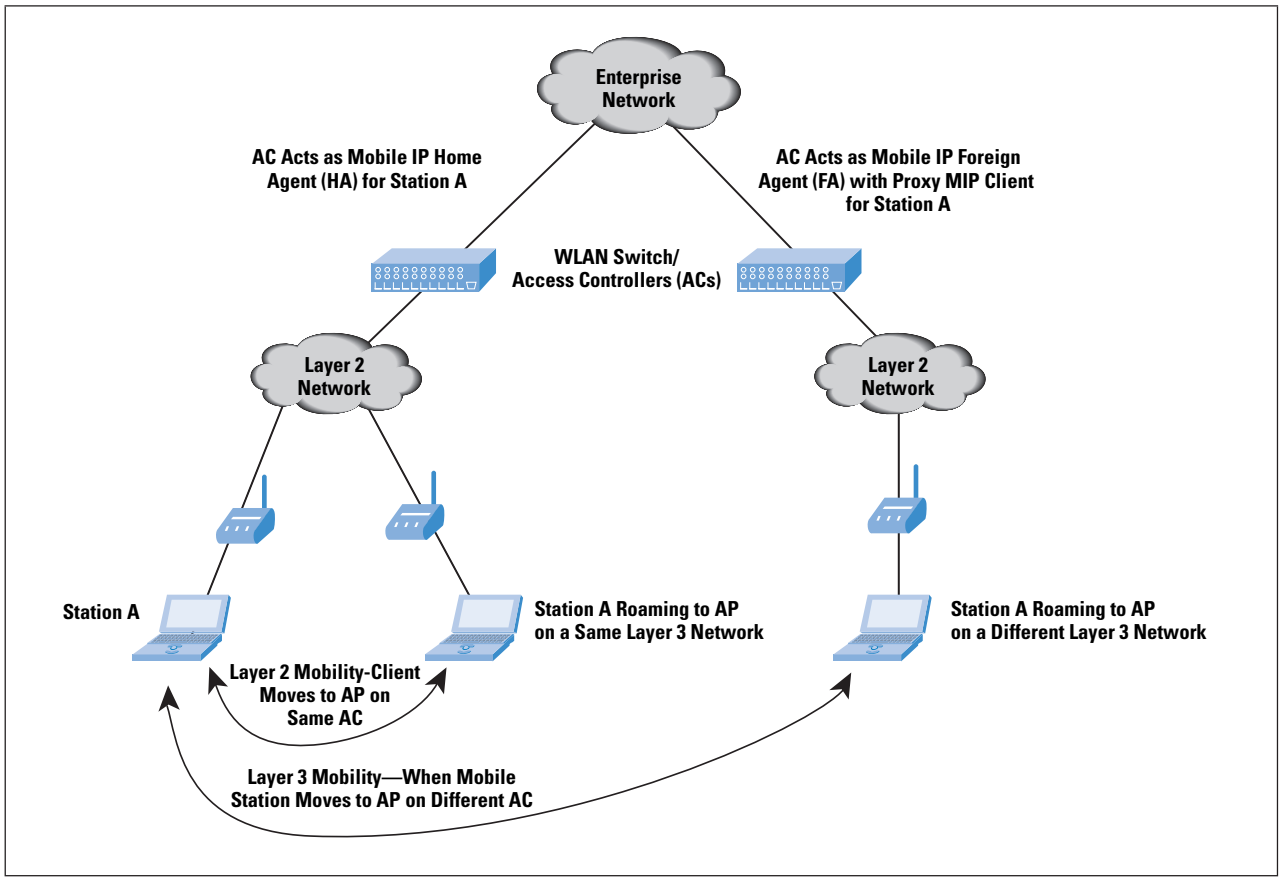
- Strips out the MIP header in the packet
- Inserts a new header to spoof the client's higher-layer applications into believing that the packets were destined for the client's IP address on the foreign network

The CMIP approach was the recommended approach for implementing MIP. However, it has the disadvantage of having to add a MIP client to every mobile station in the network—a setup that can become cumbersome when there are a large number of mobile stations.

The Centralized AC + WTP architecture offers a way of alleviating this problem. Some AC/WLAN switch vendors have implemented the MIP function on the AC so that the client never needs to be changed. Some implementations call this a *Proxy MIP* function.

The AC acts as an FA to terminate the tunnel from the HA and also performs the translation of the packets to the client's address on the visited network when forwarding packets to the client. When the client sends Layer 3 packets out, it sends them through the AC, which, in turn, modifies the headers for the source IP address and tunnels the packets to the HA. This process is called "reverse tunneling" (see Figure 4).

Figure 4: Layer 2 and Layer 3 Mobility in Centraliized WLAN Network Architecture



When you consider a large enterprise network topology with multiple ACs and APs, you can envision the MIP tunnels to be established between the various ACs. (That is, they act as Foreign Agents for one set of users and as Home Agents for another set.) From a scalability perspective, it is important that the ACs have the necessary horsepower and switching capability (switching between tunnels from the APs to the ACs to the tunnels between the ACs).

WLAN Switches and Centralized Architectures – Common Myths

Previous sections considered various aspects of the Centralized AC + WTP architecture and some of the implementation factors. This section outlines some common myths about these architectures and implementations. The intent is to examine this still-evolving area to facilitate clarity.

1. *Myth 1: ACs need to perform switching functions—hence the name WLAN switches.*

   There is no such requirement. In fact, the earliest ACs were appliances (and in some cases, PCs running Linux). The control function is the important part of the implementation—the switching is often included to accelerate the forwarding of traffic to and from the APs.

2. *Myth 2: Rogue WTP detection is a standard function of ACs.*

   This is a desired function in several implementations but is not necessarily "standard." One reason is that this is an area of differentiation among vendors (for example, the algorithms they use to classify a WTP as a rogue WTP). Another reason is that the ACs have to rely on APs or air monitors, and this reliance varies according to implementation.

3. *Myth 3: The delineation between Fat, Thin, and Fit APs is clearly defined.*

   There are several types of implementations of AP (and AC) functions, so this myth is not necessarily true. For a sample of the taxonomy (snapshot) of WTP and AC implementations, see RFC 4118[4].

4. *Myth 4: Layer 2 and Layer 3 mobility are standard in AC + WTP architectures.*

   This is not really true. The Proxy MIP implementation for Layer 3 mobility is a step in this direction, but most AC vendors rely on proprietary mechanisms for AC-AC communication and Layer 3 mobility.

5. *Myth 5: Security functions such as firewall, intrusion detection, and so on are not a function of ACs.*

   Some vendors have debunked this argument and implemented such functions in their AC. This is an area for vendor differentiation.

Summary

This article has provided the functions and deployment of WLAN switches by detailing the architectures that rely on a centralized controller managing a set of wireless termination points. It outlined some major aspects of the CAPWAP control functions and the concerns related to Layer 2 and Layer 3 mobility while implementing an AC + WTP architecture. Although protocol standardization is being done in the IETF for this emerging area, there is still sufficient scope for vendor differentiation.

IPv6 Internals

by Iljitsch van Beijnum

This article discusses some of the protocol details you should be aware of when planning a transition from IPv4 to IPv6. Although it is not intended as a complete step-by-step guide, this article explains the differences between IPv4 and IPv6 as they relate to actually operating a network. Vendor- and operating system-specific details can be found in the book from which this text was adapted, and further information is available in the references.

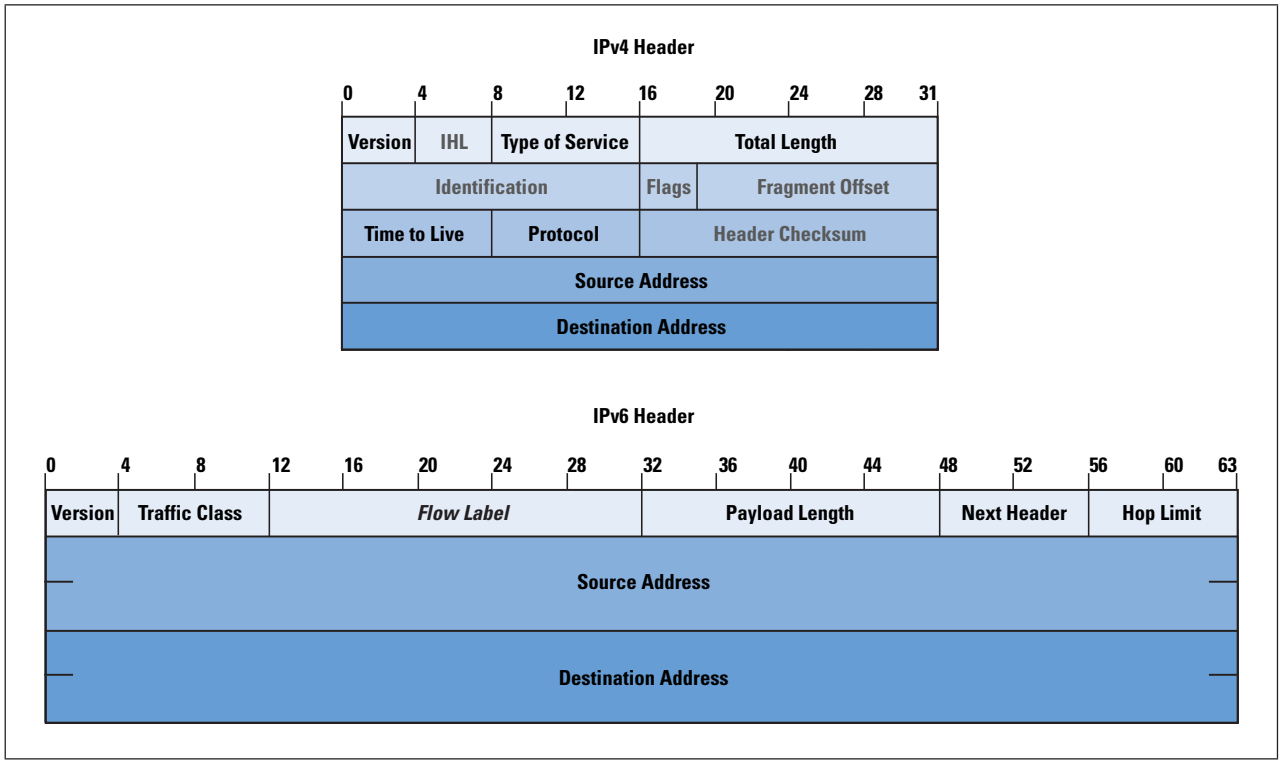
The easiest way to observe—in action—the mechanisms discussed in this article is to set up an IPv6 router on the local subnet and enable IPv6 on the operating system of your choice, if it is not enabled by default. If "native" IPv6 connectivity is not possible, you can set up automatic IPv6 tunneling or use a manually configured IPv6-in-IPv4 tunnel. Getting portable IPv6 address space from a *Regional Internet Registry* (RIR)[1] is a topic worthy of its own article, but *6to4*[2] creates 65,536 IPv6 subnets from a single IPv4 address, and service providers that provide IPv6 connectivity—either natively or over manually configured tunnels—are usually quite generous with IPv6 address space. However, you need to renumber when changing *Internet Service Providers* (ISPs), or when changing IPv4 addresses with 6to4. Most router vendors currently support IPv6 routing, but all widely used general-purpose operating systems can also route IPv6.

When you have IPv6 connectivity, the browser that comes with your system should be able to work over IPv6 (visit **`http://www.kame.net/`**), and there are v6 versions of *ping* and *traceroute* (called *ping6* and *traceroute6*) to determine IPv6 connectivity. More and more applications work over IPv6, but many still do not.

Differences Between IPv4 and IPv6

All knowledge about IPv6 begins with studying the IPv6 header format and the ways in which it is different from the IPv4 header format. Even though at the time the IPv6 specifications were written 64-bit CPUs were rare, the IPv6 designers elected to optimize the IPv6 header for 64-bit processing. For this reason, I have drawn the IPv6 header 64 bits wide in Figure 1, a little different from the way it is usually depicted. Because 64-bit CPUs can read one 64-bit-wide memory word at a time, it is helpful that fields that are 64 bits (or a multiple of 64 bits) wide start at an even 64-bit boundary. Because every 64-bit boundary is also a 32-bit boundary, 32-bit CPUs aren't affected negatively by 64-bit optimization. The IPv4 header is presented in the usual form that highlights its 32-bit background.

Figure 1: The IPv4 and IPv6 headers



The fields in the IPv4 header that are not present in the IPv6 header have gray text; the field that is present in IPv6 but not in IPv4 is shown in italic. The changes from IPv4 to IPv6 follow:

- *Version* now always contains 6 rather than 4.
- The *Internet Header Length* (IHL) field that indicates the length of the IPv4 header is no longer needed because the IPv6 header is always 40 bytes long.
- *Type of Service* is now *Traffic Class*. The original semantics of the IPv4 Type of Service field have been superseded by the *diffserv* semantics per RFC 2474[3]. However, in IPv4, both interpretations of the field are in use (although most routers either cannot or are not configured to look at the field anyway). The IPv6 RFCs do not mandate a specific way to use the Traffic Class field, but generally the RFC 2474 diffserv interpretation is assumed.
- The *Flow Label* is new in IPv6. The idea is that packets belonging to the same stream, session, or flow share a common flow label value, making the session easily recognizable without having to look "deep" into the packet. Recognizing a stream or session is often useful in *Quality of Service* mechanisms. Although few implementations actually look at the flow label, most systems do set different flow labels for packets belonging to different TCP sessions. A zero value in this field means that setting a flow label per session is either not supported or not desired.

- The *Total Length* is the length of the IPv4 packet including the header, but in IPv6, the *Payload Length* does not include the 40-byte IPv6 header, thereby saving the host or router receiving a packet from having to check whether the packet is large enough to hold the IP header in the first place—making for a small efficiency gain. Despite the name, the Payload Length field includes the length of any additional headers, not just the length of the user data.
- The *Identification, Flags,* and *Fragment Offset* fields are used when IPv4 packets must be fragmented. Fragmentation in IPv6 works very differently (explained later), so these fields are relegated to a header of their own.
- *Time to Live* (TTL) is now called *Hop Limit*. This field is initialized with a suitable value at the origin of a packet and decremented by each router along the way. When the field reaches zero, the packet is destroyed. This way, packets cannot circle the network forever when there are loops. Per RFC 791[4], the IPv4 TTL field should be decremented by the number of seconds that a packet is buffered in a router, but keeping track of how long packets are buffered is too difficult to implement, regardless of buffering time. The new name is a better description of what actually happens.
- The *Protocol* field in IPv4 is replaced by *Next Header* in IPv6. In both cases, the field indicates the type of header that follows the IPv4 or IPv6 header. In most cases, the value of this field would be 6 for TCP or 17 for the *User Datagram Protocol* (UDP). Because the IPv6 header has a fixed length, any options such as source routing or fragmentation must be implemented as additional headers that sit between the IPv6 header and the higher-layer protocol such as TCP, forming a "protocol chain."
- The IPv4 *Header Checksum* was removed in IPv6.
- The *Source Address* and *Destination Address* serve the same function in IPv6 as in IPv4, except that they are now four times as long at 128 bits.

All IPv6 hosts and routers are required to support a maximum packet size of at least 1280 bytes. For lower-layer protocols that cannot support a *Maximum Transmission Unit* (MTU) of 1280 bytes, the relevant "IPv6 over …" standard must have a mechanism to break up and reassemble IPv6 packets so that the minimum of 1280 bytes can be accommodated. In IPv4, the official minimum size is 68 bytes—too low to be workable.

Checksums

In IPv4, the IP header is protected by a header checksum, and higher-layer protocols generally also have a checksum. The checksum algorithm for the IPv4 header, *Internet Control Message Protocol* (ICMP), ICMPv6, TCP, and UDP is the same one's complement addition, except that in IPv4, UDP packets may forego checksumming and simply set the checksum field to zero. In IPv6, this practice is no longer allowed: UDP packets must have a valid checksum.

The TCP, UDP, and ICMPv6 checksums are computed over a "pseudoheader" and the TCP, UDP, or ICMPv6 header, and user data, respectively. The pseudoheader consists of the source and destination addresses, the upper-layer packet length, and the protocol number. Including this information in the checksum calculation ensures that TCP, UDP, or ICMPv6 do not process packets that were delivered incorrectly, for instance, because of a bit error in the IP header.

IPv6 no longer has a header checksum to protect the IP header, meaning that when a packet header is corrupted by transmission errors, the packet is very likely to be delivered incorrectly. However, higher-layer protocols should be able to detect these problems, so they are not fatal. Also, lower layers almost always employ a *Cyclic Redundancy Check* (CRC) to detect errors.

Extension Headers

To allow special processing along the way, IPv4 allows extension of the IP header with one or more options. These options are rarely used today, both because they do not really solve common problems and because packets with options cannot be processed in the "fast path," and many routers and firewalls block some or all options. Not unlike the checkout counters at a grocery store, many routers have several "paths" that packets may follow: a fast one, implemented in hardware or highly optimized software, that supports only the most common operations (no checks), and one or more slower paths that use more advanced but slower software code that supports less common operations such as looking at IP options. However, many modern routers have only a fast path, so using additional features does not lead to a performance penalty.

Because the header is of fixed length in IPv6, options cannot be tagged onto the IP header as in IPv4. Instead, they are put in a header of their own that sits between the IPv6 header and the TCP or UDP (or other higher-level protocol) header. The most common extension headers follow:

- *Hop-by-Hop Options:* See the section that follows.
- *Routing:* This header is similar to the *Source Route* option in IPv4.
- *Fragment:* This header is used for fragmentation; see later in this article.
- *Authentication:* This header authenticates the user data and most header fields.
- *Encapsulating Security Payload* (ESP): This header encrypts or authenticates user data.
- *Destination Options:* See the section that follows.

The Hop-by-Hop Options and Destination Options headers are container headers: they have room for multiple suboptions. The Hop-by-Hop Options are processed by all routers along the way. All other options are normally ignored by routers and processed only by the destination. Obviously firewalls, or routers configured to perform filtering, may also look at these options. The Hop-by-Hop Options, Routing, Fragment, and Destination Options extension headers are defined in RFC 2460[5]. The Authentication and ESP extension headers are part of *IP Security* (IPsec).

Note that there is no standard extension header format, meaning that when a host encounters a header that it does not recognize in the protocol chain, the only thing it can do is discard the packet. Worse, firewalls and routers configured to filter IPv6 have the same problem: as soon as they encounter an unknown extension header, they must decide to allow or disallow the packet, even though another header deeper inside the packet would possibly trigger the opposite behavior. In other words, an IPv6 packet with a TCP payload that would normally be allowed through could be blocked if there is an unknown extension header between the IPv6 and TCP headers.

ICMPv6

The IPv6 version of the ICMP generally serves the same purposes as its IPv4 counterpart, but there are some changes. In IPv4, when a router or the destination host cannot process the packet properly, it sends back an ICMP error message along with the original IP header and the first 8 bytes of the higher-layer header. For UDP and TCP, this is enough for the source of the original host to see which TCP session or UDP association generated the offending packet. Because IPv6 supports an arbitrary number of extension headers between the IPv6 header and the higher-layer header, ICMPv6 returns as much of the original packet as will fit in the minimum MTU size of 1280 bytes. In addition to error messages, which are recognizable by an ICMP type of 127 or lower, there are also informational messages, with a type of 128 or higher. Because informational messages are not the result of an error, they do not include an original packet or part thereof. The most common ICMPv6 message types follow:

1: Destination unreachable
2: Packet too big
3: Time exceeded
4: Parameter problem
128: Echo request
129: Echo reply
130: Multicast listener query
131: Multicast listener report
132: Multicast listener done
133: Router solicitation
134: Router advertisement
135: Neighbor solicitation
136: Neighbor advertisement
137: Redirect message

ICMP and ICMPv6 messages also include a "code" that indicates the exact nature of the ICMP message within a certain type. As with ICMP, ICMPv6 calculates a checksum over the control message, but unlike ICMP, the ICMPv6 checksum calculation also includes a pseudoheader. Another departure from IPv4 is the fact that hosts and routers are required to limit the number of ICMPv6 messages they send. So if a router receives 100 packets per second toward an unreachable destination, it is not supposed to send back ICMPv6 packets at the same rate of 100 per second. The ICMPv6 redirect message works slightly different from the ICMP redirect message in IPv4. Like its IPv4 counterpart, the ICMPv6 redirect can be used by a router to inform a host that it should use a different router to reach the destination in question. But routers can also use the IPv6 Redirect to tell a host that the destination is reachable on the local subnet. Thus two hosts that have addresses in different prefixes can communicate directly after receiving redirects from a router.

Neighbor Discovery

When a system wants to send an IPv6 packet to another system connected to the same subnet or link, it needs to know what MAC address (or "link address" in the new IPv6 terminology) it should address the packet to, unless the interface in question is a point-to-point interface. Neighbor discovery allows systems to discover each other's MAC addresses, similar to *Address Resolution Protocol* (ARP) on Ethernet with IPv4.

Each IPv6 system joins the "solicited node" multicast group that corresponds to each of its addresses. Because the solicited node group address consists of the prefix `ff02:0:0:0:0:1:ff00::/104` followed by the bottom 24 bits of the address in question, addresses in different prefixes based on the same interface identifier (including the link-local address) all map to the same solicited node address.

Whenever a system needs to find out the link address for another system residing on the same link, it sends a neighbor solicitation to the solicited node address to which the IPv6 address of the remote system maps. The source host includes its own MAC address in the neighbor solicitation, so the neighbor knows where to send the reply.

Neighbor Unreachability Detection

RFC 2461[6] specifies a procedure for neighbor unreachability detection. IPv6 hosts and routers actively track whether their neighbors are reachable by periodically sending neighbor discovery messages directly to the neighbor. If the neighbor answers, it is reachable; if it does not, there must be some kind of problem, and the system discards the neighbor's MAC address and tries a regular multicast neighbor discovery procedure, allowing IPv6 systems to detect dead neighbors and neighbors that change their MAC address. But it is most useful to detect dead routers. On a subnet with more than one router, a host can simply install a default route toward another router when the router that it has been using becomes unreachable.

If a router loses its IPv6 address and no longer runs IPv6, Windows XP, Linux, MacOS, and FreeBSD all switch over to another router without incident. However, turning off the active router has much more severe effects: at the very least, ongoing downloads stall for a while, and in some cases, the session breaks. I have no explanation for this difference in behavior.

Stateless Address Autoconfiguration

Hosts and routers always configure link-local addresses on every interface on which IPv6 is enabled. The link-local address is nearly always derived from the interface MAC address, but to guarantee uniqueness, it is necessary to perform *Duplicate Address Detection,* which is discussed later.

When a host has a link-local address, it can obtain one or more global IPv6 addresses by using RFC 2462[7, 12], *Stateless Address Autoconfiguration*. IPv6 routers send out *Router Advertisement* (RA) packets (ICMPv6 type 134) periodically and in response to router solicitations. The information in RAs includes:

- An 8-bit *cur hop limit* field that tells hosts what value to use in the Hop Limit field of outgoing IPv6 packets
- The *managed address configuration* (M) flag—This flag is not well-defined, but the basic idea is that when it is set, hosts use a stateful mechanism (presumably *Dynamic Host Configuration Protocol Version 6* [DHCPv6]) to configure their addresses, and when the flag is not set, they use stateless address autoconfiguration.
- The *other stateful configuration* (O) flag—This flag is similar to the M flag, but indicates that the host should use a stateful mechanism to discover nonaddress configuration information.
- A 16-bit *router lifetime* value in seconds—This value tells hosts how long the default route that was created as the result of this RA should remain valid.
- The 32-bit *reachable time* value in milliseconds—This value indicates how long a neighbor should be considered reachable after receiving a "reachability confirmation," which is generally a neighbor advertisement but could be any packet.
- The 32-bit *retrans timer* value in milliseconds—The retrans timer tells hosts how long they should wait before retransmitting neighbor solicitation messages when there is no answer.

When fields that determine a value are set to zero, this means the value is not specified in the RA, so hosts must discover that value through other means. In addition to the preceding, router advertisements may also contain one or more options, such as:

- *Source link-layer address,* the router MAC address
- *MTU,* the maximum packet size that should be used on this subnet
- *Prefix information,* which specifies the prefixes used on the subnet and their properties

The prefix information option, in turn, has its own list of attributes:

- The *address prefix* itself and its length—For stateless address autoconfiguration to work, the prefix must be 64 bits long.
- The *on-link* flag—This flag tells hosts that the prefix is "on-link," so systems with addresses within this prefix are reachable on the subnet in question without help from a router.
- The *autonomous address configuration* flag—This flag tells hosts that they can create an address for themselves by combining this prefix with an interface identifier.
- A 32-bit *valid lifetime* in seconds—This value indicates how long the prefix should be considered on-link and how long autoconfigured addresses using the prefix can be used.
- A 32-bit *preferred lifetime* in seconds—This flag tells hosts how long autoconfigured addresses using this prefix are preferred.

Duplicate Address Detection

To avoid the situation where two IPv6 systems use the same address, systems perform *Duplicate Address Detection* for (nearly) all new IPv6 addresses before they are used. Duplicate address detection is done for global unicast addresses—and not just for those created using stateless address autoconfiguration, but also for link-local addresses. For obvious reasons, there is no duplicate detection for anycast addresses, because the whole point of anycast is that multiple systems have the same address.

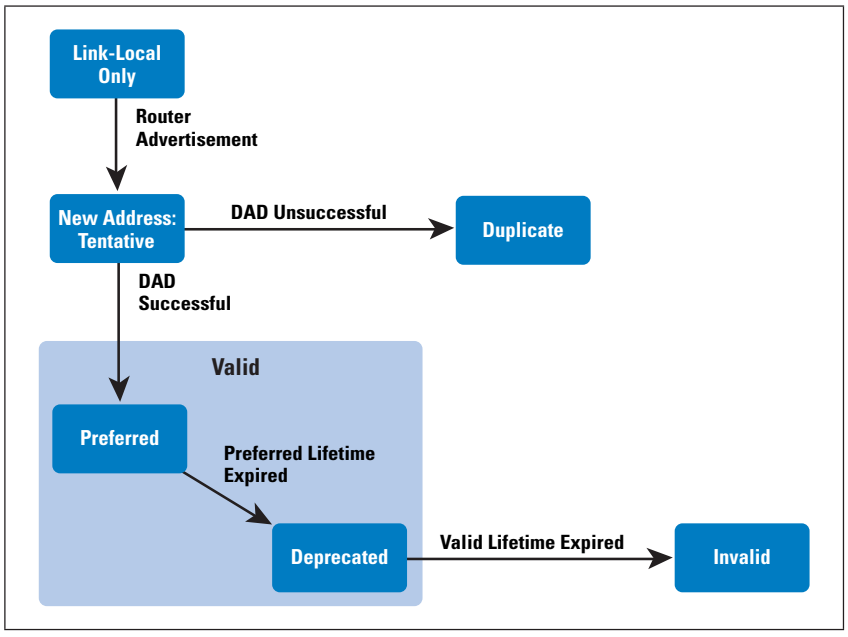


Figure 2: The Lifecycle of an IPv6 Address

As depicted in Figure 2, a host starts with only a link-local address. Duplicate address detection is also done for the link-local address, but this is not shown in the figure.

When a host receives a router advertisement that contains one or more prefixes with the autonomous address configuration flag set, the host creates addresses with interface identifiers derived from the IEEE *64-bit Extended Unique Identifier* (EUI-64) and possibly also a randomly generated one, if the host uses RFC 3041[8] address privacy. The host marks the resulting addresses as "tentative" and proceeds to execute the duplicate address detection procedure by joining the solicited node multicast group for the address in question and sending out one or more neighbor solicitation messages for the address. (If the number of duplicate address detection retries is configured to be zero, no duplicate detection is performed.) Only when there is no answer is the address used. If there is a conflict, the system is supposed to log the error and wait for manual intervention.

Address Lifetime

After successfully maneuvering past the duplicate address detection hurdle, addresses configured through stateless address autoconfiguration can be used until the "preferred lifetime" from the router advertisement message expires. In most cases, the lifetime does not expire because new RAs refresh the timers. But if there are no more RAs, eventually the preferred lifetime elapses and the address becomes "deprecated." New sessions should not use deprecated addresses but should choose "preferred" (nondeprecated) addresses, if available. However, existing sessions will continue to use the deprecated address. Eventually, the "valid lifetime" also runs out, and the deprecated address is removed from the interface, breaking any sessions that are still using the address.

Renumbering

Having different preferred and valid timers for the router advertisement itself and also for any prefixes contained in it makes it possible to do two things: renumber easily and cause more problems. It is even possible to do both at the same time. With stateless autoconfiguration, renumbering is easy: you simply give the router an address in the new prefix and set the preferred lifetime for the old prefix to zero, making hosts create one or more new addresses and deprecate any existing ones in the old prefix as soon as they receive the resulting router advertisement. After that, all new communication should start using the new address immediately. Existing TCP sessions and UDP associations continue to use the same address as before. After some time, all communication that started before the change should have stopped so that the old addresses can be removed safely.

This process is slightly more complex than it seems at first glance: as a precaution against attackers, hosts are not supposed to trust a valid lifetime of less than 7200. So make sure that the hosts have received at least one RA after setting the valid lifetime to 7200, and then set both the lifetimes to zero and remove the autonomous address configuration flag for the prefix. Two hours later, all hosts should have removed the addresses in this prefix, so you can remove the prefix from the router.

Beware that when you renumber because you are switching from one ISP to another, it is unavoidable that at some point, packets with source addresses in address space from ISP A end up at ISP B, or the other way around. If ISP B employs antispoofing or ingress filtering, it will not allow these packets through, so reduced connectivity will result. You can ask one ISP to remove the filters temporarily and then send out all your outgoing traffic over that ISP (or one that did not filter in the first place). However, do not expect too much cooperation from your ISP unless you are a valued customer.

Address Prefix and Router Lifetime Mismatch

Earlier, I mentioned the potential for causing more problems because router advertisements and the prefixes they contain have independent lifetimes. This scenario allows for four permutations:

- The RA lifetime is valid, and the prefix lifetime is valid: IPv6 works.
- The RA lifetime is invalid, and the prefix lifetime is invalid: IPv6 is disabled.
- The RA lifetime is valid, but the prefix lifetime is invalid: The system has an IPv6 default route but no global IPv6 address.
- The RA lifetime is invalid, but the prefix lifetime is valid: The system has a global IPv6 address but no IPv6 default route.

When a host has no global addresses but does have an IPv6 default route (case 3), it cannot reach the rest of the IPv6 Internet. Unfortunately, FreeBSD and MacOS hosts do not know that: they try anyway, with long delays as a result. Only after trying all the remote destination IPv6 addresses and timing out, the system falls back on IPv4 (for applications that try more than one address). Linux, on the other hand, does not install the IPv6 default route or ignores it when no global IPv6 addresses are present, so the timeout is immediate.

Windows XP does install the default route but magically manages to avoid lengthy timeouts anyway. On the other hand, Windows XP suffers timeouts when it has an IPv6 address but no default route (case 4) because Windows implements the on-link assumption: it first performs neighbor discovery on the local subnet for any IPv6 addresses. Only after neighbor discovery times out does Windows revert to IPv4. FreeBSD and MacOS, however, do not implement the on-link assumption, so they immediately notice that the IPv6 destination address is unreachable and revert to IPv4—if an IPv4 address is available and the application cycles through all addresses. With Linux, the default route does not seem to expire even though the timers eventually reach zero and lower. But addresses do expire and are removed when the lifetime for the associated prefix times out.

Address Selection

Choice is good, but it comes with problems of its own. The explicit support for multiple addresses in IPv6 requires the system or applications to choose which address to use for a given communication session. The coexistence of IPv4 and IPv6 in the same host makes this situation even more pressing. RFC 3484[9] provides guidelines in this area—it lists no fewer than 10 rules for choosing a destination address and 8 rules for selecting a source address. Most of these rules are fairly obvious, such as preferring a nondeprecated address over a deprecated one and not using a link-local source address to communicate with a destination that has a global address. It gets more interesting with the "policy table." On systems that support this mechanism, such as Windows XP and FreeBSD 5.4, the administrator can instruct the system to prefer certain address ranges over others.

Path MTU Discovery and Fragmentation

Because routers cannot fragment IPv6 packets, *Path MTU Discovery* (PMTUD) is mandatory in all cases where links with MTUs larger than 1280 bytes are used for IPv6, so it is imperative that routers generate ICMPv6 packet-too-big messages and that these messages make it back to the source of the offending packet. Filtering out these ICMPv6 messages makes it impossible to communicate reliably.

If you decide that you must filter ICMPv6 packet-too-big messages, you *must* use an MTU equal to the IPv6 mandatory minimum of 1280 bytes across your network so there is no need for PMTUD.

Upon reception of a packet-too-big message, TCP reduces its packet size to accommodate the smaller MTU on the path in question. However, protocols that run over UDP often cannot arbitrarily reduce their packet size. In IPv4, UDP packets are generally sent without the "don't fragment" bit set, so routers fragment them if necessary. In IPv6, this setup is not possible; if the packet is too large, the source host has to fragment it. The source host does this by first splitting the packet into unfragmentable and fragmentable parts. The IPv6 header and any headers that must be processed by routers along the way make up the unfragmentable part; the payload data and any headers that have to be processed only on the destination host are the fragmentable part. The fragmentable part is then split into as many parts as required to fit in the path MTU, and each part is transmitted as a packet containing the unfragmentable part, a fragment header, and one of the fragments of the fragmentable part.

The fragment header is 8 bytes, and except for a "next header" field and two reserved fields, it contains the same fragment offset, more fragments, and identification fields as the IPv4 header. The identification field is now 32 bits long and is used to indicate which fragments belong to the same original packet. All fragments except the last one have the "more-fragments" bit set and are multiples of 8 bytes.

After receiving the first fragment (which is not necessarily the first fragment of the original packet), a host waits up to 60 seconds for all other fragments to come in and, if they do, reassembles the original packet by combining all the fragments with the same source and destination addresses and identification field into a single packet. If one or more fragments is lost, the packet cannot be reassembled, so the entire packet is lost.

Note that IPv6 fragmentation has the same problem as IPv4 fragmentation: the TCP or UDP port numbers are available only in the first fragment, making it hard for firewalls and the like to filter fragmented packets. Common solutions are to reassemble the packet prior to filtering or to discard all fragments.

DHCPv6

DHCPv6 (RFC 3315[10]) is the IPv6 version of the DHCP. Because IPv6 has stateless address autoconfiguration, DHCP occupies a very different part of the landscape in IPv6 compared to IPv4. Although the details are different in the by-now-expected places (address length, use of multicasts, some streamlining), the DHCPv6 protocol itself is quite similar to the IPv4 version of DHCP. The more important differences are the way in which the protocol is used. DHCPv6 has three purposes:

- *Address configuration:* Giving out addresses to individual hosts
- *Nonaddress configuration:* Giving out other configuration information, such as DNS resolver addresses and domain search lists
- *Prefix delegation:* Giving out entire prefixes to routers (RFC 3633[11])

A DHCPv6 client interested in an address or other configuration information sends out a *solicit* message indicating its needs to the link-local scope multicast address **`ff02::1:2`**, port 547. (Server-to-client messages are addressed to port 546.) DHCPv6 servers that receive the *solicit* message either directly or forwarded by a relay and can accommodate the request respond with an *advertise* message. The client considers the offers in the various *advertise* messages and directs a *request* message to the server of its choice. The server then replies with a *reply* message, confirming the address or configuration information. Alternatively, if the client wants to receive only configuration information and no addresses or prefixes, it can send a *request-information* message, and the server immediately sends back a reply message, so only half the messages are exchanged and the whole process completes much faster. The client can also use the "rapid commit" option to indicate that it wants to use the expedited procedure for address or prefix assignment if it is fairly certain that it will take up the offer from the first DHCPv6 server that responds.

As expected, IPv6 addresses assigned with DHCPv6 come with a preferred and a valid lifetime. Sometime before this timer expires, the client sends a *renew* message, asking the server if it can continue to use the address. When it has no more use for the address, the client sends a *release* message. Less common situations have other messages.

To allow servers to recognize clients, each device that implements DHCPv6 has *DHCP Unique Identifier* (DUID). In IPv4, DHCP clients use a MAC address or user-supplied string as a Client Identifier. In DHCPv6 this client identifier is always the DUID. Devices can create their DUID in various ways, as long as the DUID is unique and not subject to change, if at all possible.

DHCPv6 supports an authentication mechanism that allows clients and servers to interact in a secure way, so third parties cannot inject false DHCP messages or modify legitimate ones. However, this mechanism must be preconfigured manually on all servers and clients, partially negating the advantages of DHCP over manual configuration.

An interesting use of DHCPv6 is *Prefix Delegation* (PD). With DHCPv6 PD, routers request a prefix that they then use to number one or more of their interfaces, supporting stateless address autoconfiguration for hosts connected to that interface. By creatively borrowing the DHCP timers and reusing them in router advertisements, a whole site can be renumbered by changing a single setting in a DHCPv6 configuration on a DHCPv6 server or a router functioning as a DHCPv6 PD server.

Ed.: This article is adapted from chapter 8 of *Running IPv6* by Iljitsch van Beijnum, published by Apress in 2005, ISBN 1590595270. The article differs from the chapter in that it has been edited for size and the vendor-specific examples have been removed. Used with permission. For information about the book, see:

Book Reviews

Electronic Brains

Electronic Brains, Stories from the Dawn of the Computer Age, by Mike Hally, ISBN 0-309-09630-8, Joseph Henry Press, 2005.

Electronic Brains is a personal account from the early days of computing that describes the childhood of a technology that is little more than 50 years old. The book originated as a BBC radio programme, still accessible at **`http://www.bbc.co.uk/radio4/science/electronicbrains.shtml`**. Mike Hally traveled over the globe looking for the first "computors" and the stories from the dawn of a new age. This book contains the results of the investigation, giving a first-hand testimony of hard work, passion, and amazing developments that shaped the second half of the last century.

Organization

Chapter 1, "From ABC to ENIAC," presents the development of what is commonly accepted as the first computer, the ENIAC, a computer that replaced calculating machines and people making the operations in ballistic trajectories analysis by hand. Credit is given to John Atanassof and Clifford Berry, the developers of ABC, possibly the first operational computer in the world.

Development of the UNIVAC, the computer famed by predicting the result of the 1952 U.S. presidential election, is presented in Chapter 2. Designed by Eckert and Mauchly, the developers of ENIAC, UNIVACs were commercial computers used for processing census data and so well marketed that the term "UNIVAC" was used as a synonym for "computer."

Chapter 3 looks at the development of the Rand 409, maybe the first mass-produced computer. The 409 was a medium-sized computer, with a price tag of US$100,000 that compared favorably against UNIVAC's $1 million, achieving a sell rate of one per week.

"Computing in Great Britain" is the focus of Chapter 4, where credit is given to Maurice Wilkes and Alan Turing. A worthy detail that gives a glimpse of the technical difficulties overcome is the description of memory based on mercury delay-lines, where binary data was stored using sound pulses on tubes filled with mercury engineered in such way that the delay from transmitter to receiver allowed the electronics to do the calculation before the data in memory was needed at the receiver side.

Perhaps the strangest computer development is set forth in Chapter 5. The *Lyons Electronics Office* (LEO) was a computer developed by a large catering company to expedite its clerical operations. LEO was possibly the first commercial computer in the world, so successful that the catering company began to produce and sell it to other corporations.

Chapter 6 describes the efforts by USSR scientists to develop computing technology. More than one development was made; it is not clear which was the first soviet computer, and the developments were secret—in some cases very specialized, such as a computer with ternary logic instead of the currently used binary logic (ENIAC used decimal logic).

Chapter 7 focuses on computing developments in Australia, work that did not last because the funds were scarce and sometimes the budget was assigned to other sciences, such as radiophysics. Here we can see that computers were used for purposes totally different than their uses in cold-war countries; for example, they were used to answer crossword puzzles—strange if we consider that the disk had a capacity of 3 KB.

A strange computer, formally known as *Hydraulic Economics Computer,* is described in Chapter 8. It was not a typical computer—it was a system developed to show the interrelation between macroeconomic variables using colored water, pumps, and valves. Universities, central banks, and Ford bought the computer, and four of them survive in different parts of the world. The emergence of IBM is the subject of Chapter 9, which presents IBM as a late adopter of computing technology that eventually became the leader of the computer age. We learn that the first computer produced by IBM was the IBM 701; after that came the IBM 1401 and then the IBM 360—the system that consolidated IBM as the ruler in the computing world.

Summary

From the ABC to the well-known ENIAC and UNIVAC, *Electronic Brains* is a testimony to the people who worked day and night to accomplish something that few others understood. Motivated mainly by passion and with little to no economic support, team spirit is a common factor in all the computer developments: "...it was like a brotherhood! We would help each other in case someone got stuck on a particular activity. I would have gone anywhere with those guys. I've never had such unified job environment. We knew we were pushing back the frontiers."

Electronic Brains is an enjoyable book that I recommend to any person with interest in computers and technology. Computer historians could scoff at the rather simple analysis of technical details, but this is not a technical book. The value of *Electronic Brains* is the first-hand account of early undertakings and the multiple-country investigation that is presented. With many anecdotes, this book will serve as a witness to the pioneers of a new era, the computing era.

Business 2010

Business 2010—Mapping the Commercial Landscape, by Ian Pearson and Michael Lyons, ISBN 1-84439-105-1, Published by Spiro Press, **http://www.spiropress.com/**

This interesting book explores how trends in technology, economic factors, social changes, and evolving attitudes to technology will reshape the business landscape by the year 2010. The book describes its subject matter in terms that are understandable and interesting to both technical and nontechnical audiences. It is valuable to technologists because it expands their perception of the future beyond that which is available through traditional sources such as vendor roadmap sessions by linking closely commercial, technical, and social trends.

Organisation

The book is divided into three main sections. The first looks at the major influences on future business: technological progress, changing attitudes, social forces, and economics. The implications of these factors are then examined, and finally the application of the analysis to business strategy is examined. These ideas are then pulled together in a succinct and easily understood conclusion.

Pearson and Lyons focus on the effect of particular techniques. Some of these, such as self-organising systems and the mimicking of natural phenomena ("biomimetrics"), are fairly unconventional, but others, such as increased miniaturisation, wireless devices, low-cost computing and networking, the semantic Web, and artificial intelligence will be more familiar. The Internet and its potential effect on financial transactions and taxation features heavily. The authors note that attitudes to technology are changing and adoption cycles are reducing, describing the impact that technology has had on the physical labour market and the likely future impact on knowledge workers. The authors consider the economic implications of the exploitation of information, looking at the relative cost of creation and reproduction when compared with more traditional goods and services.

The next three chapters look at the implications of this analysis, starting by looking at numerous trade-offs and counter-balancing forces, such as the effect of the "browser wars" and the relationships between customers and producers. The importance of customer and worker information to a commercial organisation and the problems arising from its exploitation are described. The discussion then considers how the knowledge economy changes the importance of physical assets and commercial relationships, followed by an examination of the political and organisational implications of technology.

Finally the authors look at the business effects, starting with the ease of transferring information between systems. They note that corporate intranets make both the devolving of authority through outsourcing and the imposition of increased command and control through micromanagement easier.

Pearson and Lyons suggest that new technology alters the value chains that influence businesses, leading to more temporary business relationships, their replacement by "value-nets," and the rise of the virtual company. This section concludes by looking at globalisation—how goods and services are paid for and some of the implications for taxation.

The authors ask the question—how can business adapt? They start their analysis by examining the interactions between the physical and mental worlds and cyberspace, noting that a strategic analysis works only if the forces acting on a business do not change too rapidly. As change becomes more rapid, there will be no time to develop business cases, because first-mover advantage will be the only advantage a business can have. Pearson and Lyons conclude that the critical factors in allowing cyber-economy to grow are ease of navigation and the effective use of branding. They conclude by examining who will be the winners and losers in business in the year 2010—and why.

Synopsis

This book is succinct and well-written, covering a complex but interesting field in just under 200 pages. The authors paint a convincing description of future business trends, exploring the technical, commercial, economic, and political pressures that will influence them. Their cause, effect, and potential response treatment leads the reader through the subject in a way that is both interesting and instructive. The authors are not afraid to be controversial and at times they take the reader into some very unfamiliar territory, adding extra spice to the book.

While other books are available that look at the future from a more technologically orientated perspective, this book is one of the few that manages to couple the developments in the commercial and technical worlds, thereby giving a more comprehensive viewpoint. In an age when technologists are increasingly being asked to take more of a commercial view, this can only be a good thing. The approach taken has much in common with that taken by Alvin Toffler in his books *Future Shock* and *The Third Wave*. An updated treatment like this is to be welcomed.

The Authors

Ian Pearson works for British Telecom (BT) as its chief futurologist; he is a well-known speaker on future technology trends and has published extensively in this field. Michael Lyons also works for BT and has more than 30 years of research experience in the telecoms industry. He has recently been working in the fields of decision support systems and long-term research issues, leading a research team in BT's Research and Venturing department. Pearson is described as an "unfettered thinker" and Lyons as a "pragmatic modeller," characteristics which give the book its balanced view.

Fragments

ICANN Ratifies Global Policy for Allocation of IPv6 Address Space

On September 7, 2006, the ICANN Board ratified the *Global Policy for Allocation of IPv6 Address Space*. This policy provides for the allocation of IPv6 address space from ICANN to the *Regional Internet Registries* (RIRs).

On July 13, 2006, the Secretary of the *Address Supporting Organization* (ASO) *Address Council* (AC) forwarded to ICANN the proposed global policy for allocation of IPv6 address space. This proposed global policy had been submitted to the ASO AC by the Executive Council of the *Number Resource Organization* (NRO) on June 6, 2006, and adopted by the ASO AC on July 12, 2006. Each RIR community individually discussed the policy and approved its adoption via their own policy development processes. The IPv6 Allocation Policy document is available from the ASO Website:

http://aso.icann.org/docs/aso-global-ipv6.pdf

IP addressing in China and the Myth of Address Shortage

In recent years, various sources have repeated a myth that the IPv4 address pool is close to exhaustion. Many of these stories also falsely claim that there are fewer IPv4 addresses allocated to China than to some individual US universities. The *Asia Pacific Network Information Centre* (APNIC) is committed to countering this myth and has published an article in its newsletter *Apster* on this topic. The article is available here:

http://www.apnic.net/news/hot-topics/internet-gov/ip-china.html

Calendar of Internet-related Events

The *Internet Society* (ISOC) maintains an online list of meetings and conferences, see:

http://geneva.isoc.org/events/

Don't forget to tell us if you move!

We receive quite a lot of IPJ return mail marked as "undeliverable." If you change your address please let us know by either using the IPJ subscription tool or sending an e-mail with the new information to **ipj@cisco.com**. Your cooperation is much appreciated.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

The Internet Protocol Journal

December 2006 Volume 9, Number 4

A Quarterly Technical Publication for Internet and Intranet Professionals

In This Issue

From The Editor

Internet security and stability are topics we keep returning to in this journal. So far we have mainly focused on technologies that protect systems from unauthorized access and ensure that data in transit over wired or wireless networks cannot be intercepted. We have discussed security-enhanced versions of many of the Internet core protocols, including the *Border Gateway Protocol* (BGP), *Simple Network Management Protocol* (SNMP), and the *Domain Name System* (DNS). You can find all these articles by visiting our Website and referring to our index files. All back issues continue to be available in both HTML and PDF formats. In this issue, Wesley Eddy explains a vulnerability in the *Transmission Control Protocol* (TCP) in which a sender can overwhelm a receiver by sending a large number of SYN protocol exchanges. This form of *Denial of Service* attack, known as *SYN Flooding*, was first reported in 1996, and researchers have developed several solutions to combat the problem.

Speaking of Internet stability, at 12:26 GMT on December 26, 2006, an earthquake of magnitude 6.7 struck off Taiwan's southern coast. Six submarine cables were damaged, resulting in widespread disruption of Internet service in parts of Asia. We hope to bring you more details and analysis of this event in a future issue of IPJ. The topic will also be discussed at the next *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT), which will take place in Bali, Indonesia, February 21 through March 2, 2007. For details see: **http://www.apricot2007.net**

The design and operation of systems that use Internet protocols for communication in conjunction with advanced applications—such as an e-commerce system—require the use of a certain amount of "middleware." This software, largely hidden from the end user, has been the subject of a great deal of development and standardization work for several decades. An important component of today's Web systems is the *Extensible Markup Language* (XML). Silvano Da Ros explains how XML networking can be used as a critical building block for network application interoperability.

Defenses Against TCP SYN Flooding Attacks

by Wesley M. Eddy, Verizon Federal Network Systems

This article discusses a specific *Denial of Service* (DoS) attack known as *TCP SYN Flooding*. The attack exploits an implementation characteristic of the *Transmission Control Protocol* (TCP), and can be used to make server processes incapable of answering a legitimate client application's requests for new TCP connections. Any service that binds to and listens on a TCP socket is potentially vulnerable to TCP SYN flooding attacks. Because this includes popular server applications for e-mail, Web, and file storage services, understanding and knowing how to protect against these attacks is a critical part of practical network engineering.

The attack has been well-known for a decade, and variations of it are still seen. Although effective techniques exist to combat SYN flooding, no single standard remedy for TCP implementations has emerged. Varied solutions can be found among current operating systems and equipment, with differing implications for both the applications and networks under defense. This article describes the attack and why it works, and follows with an overview and assessment of the current tactics that are used in both end hosts and network devices to combat SYN flooding attacks.

Basic Vulnerability

The SYN flooding attack became well-known in 1996, when the magazines *2600* and *Phrack* published descriptions of the attack along with source code to perform it[1]. This information was quickly used in attacks on an Internet service provider's (ISP's) mail and Telnet servers, causing outages that were widely publicized in *The Washington Post* and *The Wall Street Journal* (among other venues). CERT quickly released an advisory on the attack technique[2].

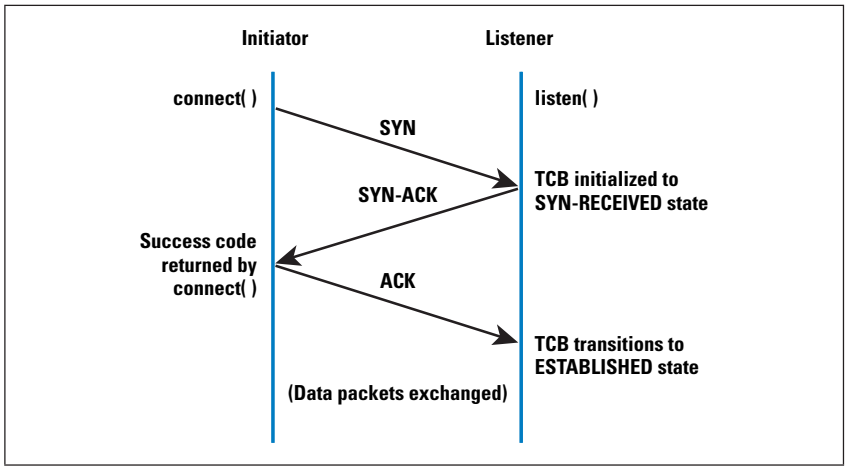

Figure 1: Normal TCP 3-Way Handshake

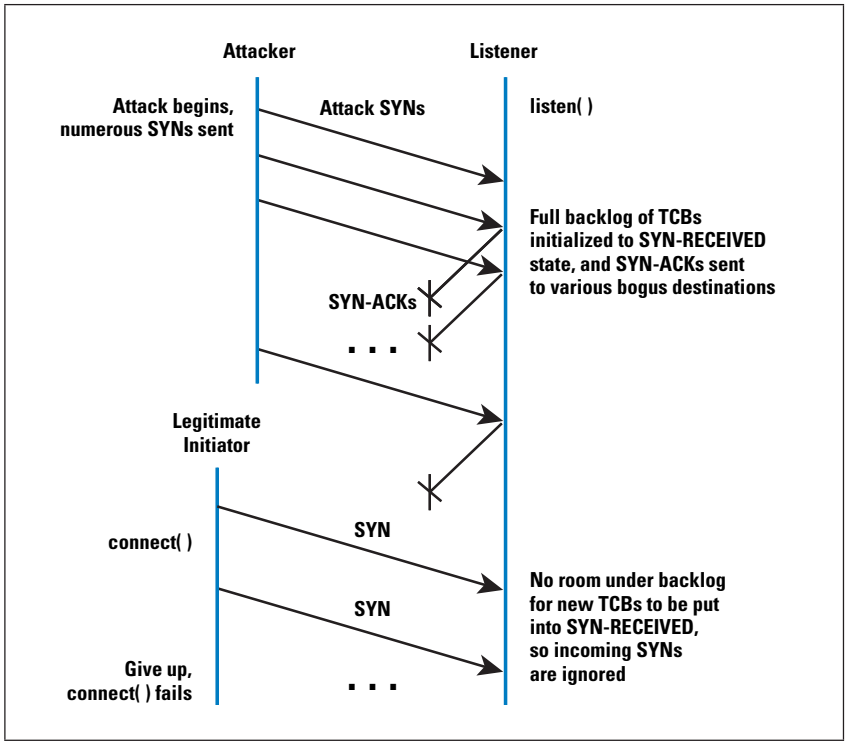
The basis of the SYN flooding attack lies in the design of the 3-way handshake that begins a TCP connection. In this handshake, the third packet verifies the initiator's ability to receive packets at the IP address it used as the source in its initial request, or its return reachability. Figure 1 shows the sequence of packets exchanged at the beginning of a normal TCP connection (refer to RFC 793 for a detailed description of this process).

The *Transmission Control Block* (TCB) is a transport protocol data structure (actually a set of structures in many operations systems) that holds all the information about a connection. The memory footprint of a single TCB depends on what TCP options and other features an implementation provides and has enabled for a connection. Usually, each TCB exceeds at least 280 bytes, and in some operating systems currently takes more than 1300 bytes. The TCP SYN-RECEIVED state is used to indicate that the connection is only half open, and that the legitimacy of the request is still in question. The important aspect to note is that the TCB is allocated based on reception of the SYN packet—before the connection is fully established or the initiator's return reachability has been verified.

This situation leads to a clear potential DoS attack where incoming SYNs cause the allocation of so many TCBs that a host's kernel memory is exhausted. In order to avoid this memory exhaustion, operating systems generally associate a "backlog" parameter with a listening socket that sets a cap on the number of TCBs simultaneously in the SYN-RECEIVED state. Although this action protects a host's available memory resource from attack, the backlog *itself* represents another (smaller) resource vulnerable to attack. With no room left in the backlog, it is impossible to service new connection requests until some TCBs can be reaped or otherwise removed from the SYN-RECEIVED state.

Depleting the backlog is the goal of the TCP SYN flooding attack, which attempts to send enough SYN segments to fill the entire backlog. The attacker uses source IP addresses in the SYNs that are not likely to trigger any response that would free the TCBs from the SYN-RECEIVED state. Because TCP attempts to be reliable, the target host keeps its TCBs stuck in SYN-RECEIVED for a relatively long time before giving up on the half connection and reaping them. In the meantime, service is denied to the application process on the listener for legitimate new TCP connection initiation requests. Figure 2 presents a simplification of the sequence of events involved in a TCP SYN flooding attack.

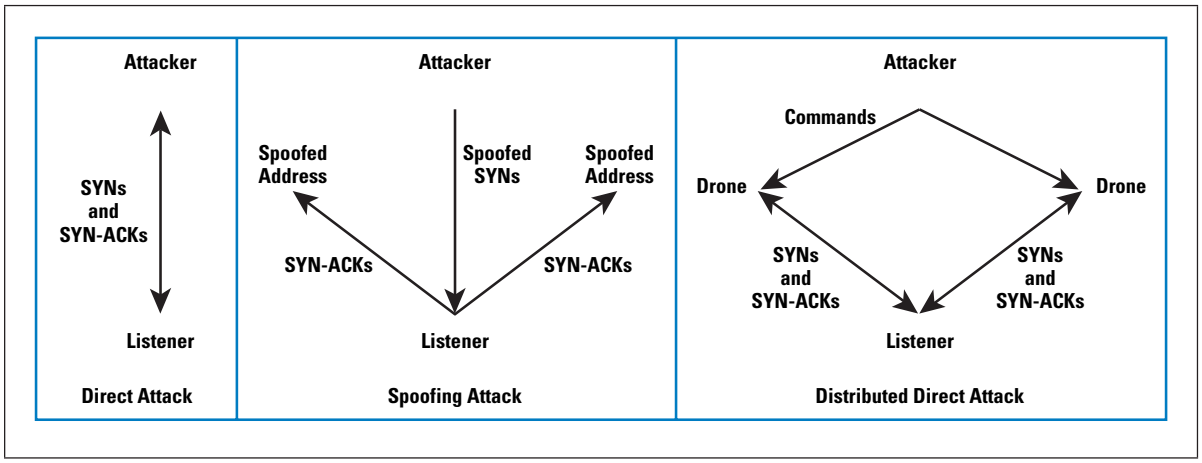
Figure 2: Attack Demonstration: Enough illegitimate TCBs are in SYN-RECEIVED that a legitimate connection cannot be initiated.



Attack Methods

The scenario pictured in Figure 2 is a simplification of how SYN flooding attacks are carried out in the real world, and is intended only to give an understanding of the basic idea behind these types of attacks. Figure 3 presents some variations that have been observed on the Internet.

Figure 3: Some Variants of the Basic Attack



Direct Attack

If attackers rapidly send SYN segments without spoofing their IP source address, we call this a *direct attack*. This method of attack is very easy to perform because it does not involve directly injecting or spoofing packets below the user level of the attacker's operating system. It can be performed by simply using many TCP *connect()* calls, for instance. To be effective, however, attackers must prevent their operating system from responding to the SYN-ACKS in any way, because any ACKs, RSTs, or *Internet Control Message Protocol* (ICMP) messages will allow the listener to move the TCB out of SYN-RECEIVED. This scenario can be accomplished through firewall rules that either filter outgoing packets to the listener (allowing only SYNs out), or filter incoming packets so that any SYN-ACKS are discarded before reaching the local TCP processing code.

When detected, this type of attack is very easy to defend against, because a simple firewall rule to block packets with the attacker's source IP address is all that is needed. This defense behavior can be automated, and such functions are available in off-the-shelf reactive firewalls.

Spoofing-Based Attacks

Another form of SYN flooding attacks uses IP address spoofing, which might be considered more complex than the method used in a direct attack, in that instead of merely manipulating local firewall rules, the attacker also needs to be able to form and inject raw IP packets with valid IP and TCP headers. Today, popular libraries exist to aid with raw packet formation and injection, so attacks based on spoofing are actually fairly easy.

For spoofing attacks, a primary consideration is address selection. If the attack is to succeed, the machines at the spoofed source addresses must not respond to the SYN-ACKS that are sent to them in any way. A very simple attacker might spoof only a single source address that it knows will not respond to the SYN-ACKS, either because no machine physically exists at the address presently, or because of some other property of the address or network configuration. Another option is to spoof many different source addresses, under the assumption that some percentage of the spoofed addresses will be unrespondent to the SYN-ACKS. This option is accomplished either by cycling through a list of source addresses that are known to be desirable for the purpose, or by generating addresses inside a subnet with similar properties.

If only a single source address is repetitively spoofed, this address is easy for the listener to detect and filter. In most cases a larger list of source addresses is used to make defense more difficult. In this case, the best defense is to block the spoofed packets as close to their source as possible.

Assuming the attacker is based in a "stub" location in the network (rather than within a transit *Autonomous System* (AS), for instance), restrictive network ingress filtering[7] by stub ISPs and egress filtering within the attacker's network will shut down spoofing attacks—if these mechanisms can be deployed in the right places. Because these ingress/egress filtering defenses may interfere with some legitimate traffic, such as the Mobile IP triangle routing mode of operation, they might be seen as undesirable, and are not universally deployed. *IP Security* (IPsec) also provides an excellent defense against spoofed packets, but this protocol generally cannot be required because its deployment is currently limited. Because it is usually impossible for the listener to ask the initiator's ISPs to perform address filtering or to ask the initiator to use IPsec, defending against spoofing attacks that use multiple addresses requires more complex solutions that are discussed later in this article.

Distributed Attacks

The real limitation of single-attacker spoofing-based attacks is that if the packets can somehow be traced back to their true source, the attacker can be easily shut down. Although the tracing process typically involves some amount of time and coordination between ISPs, it is not impossible. A distributed version of the SYN flooding attack, in which the attacker takes advantage of numerous drone machines throughout the Internet, is much more difficult to stop. In the case shown in Figure 3, the drones use direct attacks, but to increase the effectiveness even further, each drone could use a spoofing attack and multiple spoofed addresses.

Currently, distributed attacks are feasible because there are several "botnets" or "drone armies" of thousands of compromised machines that are used by criminals for DoS attacks. Because drone machines are constantly added or removed from the armies and can change their IP addresses or connectivity, it is quite challenging to block these attacks.

Attack Parameters

Regardless of the method of attack, SYN flooding can be tuned to use fewer packets than a brute-force DoS attack that simply clogs the target network by sending a high volume of packets. This tuning is accomplished with some knowledge of the listener's operating system, such as the size of the backlog that is used, and how long it keeps TCBs in SYN-RECEIVED before timing out and reaping them. For instance, the attacker can minimally send a quick flight of some number of SYNs exactly equal to the backlog, and repeat this process periodically as TCBs are reclaimed in order to keep a listener unavailable perpetually.

Default backlogs of 1024 are configured on some recent operating systems, but many machines on the Internet are configured with backlogs of 128 or fewer. A common threshold for retransmission of the SYN-ACK is 5, with the timeout between successive attempts doubled, and an initial timeout of 3 seconds, yielding 189 seconds between the time when the first SYN-ACK is sent and the time when the TCB can be reclaimed.

Assuming a backlog of 128 and that an attacker generates 40-byte SYN segments (with a 20-byte TCP header plus a 20-byte IP header), the attacker has to send only 5.12 kilobytes (at the IP layer) in order to fill the backlog. Repeated every 189 seconds, this process gives an average data rate of only 27 bytes per second (easily achievable even over dialup links). This data rate is in stark contrast to DoS attacks that rely on sending many megabits per second of attack traffic. Even if a backlog of 2048 is used, the required data rate is only 433 bytes per second, so it is clear that the ease of attack scales along with increases to the backlog—and more sophisticated defenses are needed.

Lessons Learned

The protocol flaw in TCP that makes SYN flooding effective is that for the small cost of sending a packet, an initiator causes a relatively greater expense to the listener by forcing the listener to reserve state in a TCB. An excellent technique for designing protocols that are robust to this type of attack is to make the listener side operate statelessly[3] until the initiator can demonstrate its legitimacy. This principle has been used in more recent transport protocols, such as the *Stream Control Transmission Protocol* (SCTP)[4], which has a 4-way handshake, with listener TCB state being created only after the initiator echoes back some "cookie" bytes sent to it by the listener. This echo proves to some extent that the initiator side is at the address it appears to be (that is, it has return reachability) and is not attempting a SYN flooding style of attack.

Outside of transport protocols and TCBs, security protocols also commonly use this defense technique. For instance, the *Internet Key Exchange Version 2* (IKEv2)[5] component of IPsec does not create state for a new *Security Association* until it can verify that initiators are capable of responding to packets sent to the address they claims to be using. There are other security protocols in which the listener sends out "puzzles" in response to initiation attempts and grants services or state only when puzzle solutions are returned[6]. This tactic not only verifies the addresses of initiators but also implies a computational burden that causes them to further demonstrate their genuine willingness to communicate productively.

Countermeasures

During the initial Panix attack, random spoofed source addresses were being used, but it was noted that the attack TCP SYNs all used the same source port number. A filter that denied incoming packets from this port was temporarily effective, but easy for the attacker to adapt to, and the attack segments began using random ports. Panix was able to isolate which of its ingress routers the attack was coming from and null-route packets destined for its servers coming through that router, but this solution was obviously a heavy-handed one, and seems to have also been overcome when the attacker started sending packets that were routed through a different upstream provider. Panix had mixed success in getting its providers to assist in tracing and blocking the attack, and the networking community was spurred into devising other solutions.

Two broad classes of solutions to SYN flooding attacks have evolved, corresponding to where the defenses are implemented. The first class of solutions involves hardening the end-host TCP implementation itself, including altering the algorithms and data structures used for connection lookup and establishment, as well as some solutions that diverge from the TCP state machine behavior during connection establishment, as described in RFC 793.

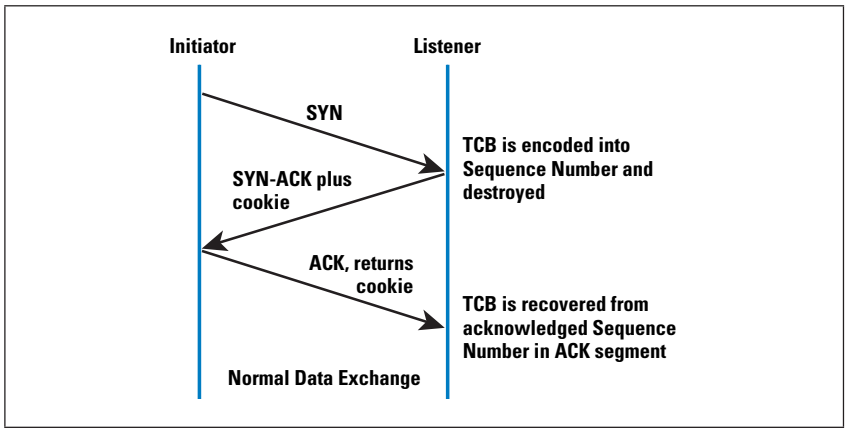
The second class involves hardening the network, either to lessen the likelihood of the attack preconditions (an army of controlled hosts or the propagation of IP packets with spoofed source addresses), or to insert middleboxes that can isolate servers on the networks behind them from illegitimate SYNs.

End-Host Countermeasures

Increasing TCP Backlog: Because the basic attack mechanism relies on overflowing a host's backlog of connecting sockets, an obvious end host-based solution is to simply increase the backlog, as is already done for very popular server applications. In at least some popular TCP implementations, this solution is known to be a poor one because of the use of linear list traversal in the functions that attempt to free state associated with stale connection attempts. Increasing the backlog is typically possible through altering the *listen()* call of an application and setting an operating system kernel parameter named SOMAXCONN, which sets an upper bound on the size of the backlog that an application can request. This step by itself should not be seriously considered as a means to defend against SYN flooding attacks—even in operating systems that can efficiently support large backlogs—because an attacker who can generate attack segments will most likely be able to scale to larger orders than the backlog supportable by a host.

Reducing the SYN-RECEIVED *Timer:* Another simple end host-based mechanism is to put a tighter limit on the amount of time between when a TCB enters the SYN-RECEIVED state and when it may be reaped for not advancing. The obvious disadvantage to this mechanism is that in cases of aggressive attacks that impose some amount of congestion loss in either the SYN-ACK or handshake-completing ACK packets, legitimate connection TCBs may be reaped as hosts are in the process of retransmitting these segments. Furthermore, there is only a linear relationship between the reduction that an administrator makes in the SYN-RECEIVED timer and the corresponding increase in packet rate that the adversary must make in order to continue attacking the server. Other alternative end-host solutions make it much more difficult for an attack to remain viable. For these reasons, a reduction in the SYN-RECEIVED timer is not an advisable defense against SYN flooding attacks.

Figure 4: Connection Establishment with SYN Cookies



SYN *Caches:* Two end-host defenses, called SYN caches and SYN cookies (described later), operate by reducing the amount of state allocated initially for a TCB generated by a received SYN, and putting off instantiating the full state[8]. In a host that uses a SYN cache, a hash table with a limited amount of space in each hash bucket is used to store a subset of the data that would normally go into an allocated TCB. If and when a handshake completing ACK is received, this data can be moved into a full TCB; otherwise the oldest bucket at a particular hash value can be reaped when needed. In Lemon's FreeBSD example[8], the SYN cache entry for a half connection is 160 bytes, versus 736 bytes for a full TCB, and 15359 entries in the SYN cache are supported.

The SYN cache data structure is robust to attackers attempting to overflow its buckets because it uses the initiator's local port number and some secret bits in the hash value. Because stacks are a more effective data structure to search than a simple linked list, stacks that use a SYN cache can have improved speed, even when not under attack. Under Lemon's tests, during an active attack a host using a SYN cache was able to establish legitimate connections with only about a 15-percent increase in latency.

SYN Cookies: In contrast to the SYN cache approach, the SYN cookies technique causes absolutely zero state to be generated by a received SYN. Instead, the most basic data comprising the connection state is compressed into the bits of the sequence number used in the SYN-ACK. Since for a legitimate connection, an ACK segment will be received that echoes this sequence number (actually the sequence number plus one), the basic TCB data can be regenerated and a full TCB can safely be instantiated by decompressing the Acknowledgement field. This decompression can be effective even under heavy attack because there is no storage load whatsoever on the listener, only a computational load to encode data into the SYN-ACK sequence numbers. The downside is that not all TCB data can fit into the 32-bit Sequence Number field, so some TCP options required for high performance might be disabled. Another problem is that SYN-ACKs are not retransmitted (because retransmission would require state), altering the TCP synchronization procedures from RFC 793.

Recent work by Andre Oppermann uses the TCP Timestamp option in conjunction with the Sequence Number field to encode more state information and preserve the use of high-performance options such as TCP Window Scaling, and TCP *Selective Acknowledgment Options* (SACK), and can also be used to preserve *TCP-Message Digest 5* (MD5) support with SYN cookies. This option is a step forward, in that it removes the major negative effect of previous SYN cookie implementations that disabled these features.

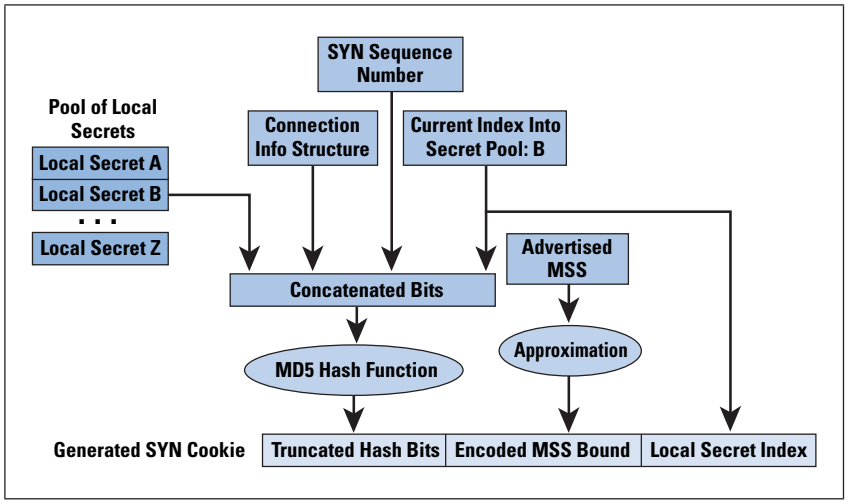


Figure 5: Process for Generation and Validation of TCP SYN Cookies.

The exact format of TCP SYN cookies is not an interoperability issue, because they are only locally interpreted, and the format and procedures for generation and validation can vary slightly among implementations. Figure 5 depicts the general process of SYN cookie generation and validation used by multiple implementations.

To compute the SYN-ACK sequence number (that is, the TCP cookie) when using TCP cookies, a host first concatenates some local secret bits, a data structure that contains the IP addresses and TCP ports, the initial SYN sequence number, and some index data identifying the secret bits. An MD5 digest is computed over all these bytes, and some bits are truncated from the hash value to be placed in the SYN-ACK sequence number. Because the sequence number is about a fourth the size of the full hash value, this truncation is necessary, but generally at least 3 bytes worth of the hash bits are used, meaning that there should still be close to a 2^{24} effort required to guess a valid cookie without knowing the local secret bits. In addition to the hash output, some of the cookie bits indicate a lower bound on the *Maximum Segment Size* (MSS) that the SYN contained, and the index bits identifying the local secret used within the hash.

To validate a SYN cookie, first the acknowledgement number in an incoming ACK segment is decremented by 1 to retrieve the generated SYN cookie. The valid value for the set of truncated hash bits is computed based on the IP address pair, TCP port numbers, segment sequence number minus one, and the value from the secret pool corresponding to the index bits inside the cookie. If these computed hash bits match those within the ACK segment, then a TCB is initialized and the connection proceeds. The encoded MSS bound is used to set a reasonable-sized MSS that is no larger than what was originally advertised. This MSS is usually implemented as three bits whose code points correspond to eight "commonly advertised" MSS values based on typical link *Maximum Transmission Units* (MTUs) and header overheads.

Hybrid Approaches: A hybrid approach combines two or more of the single defense techniques described previously. For instance, some end-host operating systems implement both a large backlog and SYN cookies, but enable SYN cookies only when the amount of the backlog that is occupied exceeds some threshold, allowing them to normally operate without the disadvantages of SYN cookies, but also allowing them to fail over to the SYN-cookie behavior and be strongly protected when an attack occurs.

Network-Based Countermeasures

Filtering: The most basic network-level defense is application of the filtering techniques described in RFC 2827[7]. Using ingress filtering, an ISP refuses to further route packets coming from an end site with IP source addresses that do not belong to that end site. Ingress filtering would be highly effective at preventing SYN flooding attacks that rely on spoofed IP packets. However, it is not currently reliable because ingress filtering policies are not universally deployed. Ingress filtering is also wholly ineffective against SYN flooding attacks that use a distributed army of controlled hosts that each directly attack. Ingress filtering is also a mechanism that an end site wishing to defend itself most often has no control over, because it has no influence upon the policies employed by ISPs around the world.

Firewalls and Proxies: A firewall or proxy machine inside the network can buffer end hosts from SYN flooding attacks through two methods, by either spoofing SYN-ACKs to the initiators or spoofing ACKs to the listener[9].

Figure 6 shows the basic operation of a firewall/proxy that spoofs SYN-ACKs to the initiator. If the initiator is legitimate, the firewall/proxy sees an ACK and then sets up a connection between itself and the listener, spoofing the initiator's address. The firewall/proxy splits the end-to-end connection into two connections to and from itself. This splitting works as a defense against SYN flooding attacks, because the listener never sees SYNs from an attacker. As long as the firewall/proxy implements some TCP-based defense mechanism such as SYN cookies or a SYN cache, it can protect all the servers on the network behind it from SYN flooding attacks.

Figure 6: Packet Exchanges through a SYN-ACK spoofing Firewall/Proxy.

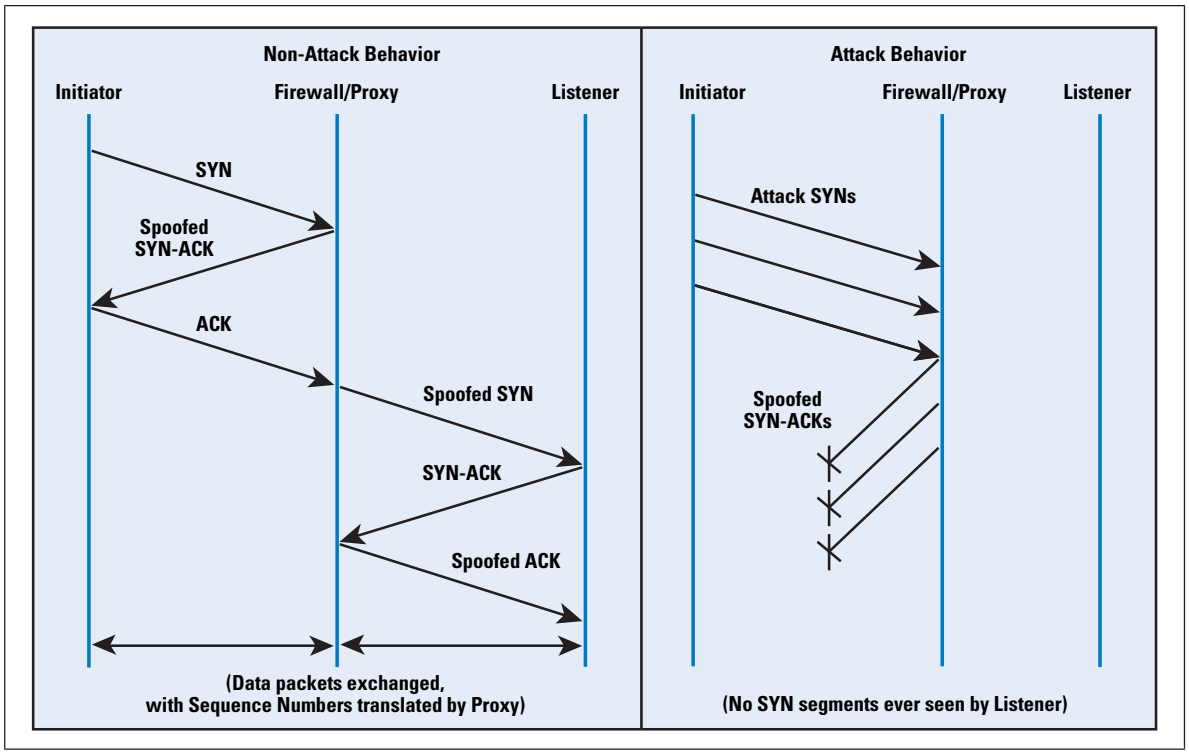

Figure 7 illustrates the packet exchanges through a firewall/proxy that spoofs ACKs to the listener in response to observed SYN-ACKs. This spoofing prevents the listeners TCBs from staying in the SYN-RECEIVED state, and thus maintains free space in the backlog. The firewall/proxy then waits for some time, and if a legitimate ACK from the initiator is not observed, then it can signal the listener to free the TCB using a spoofed TCP RST segment. For legitimate connections, packet flow can continue, with no interference from the firewall/proxy. This solution is more desirable than the mode of operation in Figure 5, where the firewall/proxy spoofs SYN-ACKs, because it does not require the firewall/proxy to actively participate in legitimate connections after they are established.

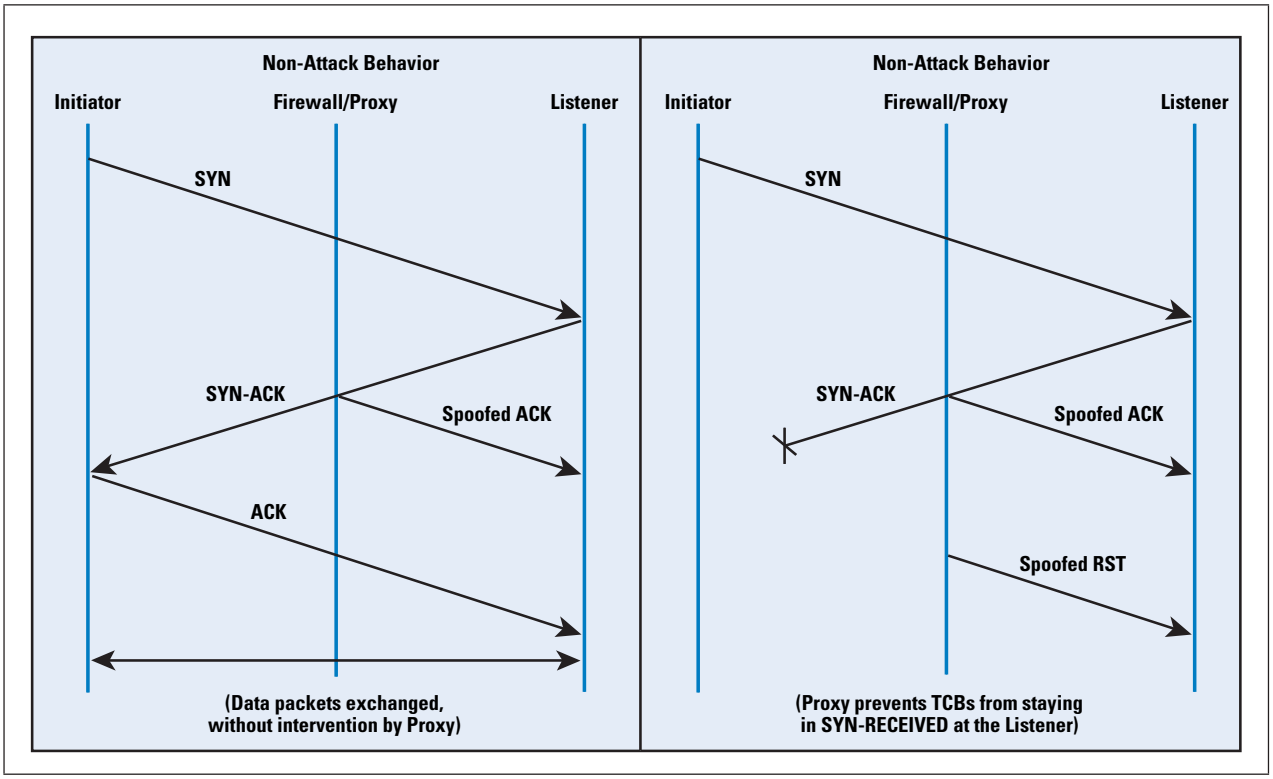
Figure 7: Packet Exchanges through an ACK-spoofing Firewall/Proxy.



Active Monitor: An active monitor is a device that can observe and inject traffic to the listener, but is not necessarily within the routing path itself, like a firewall is. One type of active monitor acts like the ACK-spoofing firewall/proxy of Figure 6, with the added capability of spoofing RSTs immediately if it sees SYNs from source addresses that it knows to be used by attackers[9]. Active monitors are useful because they may be cheaper or easier to deploy than firewall-based or filtering solutions, and can still protect entire networks of listeners without requiring every listener's operating system to implement an end-host solution.

Defenses in Practice

Both end-host and network-based solutions to the SYN flooding attack have merits. Both types of defense are frequently employed, and they generally do not interfere when used in combination. Because SYN flooding targets end hosts rather than attempting to exhaust the network capacity, it seems logical that all end hosts should implement defenses, and that network-based techniques are an optional second line of defense that a site can employ.

End-host mechanisms are present in current versions of most common operating systems. Some implement SYN caches, others use SYN cookies after a threshold of backlog usage is crossed, and still others adapt the SYN-RECEIVED timer and number of retransmission attempts for SYN-ACKs.

Because some techniques are known to be ineffective (increasing backlogs and reducing the SYN-RECEIVED timer), these techniques should definitely not be relied upon. Based on experimentation and analysis (and the author's opinion), SYN caches seem like the best end-host mechanism available.

This choice is motivated by the facts that they are capable of withstanding heavy attacks, they are free from the negative effects of SYN cookies, and they do not need any heuristics for threshold setting as in many hybrid approaches.

Among network-based solutions, there does not seem to be any strong argument for SYN-ACK spoofing firewall/proxies. Because these spoofing proxies split the TCP connection, they may disable some high-performance or other TCP options, and there seems to be little advantage to this approach over ACK-spoofing firewall/proxies. Active monitors should be used when a firewall/proxy solution is administratively impossible or too expensive to deploy. Ingress and egress filtering is frequently done today (but not ubiquitous), and is a commonly accepted practice as part of being a good neighbor on the Internet. Because filtering does not cope with distributed networks of drones that use direct attacks, it needs to be supplemented with other mechanisms, and must not be relied upon by an end host.

Related Attacks

In addition to SYN flooding, several other attacks on TCP connections are possible by spoofing the IP source address and connection parameters for in-progress TCP connections[10]. If an attacker can guess the two IP addresses, TCP port numbers, and a valid sequence number within the window, then a connection can be disrupted either through resetting it or injecting corrupt data. In addition to spoofed TCP segments, spoofed ICMP datagrams have the capability to terminate victim TCP connections.

Both these other attacks and SYN floods target a victim's TCP application and can potentially deny service to the victim using an attack rate less than that of brute-force packet flooding. However, SYN flooding and other TCP spoofing attacks have significant differences. SYN flooding denies service to new connections, without affecting in-progress connections, whereas other spoofing attacks disrupt in-progress connections, but do not prevent new connections from starting. SYN flooding attacks can be defended against by altering only the initial handshaking procedure, whereas other spoofing attacks require additional per-segment checks throughout the lifetime of a connection. The commonality between SYN flooding and other TCP spoofing attacks is that they are predicated on an attacker's ability to send IP packets with spoofed source addresses, and a similar defense against these attacks would be to remove this capability through more universal deployment of address filtering or IPsec.

Conclusion

At the time of this writing, the TCP SYN flooding vulnerability has been well-known for a decade. This article discussed several solutions aimed at making these attacks ineffective, some of which are readily available in commercial off-the-shelf products or free software, but no solution has been standardized as a part of TCP or middlebox function at the IETF level. The IETF's *TCP Maintenance and Minor Extensions* (TCPM) working group is in the process of producing an informational document that explains the positive and negative aspects of each of the common mitigation techniques[10], and readers are encouraged to consult this document for further information.

In this author's opinion, some variant of the SYN cache technique should be a mandatory feature to look for in a server operating system, and the variant can be deployed in combination with other network-based methods (address-based filtering, ACK-spoofing firewalls, IPsec, etc.) in appropriate situations. It is encouraging to see that protocol designers have learned a lesson from the SYN flooding vulnerability in TCP and have made more recent protocols inherently robust to such attacks.

Acknowledgements

Several individual participants in the IETF's TCPM working group have contributed bits of data found in the group's informational document on SYN flooding[11], some of which is replicated in spirit here.

Boosting the SOA with XML Networking

by Silvano Da Ros

In the 1990s, the widespread adoption of *object-oriented programming* (OOP) and advancing network technologies fostered the development of distributed object technologies, including *Object Management Group's* (OMG's) *Common Object Request Broker Architecture* (CORBA) and Microsoft's *Distributed Common Object Model* (DCOM). Both CORBA and DCOM follow the OOP consumer-producer service model, where applications locally instantiate any number of objects and execute methods for the objects to obtain a service. However, with *distributed* object technologies, a local application can request a service from a remote application by instantiating a remote object and executing the methods of the object using *Remote Procedure Call* (RPC) over the network. The local application executes the methods of the remote object as if the object were an inherent part of the local application.

To push toward a simpler consumer-producer service model than distributed objects, the *Service-Oriented Architecture* (SOA) was created as a worldwide standards-based application interoperability initiative[1]. SOA differs from distributed object technologies, because you no longer deal with object instantiation and method invocation to provide services between your applications[2]. Instead, you can create *Extensible Markup Language* (XML)-based standard Web services to exchange XML documents between your applications using Internet-based application layer protocols, such as *Hyper Text Transfer Protocol* (HTTP) and the *Simple Mail Transfer Protocol* (SMTP).

This is where XML networking comes into the picture. This article shows how to use SOA at the network edge, in conjunction with XML within the network, to help with the work required for enabling interoperability between your applications. The problem with SOA on its own is that to scale applications, hardware and software upgrades are required on the servers where your business logic resides. Because application integration using XML is CPU-intensive, it benefits from XML hardware built specifically for XML computations. However, the applications servers that run your business logic are effectively independent of the underlying XML processing. Therefore, to accelerate the SOA at the network level transparently to the application, XML networking technologies can be used. XML networking can provide SOA acceleration using a special middleware-enabled network layer, which this article explains. This special network layer also provides additional benefits to your applications that SOA alone cannot provide at the edge, such as dynamic message routing and transformation.

To help in the understanding of SOA acceleration with XML networking, the following section discusses SOA and its constituent technologies. Further sections explore the specifics of XML and XML-based network processing.

A Brief History of SOA

Traditionally, hand-coding proprietary interfaces were required to interoperate between your applications, as Figure 1 illustrates. This task is a trivial one if you have only a few applications, but if you have numerous disparate applications, all requiring interfaces into one another, the result is a complex, many-to-many web of connections between them. In the 1980s, *Electronic Data Interchange* (EDI) was developed to standardize the message formats that trading partners use to exchange text-based transaction data residing on mainframes, making it an early predecessor to SOA.

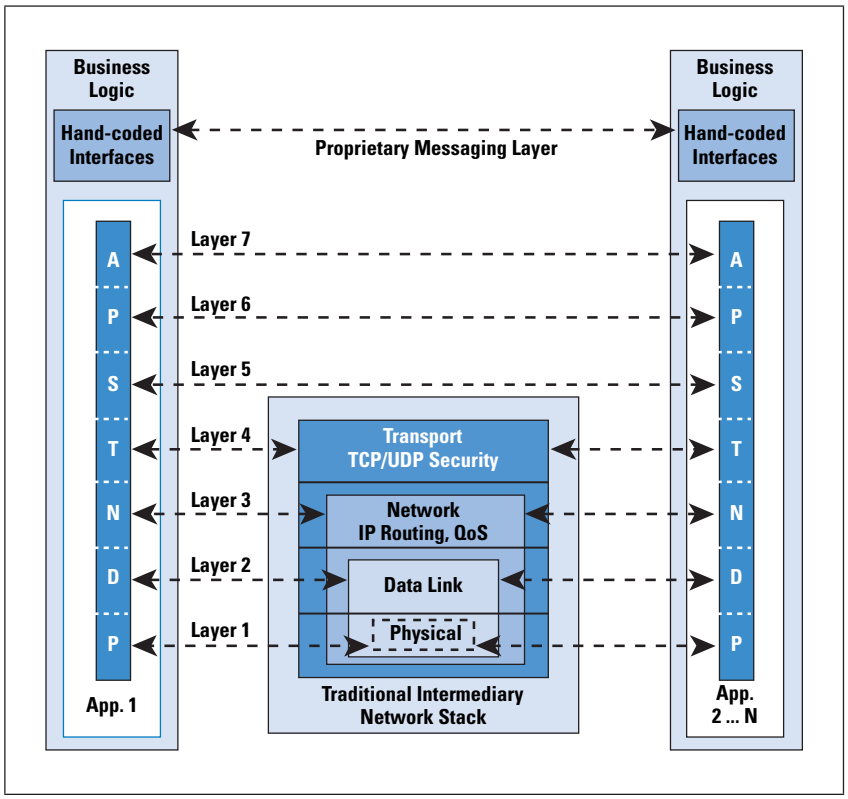

Figure 1: The Proprietary Messaging Layer

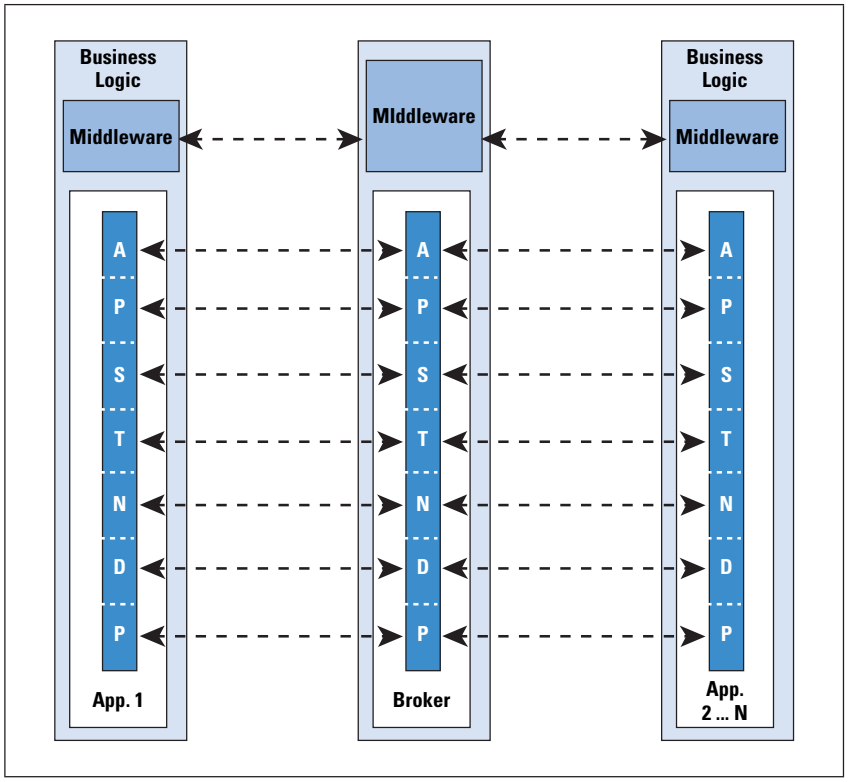
In the mid-1990s, standard middleware (or integration brokers) became available, such as CORBA and DCOM mentioned previously, to integrate advanced client-server applications. Figure 2 shows how integration brokers allow you to perform the translations between end systems over a standard messaging layer without creating application-specific interfaces between each system. During the same time, numerous software vendors, such as IBM WebSphere and TIBCO, also developed standard messaging layer protocols, which required adding vendor-specific adapters within the common integration brokers. Additionally, with newer application development environments being adopted, such as *Java 2 Sun Enterprise Edition* (J2EE) and Microsoft .NET, even more programming complexity is required when considering application interoperability without using the SOA. Fortunately, these new platforms currently support the SOA, allowing an application developed in one platform to tap into the data supplied by an application developed in the other.

Figure 2: The Standard Messaging Layer



Figures 1 and 2 illustrate how the proprietary and standard messaging layers sit above the network stack—at best, a traditional network device can operate only up to and including the transport layer. For example, by tracking TCP connection state information, a firewall device allows you to configure security services for your applications. Some firewalls can inspect the context of the application, but only to ensure the application behavior is RFC-compliant and not performing some sort of malicious activity. Additionally, at the next layer down the stack, you can configure Layer 3 *Quality of Service* (QoS) functions, such as *IP Precedence*, *Differentiated Services* (DiffServ), traffic shaping, and resource reservation, to ensure delivery of traffic to your critical applications. Although the network layers can provide these intelligent network services to your applications, they do not add any value toward accelerating your SOA.

Notice how the middleware portion in the proprietary messaging layer in Figure 1 takes up a larger portion of the application stack than the standard messaging layer from Figure 2. This situation occurs because the list of available messages that your standard messaging layer applications support is now much smaller—the broker takes care of the interfacing complexity on behalf of your applications. A reduced number of messages requires that you maintain much less middleware programming code on your applications than if every application in your network had to account for the messages of every other application.

Optimizing the SOA

Now that you understand SOA, you can better understand where XML networking fits into the scheme of things. Figure 3 illustrates how network equipment vendors can add specialized "application-aware" intelligence into Layers 5 through 7 of the OSI model.

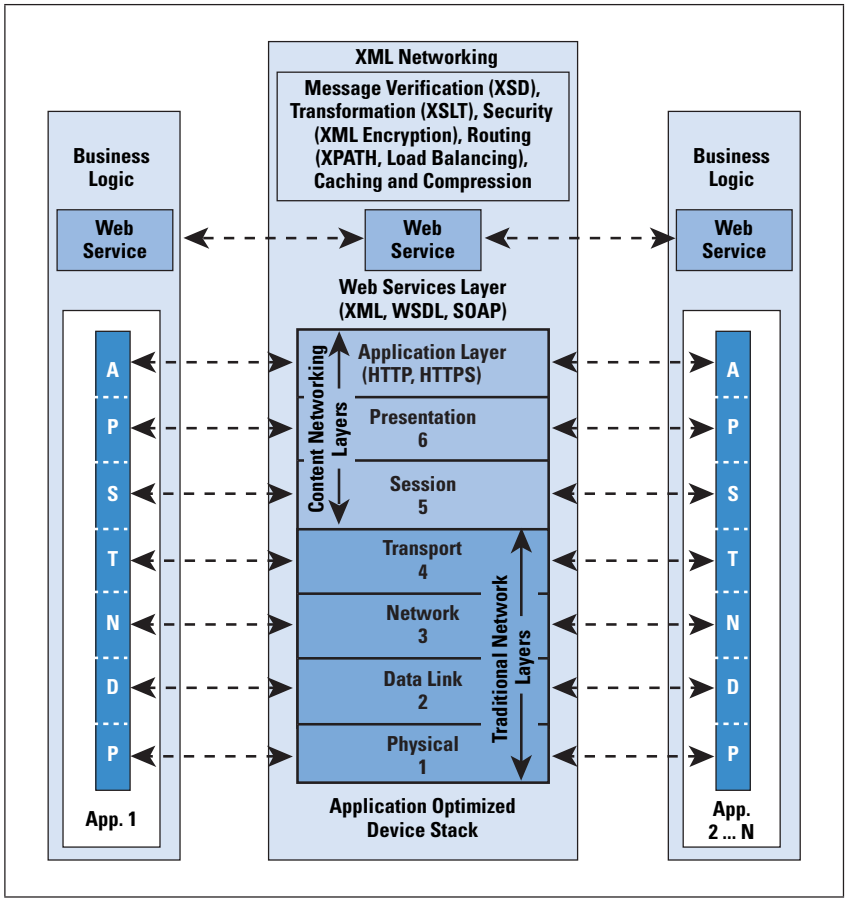
You can start by contrasting XML networking with traditional content networking technologies[3]. As you can see in Figure 3, by incorporating content networking services into the network, such as *Server Load Balancing* (SLB), caching, and *Secure Sockets Layer* (SSL) acceleration, network vendors give you the ability to transparently accelerate your applications without the need of application hardware upgrades. However, by residing only within the OSI model, content networking services and protocols provide a "network-oriented" way to accelerate your applications. In order to achieve full application awareness, you must look not only into the application headers, but also into the application payload. Although the content networking protocols can inspect into the packet payload, they are meant for providing network layer services but *not* application integration services. For example, *Network-Based Application Recognition* (NBAR) allows you to mark the IP DiffServ field in packets containing high-priority application traffic by first detecting the behavior of the application. However, like the network layers, the content networking layers cannot fulfill SOA acceleration requirements either.

In contrast, XML networking provides integration services by inspecting the full context of the application transaction and adding XML standards-based intelligence on top of the TCP/IP stack. An XML-enabled network provides you greater control, flexibility, and efficiency for integrating your applications than integration brokers. Figure 3 shows how you can inspect the XML-based "Web services" layer to accelerate your applications developed within an SOA model without the need of an integration broker.

The most popular Web services protocol is *Simple Object Access Protocol* (SOAP)[4]. With SOAP, your applications can request services from one another with XML-based requests and receive responses as data formatted with XML. Because SOAP uses XML, its Web services are self-descriptive and very simple to use.

You define your SOAP Web services with the XML-based *Web Services Description Language* (WSDL)[5]. The WSDL binds the SOAP messages to the Web services layer, as discussed later in this article. You can then transport your SOAP messages over standard application layer protocols, such as HTTP and HTTPS, between your client-server applications.

Figure 3: The Web Services Layer

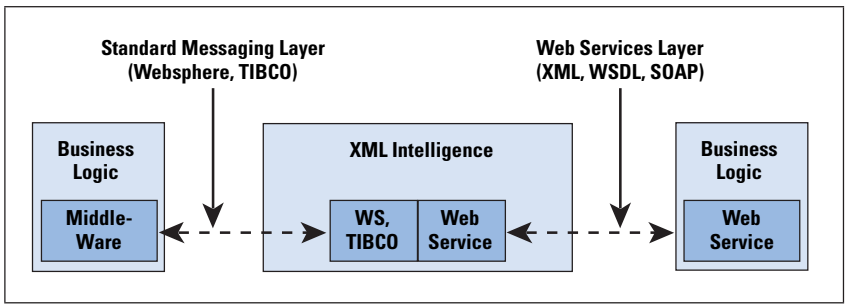


Similar to content networking technologies, XML networking can transparently add value to your applications within the network. When the XML network device receives the standard XML document from the Web services layer, you can configure the device to perform application-oriented services on the document. But because XML networking operates at the middleware layer and uses standard documents to integrate your applications, it provides you with fully standard functions using languages for:

- *Message Verification:* You can develop *World Wide Web Consortium* (W3C) *XML Schema Definitions* (XSDs) that your XML network can use to verify the syntax of your XML documents[6].
- *XML Translation:* Using *XML Stylesheet Language Transformations* (XSLT), you can translate XML documents to other non-XML formats, and conversely, directly within your network[7].
- *Context-Based Routing:* Use *XML Path* (XPATH) to route messages based on data stored within XML documents[8]. A popular example is to route stock exchange quotes to a desired location when the value of the stock drops below a certain threshold.
- *High Availability:* Messages containing specific content can be load balanced across numerous identical origin servers.

- *Data Security:* You can accelerate XML encryption computations using either hardware or software XML-accelerated devices.
- *Compression and Caching:* You can cache frequently requested XML documents and compress XML documents to reduce network bandwidth. Like XML encryption, XML caching and compression can be performed using either hardware or software XML-accelerated devices.
- *Application-Layer Request Translation:* You can use XML networking to convert non-Web service requests into standard Web service requests. As with integration brokers, vendor-specific adapters are required to translate between WebSphere MQ, TIBCO, and SOA Web services. For example, Figure 4 shows how you can use network-level XML intelligence to translate between Websphere or TIBCO messages and Web services layer XML-based messages.

Figure 4: Intelligent Protocol Switching



Introducing XML Service Languages

Now that you have a general understanding of both SOA and XML networking, you can examine the specific XML technologies used for application interoperability, including:

- *XML* is used to format application data for storage and transmission.
- *XSLT* is used to translate between one XML format to another.
- *XSD* is used to describe, control, and verify an XML document format.
- *XPath* is a way to address items in an XML document hierarchy.
- *SOAP* is a messaging protocol used to encode information in Web service request and response messages before sending them over a network.

XML has its roots in the late 1960s from the *Generalized Markup Language* (GML), which was used to organize IBM's mainframe-based legal documents into a searchable form. The *Standard Generalized Markup Language* (SGML) was officially standardized in 1986 as an ISO international norm (ISO 8879). Since then, XML has become the predominant markup language for describing content. XML differs from HTML because it is not concerned with presenting or formatting content; instead, XML is used for describing the data using tags and attributes that you define yourself. Figure 5 is a sample XML document that organizes a police department's traffic ticket information.

Figure 5: A Traffic Ticket XML Example

```
<?xml version="1.0"?>
<dept-tickets>
 <dept-chief>Greg Sanguinetti"/>
 <dept-id>12389289/>
 <ticket id="034567910" code="301">
  <offender>
   <name>John Smith</name>
   <license-number>10003887</license-number>
   <plate-number>9AER9876</plate-number>
  </offender>
  <offence-date>09/30/2005</offence-date>
  <location>
   <state>CA</state>
   <city>SJ</city>
   <intersection>West Tasman Dr.-Great America Pkwy.</intersection>
  </location>
  <officer>
   <officer-name>Paul Greene</officer-name>
   <officer-badge>7652323</officer-badge>
   <cruiser-plate-number>6TYX0923</cruiser-plate-number>
  </officer>
  <description>Failure to stop at red light</description>
  <fine>100</fine>
 </ticket>
 <ticket id="..." code="...">
 ...
 </ticket>
 <ticket id="..." code="...">
 ...
 </ticket>
</dept-tickets>
```

The XML in Figure 5 identifies the group of tickets for a police department by the department ID and the department chief's name. This example gives the data for a single traffic ticket as defined by the "ticket" element (or tag); however, you could include as many tickets as you want within the element "dept-tickets." The "ticket" element has two self-explanatory attributes (in dark blue), called "id" and "code," referring to the identification number for the individual ticket and the offense code, respectively. The sub-elements of the "ticket" element are also self-explanatory: "offender," "offence-date," "location," "officer," "description" and "fine."

In order to build a well-formed XML document, you must embrace the data for each element within its respective open and close tags (for example, <ticket>...</ticket>, or <ticket>.../>), properly nest all elements, and make sure all element names are in the proper case. You must also specify the XML version with the "<?xml version="1.0"?>" tag at the beginning of the XML document. HTML is less rigid than XML because it is case-insensitive and most Web browsers will allow you to leave out the close tags of an element. Because XML is very strict about following the correct syntax (that is, by making sure the XML is well-formed), XML processors are much easier to develop than traditional HTML Web browsers.

To verify that your documents are valid XML, you can check them against XSD files, which define the XML elements and their sequence, as discussed later in this article.

Transforming XML Using XSLT

You can use XSLT to translate one XML-based language into another. For example, you can translate standard XML into HTML. To translate the XML from Figure 5 into HTML for online viewing, you can use the XSLT file in Figure 6.

Figure 6: XSLT Translation – From XML to HTML

```
<?xml version="1.0"?>
<xslt:stylesheet version="1.0" xmlns:xsl="http://www.w3.org/1999/XSL/Transform">
 <xslt:template match="/">
  <html>
   <body>
    <br><b>Chief: </b><xslt:value-of select="dept-tickets/dept-chief"/></br>
    <br><b>Department No: </b><xslt:value-of select="dept-tickets/dept-id"/>
    </br>
    <table border="5">
     <!-- Output the HTML table headings -->
     <th>Ticket Number</th>
     <th>Offender's Name</th>
     <th>License Number</th>
     <th>State of Offense</th>
     <th>Officer's Name</th>
     <!-- Output the HTML table data -->
     <xslt:for-each select="dept-tickets/ticket">
      <tr>
       <td align="center"><xslt:value-of select="@id"/></td>
       <td align="left"><xslt:value-of select="offender/name"/></td>
       <td align="center"><xslt:value-of select="offender/license-number"/></td>
       <td align="center"><xslt:value-of select="location/state"/> </td>
       <td align="left"><xslt:value-of select="officer/officer-name"/></td>
       <td align="right">$<xslt:value-of select="fine"/></td>
      </tr>
     </xslt:for-each>
    </table>
   </body>
  </html>
 </xslt:template>
</xslt:stylesheet>
```

You must use a namespace to differentiate elements among the XML-based languages that you use in your XML document. As Figure 6 illustrates, the namespace is the string "xslt:", which prefixes all of the XSLT elements. The particular application that parses the document (whether it is your XML device or a standalone XSLT parser[9]) will know what to do with the specific elements based on the prefix. For example, an XSLT parser will look for the specific *Universal Resource Indicator* (URI) string constant that the W3C assigned to XSLT (that is, **`http://www.w3.org/1999/XSL/Transform`**) and perform the intended actions based on the elements in the document.

XML parsers do not use the URI of the namespace to retrieve a schema for the namespace—it is simply a unique identifier within the document. According to W3C, the definition of a namespace simply defines a two-part naming system (for example, "xslt:for-each") and nothing else. After you define the namespace, the XML parser will understand the elements used within the document, such as "for-each" and "value-of" specified in Figure 6. For XSD documents, you must use a different namespace URI (that is, **`http://www.w3.org/2001/XMLSchema`**), as the next section discusses.

When you configure an XSLT parser or XML networking device to apply XSLT to an XML document, the parser starts at the top of the XSLT document by matching the root XML element within the source XML file. For example, the <xslt:template match="/"> element in Figure 6 matches the "dept-tickets" root element from the XML file in Figure 5. The XSLT parser then creates the destination XML document (that is, a well-formed HTML file, in this example) and outputs the <html> and <body> tags to the new document. The XSLT parser then outputs the HTML table headers and loops through the XML document "ticket" elements, outputting selected items within the columns of the HTML table. The resulting HTML is given in Figure 7 for three sample tickets.

Figure 7: Resulting HTML Table – Source View

```
<html>
 <body>
  <br><b>Chief: </b>Greg Sanguinetti<br><b>Department No: </b>12389289
  <table border="5">
   <th>Ticket Number</th><th>Offender's Name</th>
   <th>License Plate</th><th>State of Offense</th>
   <th>Officer's Name</th><th>Fine Amount</th>
   <tr>
    <td>034567910</td><td>John Smith</td><td>10003887</td>
    <td>CA</td><td>Paul Greene</td><td>100</td>
   </tr>
   <tr>
    <td>042562930</td><td>Gerald Rehnquist</td><td>11023342</td>
    <td>CA</td><td>Joel Patterson</td><td>200</td>
   </tr>
   <tr>
    <td>182736493</td><td>Jenny Barker</td><td>47281938</td>
    <td>CA</td><td>Emily Jones</td><td>120</td>
   </tr>
  </table>
 </body>
</html>
```

Figure 8 illustrates the resultant HTML table that clients would see within a Web browser after the XSLT translation takes place.

Figure 8: Resulting HTML Table – Browser View

Ticket Number	Offender's Name	License Plate	State of Offense	Officer's Name	Fine Amount
034567910	John Smith	10003887	CA	Paul Greene	100
042562930	Gerald Rehnquist	11023342	CA	Joel Patterson	200
182736493	Jenny Barker	47281938	CA	Emily Jones	120

Verifying XML Using XSD

Because you can customize the structure and tags within an XML document, you should verify its syntax using XSDs. The XSD file in Figure 9 verifies the XML document given previously in Figure 5.

Figure 9: XSD File for Validating Traffic Ticket XML

```
<?xml version="1.0"?>
<xsd:schema xmlns:xsd="http://www.w3.org/2001/XMLSchema">
 <xsd:element name="dept-tickets">
  <xsd:complexType>
   <xsd:sequence>
    <xsd:element name="dept-chief"/>
    <xsd:element name="dept-id"/>
    <xsd:element name="ticket" maxOccurs="unbounded">
     <xsd:complexType>
      <xsd:sequence>
       <xsd:element name="offender">
        <xsd:complexType>
         <xsd:sequence>
          <xsd:element name="name"/>
          <xsd:element name="license-number"/>
          <xsd:element name="plate-number"/>
         </xsd:sequence>
        </xsd:complexType>
       </xsd:element>
       <xsd:element name="offence-date"/>
       <xsd:element name="location">
        ...
       </xsd:element>
       <xsd:element name="officer">
        ...
       </xsd:element>
       <xsd:element name="description"/>
       <xsd:element name="fine"/>
      </xsd:sequence>
      <xsd:attribute name="id"/>
      <xsd:attribute name="code"/>
     </xsd:complexType>
    </xsd:element>
   </xsd:sequence>
  </xsd:complexType>
 </xsd:element>
</xsd:schema>
```

You must define an XSD namespace with the URI "**http://www.w3.org/2001/XMLSchema**" and prefix all the XSD elements that you use in the XSD file, such as "element," "complex-type," and "attribute," with this namespace. At the top of your XSD file, you must specify the root XML element; the remaining elements within your XML document can be defined within the root element. Using the "complex-type" XSD element, you can specify elements that contain child elements (in contrast, "simple-type" indicates that the element does not contain any child elements). In this example, the "dept-tickets" element may contain a sequence of one or more child elements (as represented by the <xsd:sequence> element), including "dept-chief," "dept-id," and any number of element "ticket."

Routing Messages Using XPATH

XPATH was developed primarily to be used with XSLT to transform the XML tags within an XML document based on the path of the data. Previously, in Figure 6, you saw how to select the entire list of tickets using the XSLT "select" attribute:

```
xsl:value-of select="dept-tickets/ticket"
```

However, within an XML network, you can also use XPATH to search within an XML document to route XML messages based on the values of the document data. For example, a state government may need the headquarters police department to route unpaid tickets that are within a tolerable threshold amount to the motor vehicle department for processing—there, the driver's license can be suspended until the ticket is paid. However, those unpaid tickets that exceed a maximum threshold amount must be routed to the court service government department for processing. The court may decide to press further charges, depending on the driver's previous driving record. Additionally, severe infractions, such as drunken or reckless driving, must be routed automatically to the court, regardless of whether the ticket is paid or not. The XPATH expression "dept-tickets/ticket" given previously returns the entire list of traffic tickets. Alternatively, if you want only the unpaid tickets with a fine value of greater than $100, you could use the XPATH expression:

```
dept-tickets/ticket[@paid='no' and fine>100]
```

The XPATH symbol "@" here indicates that an attribute is being selected, and not an element. To select tickets with codes 309 and 310 (that is, fictitious codes for severe infractions), you can use the following XPATH expression:

```
dept-tickets/ticket[@code=309 or @code=310]
```

Using SOAP Web Services

SOAP provides a standard way to send transaction information over TCP/IP application protocols, such as HTTP. For example, you could create a SOAP request-response operation over HTTP for exchanging traffic ticket information between two applications. As Figure 10 illustrates, the requesting client application sends a "getFineRequest" message to the server, which in turn responds with the appropriate fine amount within a "getFineResponse" message.

Figure 10: A Sample SOAP Request-Response Operation

```
Client Request :
POST /getticketfine HTTP/1.1
Host: www.example.com
Content-Type: application/soap+xml;

<?xml version="1.0"?>
<soap:envelope
xmlns:soap="http://www.w3.org/2001/12/soap-envelope"
soap:encodingStyle="http://www.w3.org/2001/12/soap-encoding">
<soap:body>
  <tn:getFineRequest xmlns:tn="http://example.com/getticketfine">
    <tn:ticket-id>034567910</tn:ticket-id>
  </tn:getFineRequest >
 </soap:body>
</soap:envelope>

Server Response:
HTTP/1.1 200 OK
Content-Type: application/soap+xml;

<?xml version="1.0"?>
<soap:envelope
xmlns:soap="http://www.w3.org/2001/12/soap-envelope"
soap:encodingStyle="http://www.w3.org/2001/12/soap-encoding">
<soap:body>
  <tf:getFineResponse xmlns:tf="http://example.com/getticketfine">
    <tf:fine>100</tf:fine>
  </tf:getFineResponse>
 </soap:body>
</soap:envelope>
```

You encapsulate each SOAP message within the "Envelope" SOAP element. Within Envelope, you need to prefix the SOAP elements with the SOAP namespace, called "soap:" in this example, which you define as an attribute within Envelope. The "encodingStyle" attribute of the Envelope element defines the data types in the SOAP document. You must also define a custom namespace (that is, "tf," which stands for "ticket-fine"), with which you prefix all the application-specific elements.

To define the structure of the SOAP Web service running within your applications, you can use WSDL, which you develop so that your clients know the exact specification of the services that they can request, the types of responses they should expect to receive, and the protocols (for example, SOAP or HTTP) with which they should send messages.

For example, you can publish the WSDL to your clients, who may not be aware of the messages available within your Web services layer. The clients can retrieve the WSDL file and send the appropriate SOAP messages to the SOAP Web service running on your application. To publish the WSDL file to your clients, you can use a publicly available *Universal Description, Discovery and Integration* (UDDI) registry, such as XMethods[10], or you could create your own UDDI registry[11].

WSDL uses XSD to define your SOAP application data types. For example, for one application to request a fine amount (of XSD type xs:integer) for a given ticket ID (of XSD type xs:string) from your SOAP Web service called "ticketFineService," you could use the WSDL in Figure 11.

Figure 11: WSDL for SOAP Request-Response Operation

```
<?xml version="1.0"?>
<definitions name="TicketInfo"
 targetNamespace="http://example.com/ticketinfo.wsdl"
 xmlns:tns="http://example.com/ticketinfo.wsdl"
 xmlns:soap="http://schemas.xmlsoap.org/wsdl/soap/"
 xmlns="http://schemas.xmlsoap.org/wsdl/">

 <message name="getFineRequest">
  <part name="ticket-id" type="xs:string"/>
 </message>

 <message name="getFineResponse">
  <part name="value"  type="xs:integer"/>
 </message>

 <porttype name="ticketFine">
  <operation name="getTicketFine">
   <input message="tns:getFineRequest"/>
   <output message="tns:getFineResponse"/>
  </operation>
 </porttype>

 <binding name="ticketBinding" type="ticketFine">
  <soap:binding transport="http://schemas.xmlsoap.org/soap/http"/>
  <operation name="getTicketFine">
   <soap:operation soapAction="getTicketFine"/>
   <input>
    <soap:body use="encoded"/>
   </input>
   <output>
    <soap:body use="encoded"/>
   </output>
  </operation>
 </binding>

 <service name="ticketFineService">
  <documentation>WSDL File for ticketFineService</documentation>
  <port name="ticketFine" binding="ticketBinding">
   <soap:address location="http://example.com/getticketfine"/>
  </port>
 </service>
</definitions>
```

You start your WSDL file by declaring all the required namespaces. In order for the WSDL file to refer to element names that are defined within the same file (for example, "tns:getFineRequest" within the "porttype" element), you must use the "targetNamespace" element to define a custom URI that your custom namespace uses (that is, "tns," meaning "this name space").

You define the WSDL namespace for SOAP-specific elements with *xmlns: soap=http://schemas.xmlsoap.org/wsdl/soap*. For WSDL-only elements, you can use the default namespace *xmlns= http://schemas.xmlsoap.org/wsdl/*. Note that elements within the file that do not have a prefix use the default namespace.

After you create the namespaces for the WSDL file, you can then create the two messages for the transaction, "getFineRequest" and "getFineResponse," using WSDL "message" elements. WSDL ports create the request-response transaction flow using the "operation" element, by specifying which message is the request (input) and which is the response (output). After you define the transaction, you must bind it to SOAP with WSDL using the WSDL "binding" element. Additionally, to set the transport to HTTP, you must use the "binding" SOAP-specific element. You then link the operation you created previously within the WSDL "port-type" element to SOAP using the "operation" subelement within the parent "binding" element.

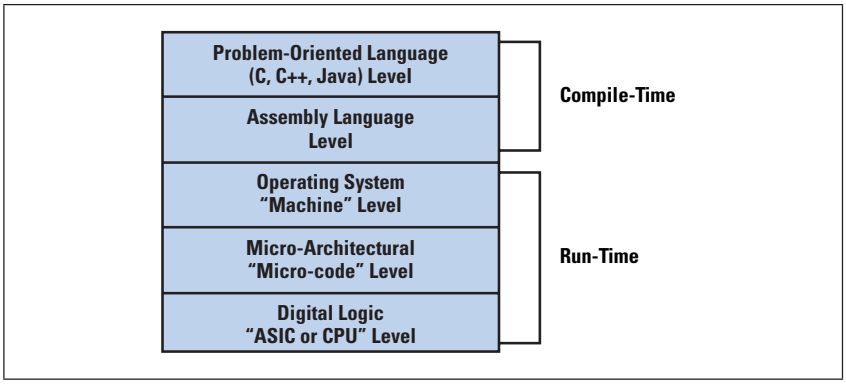
If you set the "use" element to "encoding," you do not need to use an XSD "type" attribute for defining SOAP data types in your SOAP messages. However, you must specify the "encodingStyle" URI to **`http://www.w3.org/2001/12/soap-encoding`**, as you learned previously in Figure 10. Otherwise, if you set "use" to "literal," then you would need to use the *type="xsd:string"* attribute in Figure 10 within the "tn:ticket-id" element when sending a request.

To define the SOAP Web service, you must use the WSDL "service" element. The SOAP element "address" within this element is the location where SOAP clients can send the "getTicketFine" requests, as Figure 10 illustrates.

Hardware vs. Software XML Acceleration

To help you understand the difference between hardware and software XML acceleration, Figure 12 illustrates a typical multilevel computer architecture[12]. The highest level is where you would typically program your applications. When you compile your application, the compiler would typically "assemble" your various objects into assembly language prior to generating the machine-level code. This machine code is what is normally stored in an ".exe" file, which only your operating system can understand. When you execute the ".exe" at run time, the operating system converts the machine-level code into microcode, which the digital logic level within the CPU hardware can execute directly.

Figure 12: A Multilevel Computer Architecture



Examples of software-based network applications in the past that have transitioned to hardware acceleration include IP routing, encryption, firewalling, caching, and load balancing. XML networking is also a recent candidate for hardware acceleration; it is available by XML vendors that use XML *Application-Specific Integrated Circuits* (ASICs) or *Field Programmable Gate Arrays* (FPGAs) in their products[13]. By programming the digital logic layer with the necessary circuits to perform intensive XML computations such as XSLT transformation, XML encryption, and XML schema validation, you can drastically increase the performance of the hardware platform.

However, some vendors have also found clever ways of accelerating XML computations on general-purpose hardware. Accelerating XML in software requires bypassing the additional machine-level step at run time. By "compiling" XML-based language instructions directly into microcode at the micro-architectural level, you can introduce XML computations to the underlying hardware directly at run time. That is, executing XML microcode at the digital logic level bypasses additional processing at the operating system "machine" level.

Summary

When a technology matures as a software agent running within an application, the need often arises to move the agent's functions to the network. Indeed, this was the case with numerous software-based technologies of the past, such as IP routing, encryption, stateful firewall filtration, and server load balancing.

To facilitate the interoperability of diverse applications, SOA was developed as a prescription to complexity problems faced by commonly used distributed-object technologies. As SOA matures, the need to introduce XML-based functions to the network will grow. In order to streamline the responsibilities of an SOA-based application, you can transition your XML technologies, such as XML translation, validation, and security, from within the application to an XML-enabled network.

Letters to the Editor

Time to Live

As I read the very fine article entitled "IPv6 Internals" (IPJ Volume 9, No. 3, September 2006), I was prompted to review the history of the *Time to Live* (TTL) as discussed in section 5.3.1 of RFC 1812. Being gray of head, little facts from other eras come quickly to mind. The *Xerox Network Systems* (XNS) Internet Transport on which Novell Netware was based required that no router ever store a packet in queue longer than 6 seconds. Requirements of RFC 791 were also softened in RFC 1812; rather than *requiring* the TTL to be decremented at least once and additionally once per second in queue, that document requires that the TTL be treated as a hop count and—reluctantly—reduces the treatment of TTL as a measure of time to a suggestion.

The reason for the change is the increasing implementation of higher-speed lines. A 1,500-byte datagram occupies 12,000 bits (and an asynchronous line sends those as 15,000 bits), which at any line speed below 19.2 kbps approximates or exceeds 1 second per datagram. Any time there are several datagrams in queue, the last message in the queue is likely to sit for many seconds, a situation that in turn can affect the behavior of TCP and other transports. However, 56-kbps lines became common in the 1980s, and T1 and T3 lines became common in the 1990s. Today, hotels generally offer Ethernet to the room; we have reports of edge networks connected to the Internet at 2.5 Gbps, and residential broadband in Japan and Europe at 26 Mbps per household. At 56 kbps, a standing queue of five messages is required to insert a 1-second delay, and at T1 it requires a queue depth of more than 100 messages. At higher speeds, the issue becomes less important.

That is not to say that multisecond queues are now irrelevant. Although few networks are being built today by concatenating asynchronous links, in developing countries—and on occasion even in hotels here in Santa Barbara, California—people still use dialup lines. In Uganda, some networks that run over the instant messaging capacity of GSM [*Global System for Mobile Communications*], which is to say using 9,600-bps datagrams, have been installed under the supervision of Daniel Stern and UConnect.org (**www.uconnect.org**). Much of the world still measures *round-trip times* (RTTs) in seconds, and bit rates in tens of kbps.

The TCP research community, one member of which recently asked me whether it was necessary to test TCP capabilities below 2 Mbps, and the IETF community in general would do well to remember that the ubiquity of high bandwidth in Europe, North America, Australia, and Eastern Asia in no sense implies that it is available throughout the world, or that satellite communications and other long-delay pipelines can now be ignored.

—Fred Baker, Cisco Systems
fred@cisco.com

The author responds:

Although to the casual observer the evolution of the Internet seems one of continuously increasing speed and capacity, reality is slightly different. The original ARPANET used 50-kbps modems in the late 1960s. In the next three decennia or so, the maximum bandwidth of a single link increased by a factor 200,000 to 10 Gbps. Interestingly enough, the minimum speed used for Internet connections went down to a little under 10 kbps, so where once the ARPANET had a uniform link speed throughout the network, the difference between the slowest and the fastest links is now six orders of magnitude. The speed difference between a snail and a supersonic fighter jet is only five orders of magnitude. Amazingly, the core protocols of the Internet—IP and TCP—can work across this full speed or bandwidth gamut, although changes were made to TCP to handle both extremes better, most notably in RFCs 1144 and 1323.

Even though I don't think keeping track of the time that packets are stored in buffers, as suggested in the original IPv4 specification, makes much sense even in slow parts of the network, Fred makes a good point: many Internet users still have to deal with speeds at the low end of the range; some of us only occasionally when connecting through a cellular network, others on a more regular basis. Even in Europe and the United States many millions of Internet users connect through dialup. For someone who is used to having always-on multimegabit connectivity, going back to 56 kbps or worse, 9,600 bps can be a bizarre experience. Many of today's Websites are so large that they take minutes to load at this speed. Connecting to my mail server using the *Internet Mail Access Protocol* (IMAP) takes 15 minutes. And one of my favorite relatively new applications, podcasting, becomes completely unusable: downloading a 50-minute audio program takes hours at modem speeds.

And that's all IPv4. It is possible to transport IPv6 packets over the *Point-to-Point Protocol* (PPP) that is used for almost all low-speed connections, but in practice this isn't workable because there are no provisions for receiving a dynamic address from an ISP [*Internet Service Provider*]. With IPv4, Van Jacobson did important work to optimize TCP/IP for low-speed links (RFC 1144). By reducing the *Maximum Transmission Unit* (MTU) of the slow link and compressing the IP and TCP headers, it was possible to achieve good interactive response times by avoiding the situation where a small packet gets stuck between a large packet that may take a second or more to transmit over a slow link while at the same time reducing the header overhead. Although the IETF has later done work on IPv6 header compression, it doesn't look like anyone has bothered to implement these techniques, and the minimum MTU of 1,280 bytes creates significant head-of-line blocking when IPv6 is used over slow links.

Another example where low bandwidth considerations are ignored is the widespread practice of enabling RFC 1323 TCP high-performance extensions for all TCP sessions. RFC 1323 includes two mechanisms: a window scale factor that allows much larger windows in order to attain maximum performance over high-bandwidth links with a long delay, and a timestamp option in the TCP header that allows for much more precise round-trip time estimations. With these options enabled, every TCP segment includes 8 extra bytes with timestamp information. In addition to increasing overhead, the timestamp option introduces an unpredictable value into the TCP header that makes it impossible to use header compression, thereby negating the usefulness of RFC 1144. To add insult to injury, almost no applications allocate enough buffer space to actually use the RFC 1323 mechanisms.

Moral of the story for protocol designers and implementers: spend some time thinking about how your protocol works over slow links. You never know when you'll find yourself behind just such a link.

Gigabit TCP and MTU Size

I appreciated Geoff Huston's thorough description about the current obstacles and research involving Gigabit TCP (IPJ, Volume 9, No. 3, June 2006). I have already shown the article to many of my colleagues. It appears that Geoff did not address one of the solutions, which is to increase the networkwide *Maximum Transmission Unit* (MTU). In theory that would allow the existing TCP congestion control to handle higher-speed connectivity. Perhaps he did not address the issue because it is infeasible to increase the MTU setting Internetwide, especially with 10-Gigabit Ethernet interfaces sporting a default MTU setting of 1,500 bytes. On the other hand, projects that own their own backbone infrastructure may find increasing the default MTU a feasible approach.

For more information about raising the MTU, please see: **http://www.psc.edu/~mathis/MTU/**

—Todd Hansen, UCSD/SDSC
tshansen@hpwren.ucsd.edu

The author responds:

Yes, it's true that increasing the size of the packet makes sound sense when the available bandwidth has increased. If the bandwidth increases by one order of magnitude and the packet size is increased by the same amount, then it is theoretically possible to effectively increase the throughput of the system without changing the packet processing load.

Effectively, if you regard the protocol interaction as a time sequence, then a coupling of increased bandwidth and comparably increased packet size preserves the time sequence interaction. Of course, as bandwidth on the network has increased we have not seen a comparable increase in MTU sizes, and today's networks exhibit a wide variety of MTUs and the importance of *Path MTU Discovery*, and coherent transmission of related MTU ICMP [*Internet Control Message Protocol*] messages becomes more critical as a consequence. Although the article concentrated on modifications to the TCP control algorithm, there is no doubting the importance of high-speed TCP senders and receivers using large TCP buffers to maximize the payload throughput potential.

Book Review

Internet Measurement

Internet Measurement: Infrastructure, Traffic & Applications, by Mark Crovella, Balachander Krishnamurthy, ISBN 0-470-01461-X, Wiley, 2006.

This book is a comprehensive reference guide to about 900 journal, conference, and workshop papers, and RFCs on the important and rapidly advancing field of Internet measurement. Interest in this growing field arises for three major reasons: commercial, social, and technical. Readers need nothing more than a keen interest in a methodical study of the subject matter from either a practical or research perspective to glean something from this book.

Organization

The book is centered on three architectural pillars relevant to measurement: *infrastructure, traffic,* and *applications*. Within each of these pillars, the topics are organized into four sections: *properties, challenges, tools,* and *state-of-the-art*. In the properties section, the authors review metrics that are important to measure in each area. In the challenges section, they discuss various difficulties and limitations that arise when trying to measure the metrics. The tools section covers some of the popular methods and products used to measure these metrics and work around the challenges mentioned previously. The intent is not to provide "user guides" for these tools. The state-of-the-art section presents the latest measurement results about covered properties and metrics, noting that they are subject to relatively fast obsolescence because of the rapidly evolving Internet.

The first three chapters provide background material. The first chapter provides an obligatory introduction to the Internet architecture, including how the "end-to-end" principle has been used for nearly 20 years to guide many design decisions in the Internet. The second chapter provides the analytic background necessary to study the Internet and cast its measurements in quantitative terms. The third chapter examines the nuts and bolts of Internet measurement, addressing the practical topics to consider in designing and implementing them, including the role of time and its sources.

The second part of this book also consists of three chapters, which cover the three pillars in depth. The first chapter defines metrics of interest for measuring the Internet and describes some of the barriers to their measurement, in particular "middleboxes," *Network Address Translators* (NATs), firewalls, and proxies that deviate from the end-to-end architecture principle, may block *User Datagram Protocol* (UDP) or *Internet Control Message Protocol* (ICMP) packets, or hinder visibility to endpoint IP addresses. The authors next explore various tools and methods for active and passive measurement, estimation, and inference of these metrics.

Readers may wonder why two important metrics are left out—router reliability and high availability—where *Open Shortest Path First* (OSPF) and the *Border Gateway Protocol* (BGP) "Graceful Restart" would be of interest.

The next chapter focuses on traffic properties that are important to understand, measure, and model. The authors examine the challenges in capturing, processing, storing, and managing large volumes of packets and flows, as well as those related to their statistical characterization. Readers engaged in data modeling and performance analysis will benefit from this chapter. The last chapter in this part of the book examines some popular applications: The *Domain Name System* (DNS), Web, and *Peer-to-Peer* (P2P). The authors discuss the shifts in application mix from the 1980s, when FTP was dominant, to the 1990s, when the *Hypertext Transfer Protocol* (HTTP) became dominant, to today, when by most accounts P2P is the dominant Internet protocol. Next, there is a thorough coverage of the what (properties), why (justification), and how to (tools) facets of measurement of the three popular applications, as well as some coverage of online games and streaming media.

The third part of the book covers material that spans multiple areas. Its first chapter deals with anonymization of collected measurement data, which arises because of the need for data sharing, while preserving identity-related, personal-sensitive, or business-sensitive information for applications previously examined. The second chapter provides a short—but important—coverage of the key areas where Internet measurement has played a role in security enforcement. Various attack types and tools to combat them are discussed. The third chapter examines numerous low-level monitoring tools for high-speed traffic capture, as well as an insightful look at the software architecture of two toolsets, *dss* and *Gigascope,* reflecting the experience of one of the authors at AT&T Labs with them. It also reviews some large-scale measurement platforms at the *Cooperative Association for Internet Data Analysis* (CAIDA), the *Réseaux IP Européens* (RIPE) community, and the *High Energy Physics* (HEP) community. The book concludes with a recap of trends, concerns, and emerging questions in Internet measurement.

Synopsis

The authors have blended their academic research and practical experience in Internet measurement and traffic modeling to provide the reader with a structured view to these vast subjects. I would have liked to see a more extensive coverage of *Voice over IP* (VoIP) and its associated performance measurement protocols, *RTP Control Protocol* (RTCP), RTCP *Extended Report* (XR), and RAQMON, given the gradual but inevitable shift of voice traffic from the *Public Switched Telephone Network* (PSTN) to the Internet with *Session Initiation Protocol* (SIP) peering.

Most probably, this book had already been published when the *Federal Communications Committee* (FCC) issued an order in May 2006 for all VoIP service providers to demonstrate compliance with the *Communications Assistance for Law Enforcement Act* (CALEA) wiretapping requirement within a year. This directive represents a notable departure from data anonymization principles covered in the book.

Overall, I consider this book an excellent reference source for diverse research and practical articles published in the field of Internet measurement. I highly recommend it to network planners, engineers, and managers responsible for instrumentation, traffic modeling, or performance analysis.

Read Any Good Books Lately?

Then why not share your thoughts with the readers of IPJ? We accept reviews of new titles, as well as some of the "networking classics." In some cases, we may be able to get a publisher to send you a book for review if you don't have access to it. Contact us at **ipj@cisco.com** for more information.

Fragments

Bob Braden and Joyce K. Reynolds receive the 2006 Postel Service Award

Bob Braden and Joyce K. Reynolds are this year's recipients of the Internet Society's prestigious *Jonathan B. Postel Service Award*. The award was presented "For their stewardship of the RFC (*Request for Comments*) series that enabled countless others to contribute to the development of the Internet." The presentation was made by Internet pioneer Steve Crocker (a member of this year's Postel award committee and author of the very first RFC) during the 67th meeting of the *Internet Engineering Task Force* (IETF) in San Diego, California.

The award is named after Dr. Jonathan B. Postel to commemorate his extraordinary stewardship exercised over the course of a thirty year career in networking. Between 1971 and 1998, Postel managed, nurtured and transformed the RFC series of notes created by Steve Crocker in 1969. Postel was a founding member of the Internet Architecture Board and the first individual member of the Internet Society, where he also served as a trustee.

"It is a pleasure and an honor for the Internet Society to recognize the contribution of Bob and Joyce to the evolution of the Internet," said Crocker. "Since its humble beginnings, the RFC series has developed into a set of documents widely acknowledged and respected as a cornerstone of the Internet standards process. Bob and Joyce have participated in this evolution for a very long time and have been primarily responsible for ensuring the quality and consistency of the RFCs since Jon's death in 1998."

Joyce K. Reynolds worked closely with Postel, and together with Bob Braden she has been co-leader of the RFC Editor function at the University of Southern California's *Information Sciences Institute* (ISI) since 1998. In this role she performed the final quality control function on most RFC publications. Reynolds has also been a member of the IETF since 1988, and she organized and led the User Services area of the IETF from 1988 to 1998. In her User Services role, she was an international keynote speaker and panelist in over 90 conferences around the world, spreading the word on the Internet.

Bob Braden, who has more than 50 years of experience in the computing field, joined the networking research group at ISI in 1986. Since then, he has been supported by NSF for research concerning NSFnet and the DETER security testbed, and by DARPA for protocol research. Braden came to ISI from UCLA, where he had technical responsibility for attaching the first supercomputer (IBM 360/91) to the ARPAnet, beginning in 1970. Braden was active in the ARPAnet Network Working Group, contributing to the design of the FTP protocol in particular. He also edited the Host Requirements RFCs and co-chaired the RSVP working group.

The Jonathan B. Postel Service Award was established by the *Internet Society* (ISOC) to honor those who, like Postel, have made outstanding contributions in service to the data communications community. The award is focused on sustained and substantial technical contributions, service to the community, and leadership. With respect to leadership, the nominating committee places particular emphasis on candidates who have supported and enabled others in addition to their own specific actions.

Previous recipients of the Postel Award include Jon himself (posthumously and accepted by his mother), Scott Bradner, Daniel Karrenberg, Stephen Wolff, Peter Kirstein, Phill Gross and Jun Murai. The award consists of an engraved crystal globe and $20,000.

ISOC (**http://www.isoc.org**) is a not-for-profit membership organization founded in 1992 to provide leadership in Internet related standards, education, and policy. With offices in Washington, DC, and Geneva, Switzerland, it is dedicated to ensuring the open development, evolution and use of the Internet for the benefit of people throughout the world. ISOC is the organizational home of the IETF and other Internet-related bodies who together play a critical role in ensuring that the Internet develops in a stable and open manner. For over 14 years ISOC has run international network training programs for developing countries and these have played a vital role in setting up the Internet connections and networks in virtually every country connecting to the Internet during this time.

First Internet Governance Forum Meeting Concludes

The inaugural meeting of the *Internet Governance Forum* (IGF) took place in Athens, Greece from October 30 – November 2, 2006. For more information see: **http://www.intgovforum.org**

The Government of Brazil will host the next IGF meeting. It will take place in Rio de Janeiro November 12 – 15, 2007.

ARIN to Provide 4-Byte AS Numbers

On August 30, 2006, the *American Registry for Internet Numbers* (ARIN) Board of Trustees, based on the recommendation of the Advisory Council and noting that the Internet Resource Policy Evaluation Process had been followed, adopted the following policy proposal: "2005-9: 4-Byte AS Number."

Per the implementation schedule contained in the policy (*Number Resource Policy Manual* [NRPM] Section 5.1), commencing January 1, 2007, ARIN will process applications that specifically request 32-bit AS Numbers.

For more information see: **http://www.arin.net/registration**

Celebrating the 25th Anniversary of the TCP/IP Internet Standards

Two of the core protocols that define how data is transported over the Internet are now 25 years old. The *Internet Protocol* (IP) and the *Transmission Control Protocol* (TCP), together known as "TCP/IP," were formally standardized in September 1981 by the publication of RFC 791 and RFC 793.

Vint Cerf and Robert Kahn are widely credited with the design of TCP/IP, and many others involved in the ARPANET project made significant contributions. The core of the documents was RFC 675, published in December 1974 by Cerf together with co-authors Carl Sunshine and Yogen Dalal. The subsequent sequence of documents leading up to RFC 791 and 793 benefited from the participation of many people including Dave Clark, Jon Postel, Bob Braden, Ray Tomlinson, Bill Plummer, and Jim Mathis, as well as other unnamed contributors to the definition and implementation of what became the Internet's core protocols.

"We can't yet say that the Internet is mature," says Brian Carpenter, chair of the IETF, "but it's a great tribute to its pioneers that the two most basic specifications that were published a quarter of a century ago are still largely valid today. I hope the IP version 6 standard will do as well."

The *Request For Comments* (RFC) series, which was launched in 1969 by Steve Crocker at UCLA (and edited for many years by the late Jon Postel), continues today as the public archive of the Internet's fundamental technology. Since 1977 it has been hosted by The University of Southern California's *Information Sciences Institute* (ISI). ARPA support ended in 1998, at which time ISOC took over providing funding for the publication of Internet standards. More recently, ISOC extended its support to include other areas critical to the open development of Internet standards.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

The Internet Protocol Journal

March 2007 Volume 10, Number 1

A Quarterly Technical Publication for Internet and Intranet Professionals

In This Issue

From The Editor

Every time you dial into a service provider network or connect to a wired or wireless network that offers Internet access, you are most likely using several components of what is referred to as *Authentication, Authorization, and Accounting*, or "AAA" for short. The AAA space is quite complex, so when we asked Sean Convery to give us an overview of these technologies, he decided to divide his survey into two parts. Part One—subtitled "Concepts, Elements, and Approaches"—is included in this issue. Part Two, which discusses protocol details and applications, will follow in our next issue.

The *Domain Name System* (DNS) has been discussed previously in this journal. The most critical part of the DNS is the collection of *Root Servers*. For protocol reasons, there are only 13 "logical" root servers, but a system of more than 100 servers has been deployed using a technique known as *anycast*. Steve Gibbard examines the distribution of the root servers in different parts of the world and discusses operational aspects of the DNS.

If you are tracking any part of the IETF process, you should be aware of several important resources. First, the IETF *Education Team* (**http://edu.ietf.org/**) offers training sessions and educational materials. Second, the *IETF Journal* (**http://www.isoc.org/ietfjournal**) publishes timely reports and updates on the activities of the IETF.

Finally, the IETF *Tools Team* (**http://www.ietf.org/tools.html** and **http://tools.ietf.org**) provides many tools and applications for protocol developers. Marshall Rose and Carl Malamud take a closer look at one of these tools, namely a system for writing Internet Drafts and RFCs using XML.

Network Authentication, Authorization, and Accounting
Part One: Concepts, Elements, and Approaches

by Sean Convery, Identity Engines

Network *Authentication, Authorization,* and *Accounting* (AAA, pronounced "triple-A") is a technology that has been in use since before the days of the Internet as we know it today. Authentication asks the question, "Who or what are you?" Authorization asks, "What are you allowed to do?" And finally, accounting wants to know, "What did you do?" These fundamental security building blocks are being used in expanded ways today. This article, the first in a two-part series, focuses on the overall concepts of AAA, defines the elements involved in AAA communications, and discusses high-level approaches to achieving specific AAA goals. Part two of the article, to be published in a future issue of IPJ, will discuss the protocols involved, specific AAA applications, and considerations for the future of AAA.

AAA, at its core, is all about enabling mobility and dynamic security. Without AAA, a network must be statically configured to control access; IP addresses must be fixed, systems cannot move, and connectivity options should be well defined. Even the earliest days of dialup access broke this static model, thereby requiring AAA. Today, the proliferation of mobile devices, diverse network consumers, and varied network access methods combine to create an environment that places greater demands on AAA.

AAA has a part to play in almost all the ways we access a network today. Emerging technologies such as *Network Access Control* (NAC) extend AAA even into corporate Ethernet access (historically the "trusted" network that set the benchmark level of security that all other types of access had to match). Today, wireless hotspots need AAA for security, partitioned networks require AAA to enforce segmentation, and remote access of every kind uses AAA to authorize remote users.

It is not clear when the term AAA first gained acceptance, but an examination of academic papers finds "authentication, authorization, and accounting" used as a discrete term (albeit without the AAA acronym) as early as 1983 in an IEEE paper[1]. Though mired in pre-Internet *Open Systems Interconnection* (OSI)-centric terminology, the ordering of the "A's" is the same as today's usage.

For most network administrators, the genesis of AAA coincided with the development of the *Remote Authentication Dial-In User Service* (RADIUS) protocol[2]. RADIUS was developed by Livingston Enterprises (now part of Alcatel-Lucent) in the early 1990s, became an Internet standard through the IETF in 1997, and today is the most widely accepted AAA protocol.

Another widely adopted AAA protocol, which predates RADIUS as an RFC by four years, is the *Terminal Access Controller Access Control System* (TACACS)[3]. Though never an Internet standard, TACACS evolved into XTACACS and then TACACS+, the latter of which is the only version of TACACS in use today.

Before we delve into the details of these protocols, it is important to understand the roles played within a AAA system.

Core Components of AAA

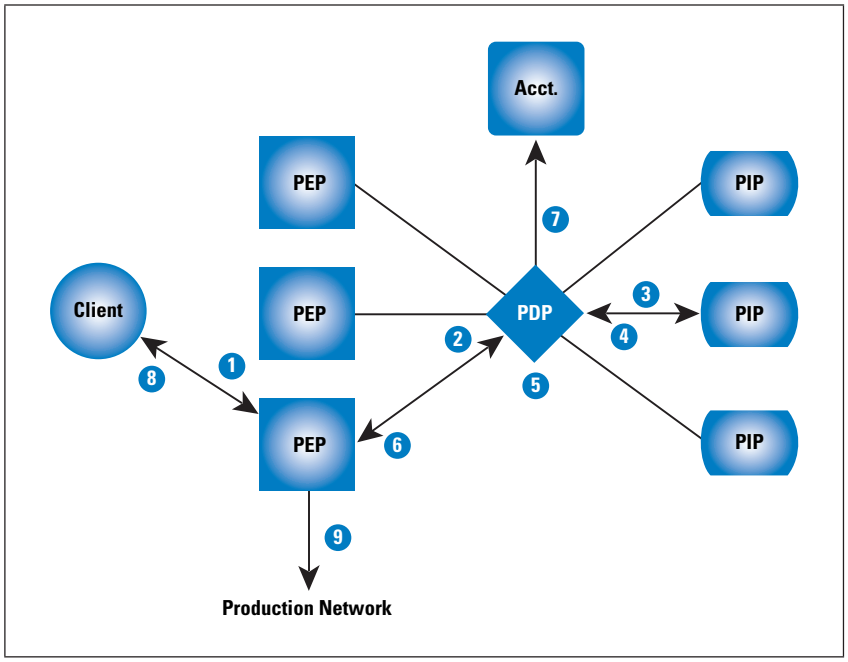
- *Client:* The client is the device attempting to access the network. The client either authenticates itself, or it acts as a proxy to authenticate the user.
- *Policy Enforcement Point (Authenticator):* The Policy Enforcement Point (PEP) is sometimes called the authenticator or *Network Access Server* (NAS). The PEP is the network device that brokers the access request for the client. The PEP can be a dial-in server, VPN concentrator, firewall, gateway *General Packet Radio Service* (GPRS) support node, Ethernet switch, wireless access point, or an inline security gateway. The PEP is responsible for enforcing the terms of a client's access. This enforcement varies based on the capabilities of the PEP and is discussed later in this article.
- *Policy Information Point:* The Policy Information Point (PIP) is a repository of information to help make the access decision. It could be a database of device IDs, a user directory such as the *Lightweight Directory Access Protocol* (LDAP), a *one-time password* (OTP) token server, or any other system that houses data relevant to a device or user access request.
- *Policy Decision Point (AAA Server):* The Policy Decision Point (PDP) is the brain of the AAA decision. It collects the access request from the client through the PEP. It also queries any relevant PIPs to gather the information it needs to make the access decision. The PDP, as its name implies, is the entity that makes the final decision around network access. It also can send specific authorizations back to the PEP that apply settings or constraints to the client's network traffic.
- *Accounting and Reporting System:* Whether on a dedicated system or built as part of a PDP, tracking use of the network with accounting is one of the best features of AAA. With all forms of network access now offering controlled access, the AAA service can tell you who got on the network, from where, and what that person was granted access to.

It is important to note that the preceding categories are logical containers of functions and not necessarily dedicated physical devices. Often elements are combined, such as PEP with PDP, and PDP with PIP.

Example AAA Flow

Now that we have examined the components of a AAA solution, walking through a typical use case will help cement our understanding of the role that each entity plays. Figure 1 shows an example of a client attempting to gain access to the network.

Figure 1: A Client Connects to a AAA-Protected Network



1. The client attempts to connect to the network, is challenged for identity information, and sends this information to the PEP. In this example, let's assume the client is a laptop with a worker attempting to access an organization's VPN from a remote location. Additionally, we'll assume this is a valid, permitted use of the network.
2. The PEP sends the collected identity information to the PDP. In some cases (discussed in part two of this article), the PEP cannot see the specific identity information provided but instead relays the information directly to the PDP.
3. The PDP queries any configured PIPs for information about the client and validates that the credential provided by the client is valid. In this example, the PIP is an LDAP directory.
4. The PIP returns a success or failure message from the credential validation step and sends additional information about the client to the PDP for evaluation. This information could include the role of the user, the home location for the user, and so on.
5. The PDP evaluates information learned about the client through the client, PEP, and PIP; the role of the PEP and PIP that serviced the request; and any contextual information (such as time of day) against its configured policies. Based on this information, the PDP makes an authorization decision.

6. The PDP sends the PEP the authentication result and any authorizations specific to the client. These authorizations trigger specific PEP actions to apply to the client. For example, the authorization data might trigger specific *Access Control Lists* (ACLs) or IP pool assignments for the client.
7. The PDP also sends the result of this transaction to the accounting system.
8. The PEP applies the authorization profile learned from the PDP and sends the "authentication successful" message to the client. The PEP can also be configured to send accounting information on this new connection to the accounting and reporting system.
9. The client accesses the production network through the PEP.

Elements of Authentication

When performing authentication, numerous elements can be evaluated before a PDP reaches its access decision. At a high level, these elements can be broken down into three categories: the principal itself (the user, device, or service requesting access), the credential the principal submits (shared key, one-time password, digital certificate, or biometric credential), and the contextual information describing the transaction (location, time of day, software state, and so on).

- *Principal:* The principal is the entity requesting authorization. It is generally some combination of user, device, or service. When concerned with a user, the PIP can provide attributes about the user such as role or group affiliations, job title, e-mail address, physical address, and so on. In specific applications, it can include much more granular information. For example, a higher-education facility might be interested in knowing a student's class schedule when servicing the student's authentication request. When the principal is a device, the same thinking applies. The PIP can inform the PDP if the device is a managed asset, what its basic usage parameters are, and so on. User and device authentication can be carried out sequentially for the same transaction, often involving device authentication first and then user authentication. Lastly, a service such as a network management process can authenticate. In this case, the service almost always looks like a user to the AAA infrastructure and is handled accordingly.
- *Credential:* The next element the PDP considers is the credential the user or device submits as proof of identity. There are four main types of credentials: shared key (password), *one-time password* (OTP), digital certificate, and biometric credential. This section examines each of these types. The first and most widely used form of credential is the shared key, typically a user password. AAA deployments that use shared keys can be subdivided based on the protocol the system uses to verify the password, including the *Password Authentication Protocol* (PAP)[4], *Challenge Handshake Authentication Protocol* (CHAP)[5], and *Microsoft CHAP Extensions* (MS-CHAP) Versions 1[6] and 2[7]. PAP authentication is a plaintext authentication method that is not recommended for use in security-sensitive environments.

However, many newer protocols provide a secure transport for PAP, making its use in AAA still quite common. Some of these methods are discussed in part two of this article. CHAP improves on the security of PAP by not sending the password in the clear but rather a challenge based on a hash of the password. MS-CHAP is a Microsoft extension to CHAP that tunes things a little bit for Microsoft environments. Version 2 of MS-CHAP addresses security weaknesses in Version 1. MS-CHAPv2 is quite common today in Microsoft environments. CHAP in all its forms is vulnerable to dictionary attacks because even if a hash cannot be decrypted, common passwords can be guessed and those hash values can be computed.

A second, also widely used credential type is the OTP. At login time, users refer to their personal token to get the OTP they will type in. The token is generally provided in hardware or software form. Tokens are designed to generate seemingly random passwords that are synchronized with a token server acting as a PIP. The OTP can be sent in the clear because it is used only once; after a configurable time (for example, 30 seconds) a new password is generated. When an OTP is combined with a *Personal Identification Number* (PIN), two-factor authentication is achieved because the client needs to have something (the token) and know something (the PIN).

The third type of credential is the *digital certificate*. Digital certificates can be stored either locally on the client or on some sort of removable device such as a smartcard. A full discussion of asymmetric-key cryptography is outside the scope of this article, but at a high level, certificates work by asserting the identity of their bearer by having the certificate signed by a trusted *Certificate Authority* (CA). CAs can be external entities such as a government or commercial enterprise or they can be internal to a given organization. The certificate itself can be freely distributed, because the only way it can be validated as belonging to the rightful owner is in combination with the private key. Because they reside on the client, certificates are most often used to authenticate a physical entity rather than an individual. However, smartcards are changing this paradigm by enabling users to take their digital certificate (and private keys) with them, thereby disassociating the certificate from the machine itself. Similar to an OTP without a PIN, a digital certificate or smartcard alone does not provide two-factor authentication. Certificate deployments, particularly smartcards, are addressing this problem by requiring a PIN to unlock access to the credential.

The fourth and least widely deployed type of credential is the *biometric credential*. Biometrics[12] ignores something you *have* and something you *know* and instead focus on something you *are*. Fingerprint scanners, iris scanners, and facial recognition are all forms of biometric authentication. Because biometrics is the newest form of credential, it is currently experiencing heightened anticipation among users regarding potential applications—and also scrutiny for potential weaknesses.

- *Contextual:* The last element the PDP typically considers in its authentication decision is the contextual information associated with the AAA request, including the network and physical location of the request, the type of access provided by the PEP, the time of day, and potentially other elements such as network load, security threat level, and so on. A relatively new entrant into this set of contextual information is client device posture, typically discussed under the rubric of *Network Access Control* (NAC). NAC or posture checks examine the software state of the client before it connects. NAC data allows the PDP to assess the degree of risk posed by the connecting client before granting the client access to the network. For example, if a system is running an out-of-date operating system, has no current security applications running, or otherwise exhibits high-risk behavior, it may not be granted access to the network. NAC will be discussed in more detail in part two of this article.

Authorization Approaches

At its core, authorization means determining what a client is allowed to do on the network. However, the granularity of this authorization is only as good as the sophistication of the PDP and the enforcement capabilities of the PEP. This section examines the authorization options for network AAA, including Layer 2 segmentation, Layer 3 filtering, and Layer 7 entitlements. It closes with an examination of some of the challenges encountered when sending or "provisioning" the authorizations from the PDP to the PEP.

- *Null Authorization (Authentication Only):* Strangely the most common authorization in AAA is no authorization at all. After the authentication event occurs, the client is immediately granted full access to the network. This characteristic is a holdover from the original goal of remote-access AAA: to perform an authentication check that simply determines whether the client should be trusted as if it were connected to the organization's home network. Because these home networks employed no segmentation or filtering within them, it was natural that remote-access techniques such as dialup and VPN would likewise employ neither. Today however, authentication is increasingly being used for all forms of network access, with a goal of providing clients with network rights commensurate with their role in the organization. This latter goal requires a strong authorization foundation through the cooperation of the PDP and PEP.
- *Layer 2 Segmentation:* For wireless access points and Ethernet switches, the most common form of authorization enforcement is Layer 2 segmentation, which works by splitting the network into multiple logical segments, isolating certain classes of client from one another. This process is most typically achieved by deploying *Virtual LANs* (VLANs), which separate the members of one VLAN from other VLANs in the same Layer 2 network—even though the VLANs traverse the same physical network infrastructure.

VLANs can be used to restrict access to specific resources by working in coordination with VLAN-specific ACLs on Layer 3 devices upstream from the Layer 2 device. For access points, a given wireless *Service Set Identifier* (SSID) can be associated with a VLAN on the wired side of the access point. *Multiprotocol Label Switching* (MPLS) is more commonly associated as a WAN transport, but there is nothing to prevent labels for traffic based on AAA. More commonly, the client is associated with a VLAN and the VLAN is associated with an MPLS label further into the infrastructure.

- *Layer 3 Filtering:* Layer 3 filtering authorizes access to resources through ACLs configured on Layer 3 devices (routers, Ethernet switches, security gateways, and so on). These ACLs (which generally encompass Layer 4 of the OSI stack as well) can enforce authorizations to a range of hosts, specific hosts, or services on those hosts. As mentioned earlier, Layer 3 filtering can be combined with Layer 2 segmentation to provide aggregate authorizations for an entire VLAN. This filtering is the most common technique on network infrastructure devices, whereas security gateways tend to apply ACLs to specific clients. Additionally, technologies such as *IP Security* (IPsec)[8] provide a Layer 3 filtering capability by allowing only certain types of traffic to travel through the VPN tunnel.
- *Layer 7 Entitlements:* Increasingly, security gateways are able to go beyond Layer 3 and 4 filtering and are starting to become application-aware, meaning that the authorizations handed from the PDP to the PEP can be very granular, focusing on the specific applications that are needed rather than broader filters based on segments or hosts on the network. Because this technology is still relatively new, there are no standards yet to make this interaction work transparently. As a result, most granular application filters are written on the PEP itself in order to allow the PDP to trigger a preexisting profile on the PEP. These sorts of provisioning challenges are discussed further in the next section.
- *Provisioning Challenges:* In AAA parlance, the term "provisioning" refers to communicating a user's session rights and constraints to the PEP so that the PEP can grant and enforce these permissions. One of the most difficult aspects of provisioning access rights on a PEP is communicating the decision of the PDP in a format the PEP can understand. This fact is one of the reasons that many PEPs come with a lightweight PDP. This approach solves the narrow problem for that PEP but creates management challenges when coordinating network AAA across a broader enterprise, because the enterprise AAA policies must be implemented individually on each unique type of PEP on the network. Because RADIUS is the most commonly used network AAA protocol, it is natural to communicate the PDP decision using that protocol. RADIUS attributes such as the "filter-id" allow the PDP to trigger a preexisting filter on the PEP.

In addition, many PEP vendors support *Vendor Specific Attributes* (VSAs) in RADIUS to enable the PDP to speak the language of the PEP more specifically. This process works well but creates a significant amount of work on the PDP to enable it to translate the policy result and correctly communicate it to each type of PEP. Another option soon to be sanctioned by the standards bodies is an extension to RADIUS that enables the sending of standard IP ACLs using RADIUS attributes[9].

One further option for provisioning is through the *Simple Network Management Protocol* (SNMP), which is typically used to assign Layer 2 ports to VLANs or to enable or disable interfaces. This process can work, but remember that the version of SNMP typically in deployment is still SNMPv2c, which is *User Datagram Protocol* (UDP)-based (connectionless) and unencrypted. Therefore, the SNMP traffic is prone to packet loss when links are congested or devices are busy, thereby requiring costly application layer retransmission schemes. It also means the transmissions themselves are vulnerable to inspection or modification. These attributes make SNMP generally a poor choice for security-sensitive tasks. RADIUS also uses UDP, but supports basic retransmission as part of the protocol.

Another provisioning method used today is standard *Secure Shell* (SSH) Protocol or HTTPS-based configuration. This method manages a device through standard administrative interfaces to set enforcement techniques. Although this method gives the PDP full access to the features of the PEP, it is very difficult to coordinate the dynamic aspects of the client AAA event with the static elements of the running configuration of the PEP. Finally, new protocols are emerging to make provisioning easier. NETCONF[10] is an *Extensible Markup Language* (XML)-based protocol designed as a replacement for network management applications connecting to devices over the *command-line interface* (CLI).

As this section has shown, there are numerous approaches to authorization in AAA. Each PEP has its own capabilities, but the challenge for a diverse network is to consistently authorize clients, regardless of the given PEP they access the network through.

Accounting Techniques

Accounting is an increasingly critical step in the overall AAA process. Regulatory controls are starting to mandate better auditing of network access. The last stage of AAA, accounting simply records which clients accessed the network, what they were granted access to, and when they disconnected from the network. Accounting has always been widely used in the *Internet Service Provider* (ISP) space because auditing network access is the basis for billing ISP customers. Increasingly, accounting is being used as a way to correlate client attribute information (username, IP address, etc.) with actions and events on the network.

This correlation can make other systems that are not user-aware more intelligent in the security decisions that they make. For example, a network *Intrusion Detection System* (IDS) can learn a lot about the behavior of a given IP address. However, when that information is correlated with the user assigned to that IP address—and the permissions that user should have—the relevance of the IDS data increases dramatically.

One of the design considerations of accounting systems is that, given the centralized nature of audit and the decentralized nature of access, they are generally out-of-band with the client's normal communications. This makes them excellent resources to refer to when the network administrator wants to know when the client connected and what the client was granted access to. However, their out-of-band nature makes them poor resources for determining what the client actually did while connected to the network. This information can be learned by the network, as mentioned earlier, by coordinating the AAA accounting information with the rest of the network enforcement and monitoring systems.

Summary and Part Two Teaser

This first part of this article introduced AAA and described many of the foundation concepts necessary to gain a sound understanding of the overall system. After defining the elements involved, a sample flow of a AAA event was described. Additionally, the high-level approaches to authentication, authorization, and accounting were discussed. Part two of this article will discuss the protocols used in AAA, including not just RADIUS, *Extensible Authentication Protocol* (EAP), TACACS+, and Diameter, but many others. Additionally, specific applications of AAA technology will be described, and some conclusions will be drawn as to what the future holds for AAA.

Geographic Implications of DNS Infrastructure Distribution

by Steve Gibbard, Packet Clearing House

The past several years have seen significant efforts to keep local Internet communications local in places far from the well-connected core of the Internet. Although considerable work remains to be done, Internet traffic now stays local in many places where it once would have traveled to other continents, lowering costs while improving performance and reliability. Data sent directly between users in those areas no longer leaves the region. Applications and services have become more localized as well, not only lowering costs but keeping those services available at times when the region's connectivity to the outside world has been disrupted. I discussed the need for localization in a previous paper, "Internet Mini-Cores: Local connectivity in the Internet's spur regions."[1] What follows here is a more specific look at a particular application, the *Domain Name System* (DNS).

Most Internet applications depend on the DNS, which maps human-readable domain names to the *Internet Protocol* (IP) addresses computers understand. Two Internet hosts may have connectivity to each other but be unable to communicate because no DNS server can be reached. This article examines the placement of DNS servers for root and top-level domains and the implications of that placement on the reliability of the services these servers provide in different parts of the world. It is not a "how-to" guide to the construction of DNS infrastructure and does not contain recommendations on DNS policy; it is rather a look at the placement of DNS infrastructure as currently constructed.

Although it is possible to access Internet resources without the DNS by entering numeric IP addresses directly, this type of access is not generally done. IP addresses, such as **`209.131.36.158`**, are difficult to remember, are generally unpublished outside the DNS, and often change without notice. Local caching of DNS information can mask temporary problems with DNS data for commonly accessed domain names, but caches are emptied when caching resolvers are restarted, data in caches expires, and nothing is cached until the first time it is accessed by a local user.

It should be noted that information about DNS deployment is changing rapidly. Several organizations are working on new DNS deployment. Information in this article can be considered current, to the best of my knowledge, as of May 2006.

DNS Hierarchy

The DNS is a hierarchy of domains within domains. The levels of the hierarchy are separated by dots. At the top of the hierarchy is the *root,* usually invisible but sometimes represented as a trailing dot. Using **www.yahoo.com** as an example, the **com** domain is contained within the root. **Com** contains **yahoo**, and **yahoo** contains **www**. Domains in the position **com** takes in this example are known as *Top-Level Domains,* or TLDs; they are the first level in the root domain. Domains in the position of **yahoo** are known as *Second-Level Domains*. In this example, **www** occupies the third level, and so forth.

The information that makes up the Domain Name System is stored on DNS *servers*. That information is divided into *zones,* which for our purposes are synonymous with domains. Each zone is stored on a set of *authoritative servers,* which are queried when users or applications attempt to access a service on the Internet. In the simplest case, a domain name query works like the following:

A *caching resolver* (so named because it caches information it receives) that has not yet cached any DNS zone data receives a query for **www.yahoo.com**. Because its cache is empty, it uses the *hints* distributed with the DNS software to contact one of the root servers and asks, "Where is **www.yahoo.com**?" The root server replies with a list of servers for **.com**. The caching server then asks one of the **.com** servers, "Where is **www.yahoo.com**?" and gets a response that directs it to servers for **yahoo.com**. It asks the same question of those servers and finally gets an answer to the question it was asking.

Generally several servers can answer questions about any domain, but if all the servers for any single level are broken or unreachable, the query fails and the service the user is looking for is unreachable. It is therefore important that the DNS be reliable, and that the servers for each zone throughout the hierarchy be reachable from anywhere the servers they point at are being used.

Root Servers

Without root servers, none of the DNS works. As of this writing, 117 root servers exist worldwide, operated by 12 different organizations.[2] Root servers are added frequently, so the number may be significantly greater by the time this article is in circulation.

Because of protocol limitations, the root servers can use only 13 IP addresses. Each root-server operator is responsible for one or two of those addresses. Using a technique called *anycast,* which allows servers in separate locations to share a *single* IP address, six of those operators operate multiple servers using the same IP address[3], meaning that only 13 of them are visible at the same time from any single location, but those 13 should in most cases include the topologically closest one.[4]

The distribution of root servers is rather uneven. North America and Europe have similar numbers: 38 in North America and 35 in Europe. The 35 in Europe are distributed fairly evenly, with the largest concentrations (four each) in London and Amsterdam, Europe's two largest Internet hubs. North America has 8 in Washington, D.C., 8 in the San Francisco Bay Area, and 5 in Los Angeles. In the United States, all cities that host root servers are on the coasts except Atlanta and Chicago. All seven of the remaining IP addresses represented by only a single server, known as *unicast roots,* are in the Washington, D.C., San Francisco, and Los Angeles areas.

Australia has two root servers in Brisbane, one in Perth, and one in Sydney. New Zealand has two, one in Wellington and one in Auckland. Singapore and the wealthier parts of East Asia are well-covered, and there are two root servers in Jakarta and one each in Bangkok and Kuala Lumpur. A year ago, there were none in the vast expanse between Bangkok and Dubai, but three have recently been added in India, along with others in Dhaka and Karachi. Mainland China and the former USSR each have two. There are three in Africa: two in Johannesburg and one in Nairobi. Another will be installed in Nairobi shortly, but most of the rest of Africa lacks direct connectivity to Johannesburg or Nairobi and must cross satellite or intercontinental fiber links to reach the nearest root servers. All four of the root servers in South America are in Brazil and Chile, with two in Sao Paulo and one each in Brasilia and Santiago de Chile.

With some exceptions, root-server density tends to correlate strongly with per-capita income. This fact is not surprising—it is true for other forms of infrastructure as well—but it means that those with the greatest dependence on external infrastructure are those least able to pay for external connectivity.

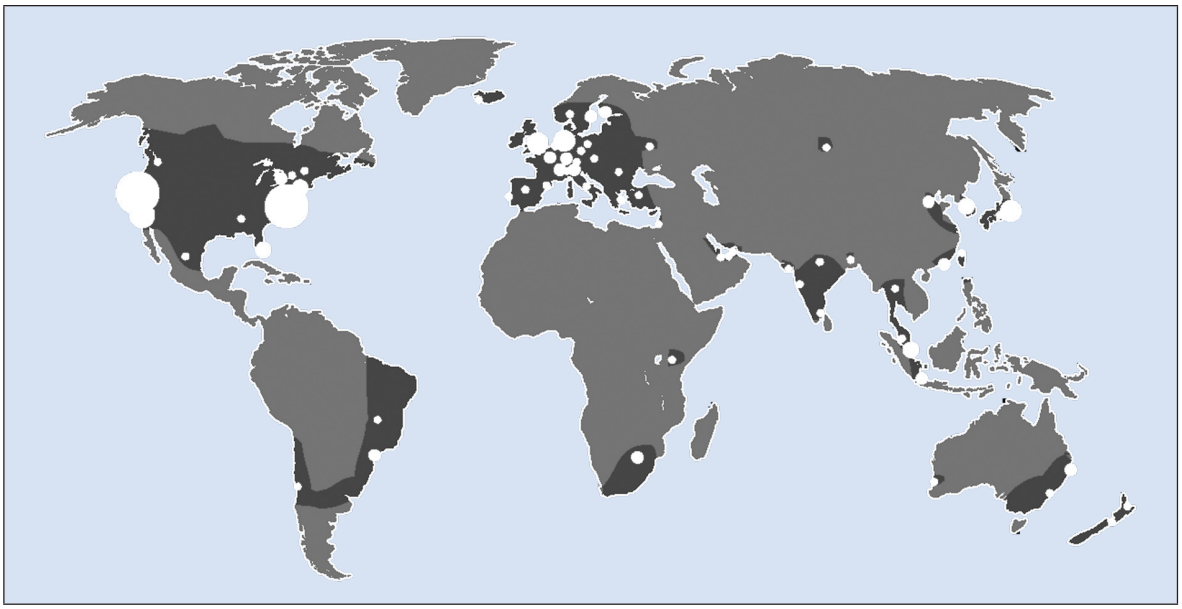
Root-Server Placement

In areas that have local root servers, finding the name servers for a top-level domain should be fairly reliable. In areas without local root servers, the ability to query the root servers is dependent on other long-distance infrastructure. In some places this infrastructure is well-developed, so this problem is not a significant one. Elsewhere long-distance infrastructure is slow, expensive, and unreliable, consisting of satellite links or a single fiber connection that may take several days to fix if it breaks.

Sri Lanka, for example, is connected to the rest of the world by a single fiber connection, which was cut in 2004 by a ship that dragged anchor in the Colombo harbor.[5] Although Sri Lanka has an exchange point that should have allowed connectivity to local Internet services, news reports said that Sri Lanka's "Internet and long-distance phone service" had been cut off. I have not received a good account of what Internet connectivity looked like from anyone in Sri Lanka at the time, but it is likely that even local Internet connections would not have worked without a local root server.

Sri Lanka is not an isolated case. The dots in Figure 1 show the locations of all root servers. The light grey areas are regions in which multiple fiber paths are available to root servers. The remainder of the world can reach root servers only by a single fiber path or by satellite. Large areas of the world are poorly covered.

Figure 1: Root Server Locations and Areas of Redundant Connectivity



Root-Server Expansion

Four of the 12 root-server operators are presently working to install root servers in areas that lack them. Although the 117 root servers currently in operation are a big improvement over the 13 that were in operation three years ago, many regions still do not have any. Those root-server operators are installing servers wherever they can get the funding to do so.

Funding is generally provided either by grants, especially from the *Asia Pacific Network Information Centre* (APNIC) in the Asia-Pacific region, by local governments or *Internet Service Provider* (ISP) associations. Because the addition of new anycast copies of root servers is relatively easy given sufficient funding, the main limitation preventing the installation of root servers in new locations is lack of funding.

One question probably best addressed in a more central manner is whether it makes sense to have many copies of one or two root-server IP addresses in some regions or whether it would be better to have more of a mix of root-server IP addresses. Currently, only 6 of the 13 root-server addresses are anycasted, only 4 are anycasted in large numbers, and 2 of those focus on specific regions, meaning that in many of the more remote parts of the world the only nearby root servers are *Internet Systems Consortium* (ISC)'s "F" and Autonomica's "I" roots, and some places have several of one of those closer than the next one of the other.

Because some DNS resolvers have their own mechanisms for finding the closest server and for handling failures of types that do not include route withdrawals, having multiple IP addresses nearby seems like a good thing. A more complex question is whether it would be worthwhile to anycast all 13 of them widely, or if there is some smaller number that would be sufficient to have nearby. Previous research on this topic has assumed a limit of 13 root servers, producing conclusions that are not applicable to the modern Internet.[6]

This article should not be seen as a criticism of the places with large numbers of root servers. Although the U.S. distribution looks strange, with the San Francisco Bay and D.C. area clusters perhaps excessive, it comes close to following the Internet topology in the United States. Indeed, the U.S. concentration may be appropriate to handle server load. Western Europe's dense but relatively even distribution of root servers through the region appears to be an optimal distribution, because most populated areas have multiple root servers nearby. Likewise, Jakarta is one of the very few cities in the developing world to have more than one, and that provides local redundancy that much of the developing world lacks. If root-server deployment were funded from a single global budget, the distribution across the world's regions would look very unfair. But because Internet infrastructure is mostly funded locally, Jakarta and Western Europe are examples other regions could emulate.

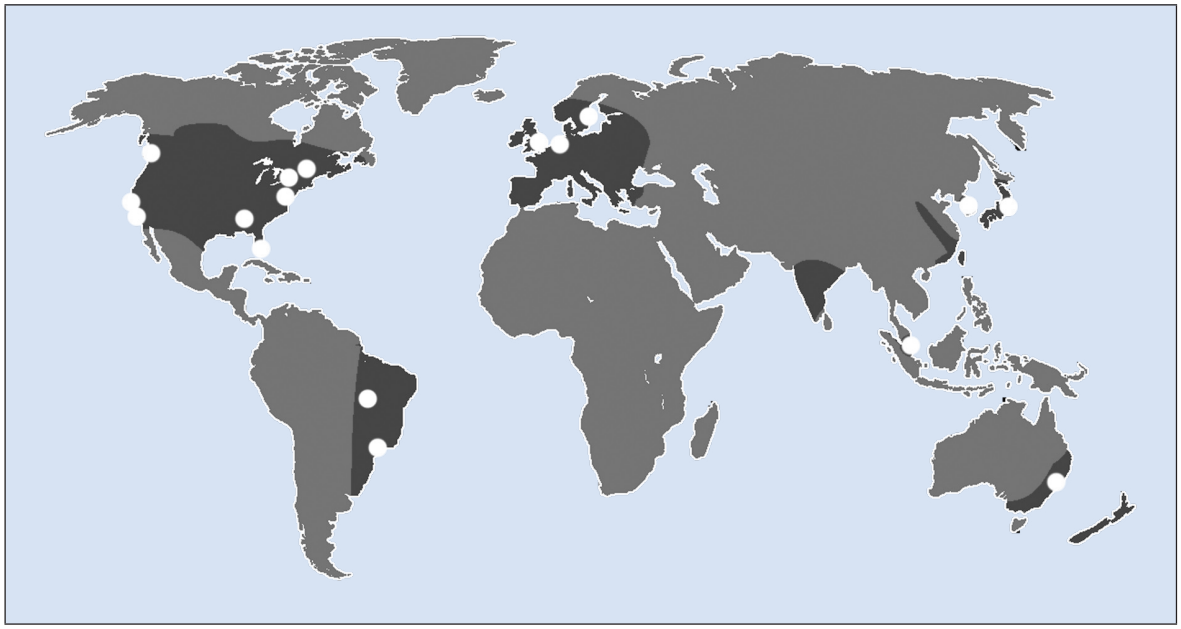
TLD Distribution

Use of the DNS also requires access to TLD servers. To access something in the **.com** domain, a user's local DNS resolver must be able to reach the **.com** servers. This statement is true for any TLD, whether it is a *generic TLD* (gTLD), such as **.com**, **.net**, and **.org**, or a *country code TLD* (ccTLD). Unlike the root, it is not necessary that all TLDs be reliable from all locations; if a TLD is not used to name local resources in a region, having local access to that TLD will not help if that the region gets cut off from the rest of the world.

gTLD Distribution

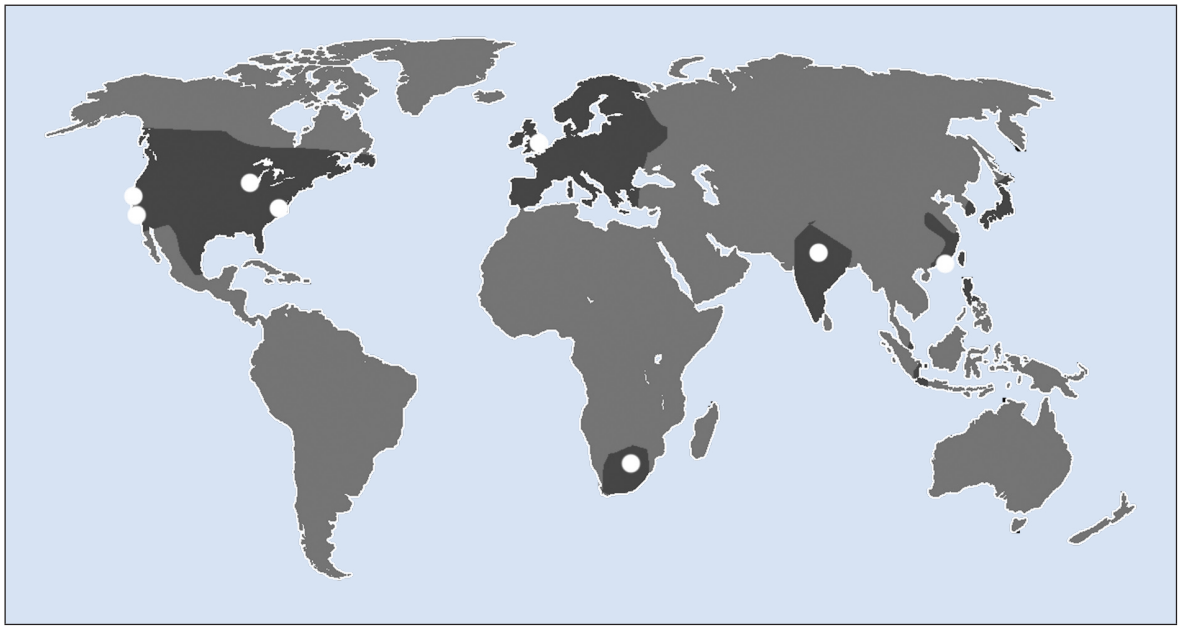
Of the gTLDs, **.com** is by far the largest. It is well-connected to the Internet core, the area with well-meshed internal connectivity mainly comprising North America, Western Europe, East Asia, and Singapore. (See Figure 2.) The **.com** servers are located in Australia, Brazil, Japan, South Korea, the Netherlands, Sweden, the United Kingdom, and the U.S. states of California, Florida, Georgia, Virginia, and Washington. The **.com** servers are well-connected to areas well-connected to those regions but poorly connected to Africa, South Asia, and parts of South America.

Figure 2: Server Locations for .com and .net and Areas of Redundant Connectivity



UltraDNS, the operator of **.org**, **.info**, **.mobi**, and **.coop**, among others, is also somewhat well-connected to the Internet core, although not to the extent the **.com** servers are. It has publicly accessible servers in four metropolitan areas in the United States as well as in London and Hong Kong. It has a couple of noncore locations, in Delhi and Johannesburg. UltraDNS also has servers in other locations, accessible only to the resolvers of certain large ISPs. Because those servers are not available to the general public in their regions, they are omitted from discussion here. (See Figure 3.)

Figure 3: Server Locations for .org, .info, and .mobi and Areas of Redundant Connectivity



Other gTLDs do not do considerably better. Table 1 shows the locations of all the gTLDs.

Table 1: Locations of TLD Servers

gTLD	Locations by Country or U.S. State
.aero	Switzerland, Germany, India, Hong Kong, United Kingdom, and the following states in the United States: California, Illinois, and Virginia
.biz	Australia, Hong Kong, Netherlands, New Zealand, Singapore, United Kingdom, and the following states in the United States: California, Florida, Georgia, New York, Virginia, and Washington
.com	Australia, Brazil, Canada, Japan, South Korea, Netherlands, Sweden, Singapore, United Kingdom, and the following states in the United States: California, Florida, Georgia, Virginia, and Washington
.coop	United Kingdom and the following states in the United States: California, Illinois, and Massachusetts
.edu	Netherlands, Singapore, and the following states in the United States: California, Florida, Georgia, and Virginia
.gov	Canada, Germany, and the following states in the United States: California, Florida, New Jersey, Pennsylvania, and Texas
.info	India, Hong Kong, South Africa, United Kingdom, and the following states in the United States: California, Illinois, and Virginia
.int	Netherlands, United Kingdom, and California in the United States
.jobs	Netherlands, Singapore, and the following states in the United States: California, Florida, Georgia, and Virginia
.mil	The following states in the United States: California, Maryland, Virginia, and other unknown locations
.mobi	India, Hong Kong, South Africa, United Kingdom, and the following states in the United States: California, Illinois, and Virginia
.museum	Sweden and California in the United States
.name	Singapore, United Kingdom, and the following states in the United States: California, Florida, Georgia, Virginia, and Washington
.net	Australia, Brazil, Canada, Japan, South Korea, Netherlands, Sweden, Singapore, United Kingdom, and the following states in the United States: California, Florida, Georgia, Virginia, and Washington
.org	India, Hong Kong, South Africa, United Kingdom, and the following states in the United States: California, Illinois, and Virginia
.pro	Canada and the following states in the United States: Illinois and Texas
.travel	Australia, Hong Kong, Netherlands, New Zealand, Singapore, United Kingdom, and the following states in the United States: California, Florida, Georgia, New York, Virginia, and Washington

Although gTLDs are typically marketed for their applicability to specific types of organization, or in the case of **.com** because it is the only domain many people have heard of, geography should also be considered in selecting domains. Most of the gTLDs have reasonable coverage throughout the Internet core region, but there are exceptions. The **.int** and **.museum** domains are hosted only in North America and Europe, and **.pro** is hosted only in North America.

Outside the Internet core there is little gTLD presence. Only **.biz**, **.travel**, **.com**, and **.net** are present in Australia and New Zealand. South Africa and India have **.aero**, **.info**, **.mobi**, and **.org**, making them the only gTLDs hosted in either Africa or the South Asian region. South America hosts only **.com** and **.net**, with servers in two cities in Brazil. Taken together, these are the only Southern Hemisphere gTLD locations as of this writing, and no gTLD has any presence in parts of the world without external fiber-optic connectivity, although that may be changing.

Where gTLDs should be hosted, and with what scope, are somewhat open questions. Should these domains address resources anywhere, or should their scope be local? This question is really one for the *Internet Corporation for Assigned Names and Numbers* (ICANN), or for the gTLD sponsors or registries, and beyond the scope of this article. Verisign, the company that administers **.com** and **.net**, points out that database replication with the amount of changes in the **.com** zone is a significant problem over slow network links.

ccTLD Distribution

Questions about where ccTLDs, the top-level domains assigned to individual countries, ought to work seem more straightforward. Working effectively in their own countries seems like the top priority, with connectivity to the Internet core and to other regions with which people in the country communicate regularly being somewhat lower priorities. Just over two-thirds of ccTLDs are hosted in their own countries; refer to Figure 4 for the bigger countries, and the online appendices for the full list. Although the third of ccTLDs not hosted in their own countries include some marketed more for international use than global use—Cocos Island's **.cc**, Tonga's **.to**, Turkmenistan's **.tm**, and Tuvalu's **.tv**, among others—those are very much the exception.

Indonesia has local access to the root and to its ccTLD (**.id**). Pakistan has a root server, but no local access to its ccTLD (**.pk**). Let's compare what happens when someone in Indonesia does a lookup on an **.id** domain name with what happens when someone in Pakistan does a lookup of a name in the **.pk** domain.

In Indonesia, the query goes to a root DNS server at the Indonesian Internet Exchange in Jakarta, where it is answered with the locations of the **.id** servers, several of which are also in Indonesia. The query then goes to the local **.id** server and is answered locally, whereupon the user can start sending traffic to the host he or she was trying to connect to, which is presumably also local. The traffic need not leave Indonesia, and if all the parties involved are in Jakarta it need not leave town.

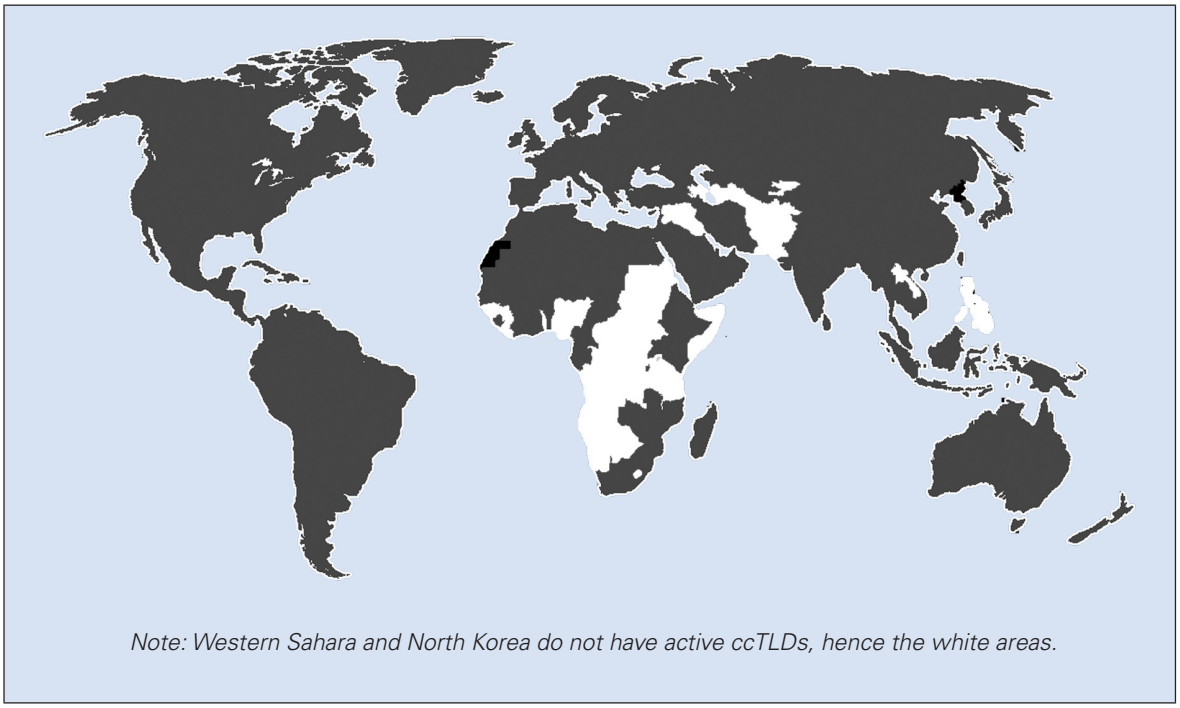
The Pakistani case is quite different. Until early 2006, there were no root servers in Pakistan, nor were there local servers for the **.pk** domain. There is now a root server in Karachi, but lacking servers for any TLDs it is of limited utility. DNS resolvers start out querying the local root server, but the response directs them to servers for the **.pk** domain, all located in the United States, at least 10 time zones away. They then send their lookup packets across the single fiber connection all the way to the United States and wait for the response. At best, this process is slow. If that fiber connection goes down, or if there is any other problem between Pakistan and these U.S. servers, local communications in Pakistan are crippled.

The situation with traditional gTLDs (**.com**, **.net**, and **.org**) in Indonesia and Pakistan is somewhat different. In Indonesia, local root servers provide addresses for the **.com**, **.net**, and **.org** servers. The **.com** and **.net** lookups can be handled in Singapore, 18 milliseconds away. Theoretically, **.org** lookups can be handled in Hong Kong, but *traceroutes* indicate **.org** queries being answered in California instead. Thus, in Indonesia, **.id** is hosted mostly locally, **.com** and **.net** are nearby, and **.org** is considerably farther away. In Pakistan, in contrast, **.pk** queries and **.org** queries are answered from the United States, more than 200 milliseconds away, while **.com** and **.net** are answered from Singapore, 80 milliseconds away. For Pakistani users of all TLDs, there are single points of failure, but **.com** and **.net** do appear to be somewhat better connected than **.pk**.

In Nairobi, Kenya, there are local copies of a root server and the local ccTLD (**.ke**). All external connectivity is by satellite, and most ISPs have only a single satellite link. Two Internet users in Nairobi wanting to communicate can do a lookup on the local root server to find the servers for **.ke** and can do a lookup on a local **.ke** server to find the servers for a subdomain of **.ke**. Assuming the subdomain being used is served locally, they can do a local lookup for a host within that subdomain and then send data across the local exchange point. Thus the two users in the same town can send data back and forth without having to send any data elsewhere.

According to Verisign, Nairobi will soon have servers for **.com** and **.net** as well. In contrast, to use the **.org** domain they can again obtain addresses of the **.org** server from their local root server, but the lookup of the **.org** domain must go over a satellite link to Europe in order to be answered by a server in London. If the satellite link is up, this process adds half a second of latency to the query. If the satellite link is down, whatever local resource they are trying to connect to is out of reach.

Figure 4: Countries that Host Their Own ccTLDs in Grey; Those that Do Not in Black



Note: Western Sahara and North Korea do not have active ccTLDs, hence the white areas.

There is also a concern about ccTLDs not served from the global core; if their region or upstream provider is cut off from the Internet outside their region, the rest of the world is unable to see that ccTLD. (See Table 2). This situation may or may not be of concern; if all Internet resources within that ccTLD become unreachable in the same outage, the DNS portion of the outage may have no additional effect. However, if there is anything in that ccTLD that is not in the ccTLD's region, or if people or systems outside prefer to get a DNS response for an unreachable IP address rather than no DNS response at all, it may be of concern. Indeed, having servers that are well-connected to "the Internet as a whole" is a recommendation of RFC 2182, though the RFC does not consider the case of large portions of the Internet not being well-connected to each other.

Table 2: TLDs Not Served in the "Internet Core" Region

TLD	Country	Location of DNS Servers
BB	Barbados	Barbados
BD	Bangladesh	Bangladesh
BH	Bahrain	Bahrain
CN	China	China
EC	Ecuador	Ecuador
GF	French Guiana	French Guiana and Guadeloupe
JM	Jamaica	Jamaica
KG	Kyrgyzstan	Kazakhstan
KW	Kuwait	Kuwait
MP	Northern Mariana Islands	Guam
MQ	Martinique	Guadeloupe and Martinique
PA	Panama	Brazil, Chile, Costa Rica, and Panama
PF	French Polynesia	French Polynesia
QA	Qatar	Qatar
SR	Suriname	Suriname
TJ	Tajikistan	Tajikistan
ZM	Zambia	South Africa and Zambia

Lack of Exchange Points and Local Peering

In the "Internet Mini-Cores" article[1], I noted that local hosting of critical infrastructure is moot if there is not either a local exchange point or a monopoly transit provider in the region. If data needed in a poorly connected region must leave the area and return to reach the user requesting it, the communication has double the latency, and possibly double the reliability problems, that it would have if it were hosted somewhere in the core. For the specific examples used in this article, I have mostly chosen areas that do have exchange points. I have not analyzed the underlying local infrastructure in all countries.

Methodology

The addresses of DNS servers for a TLD are available through several means: by looking at the root zone, by doing *digs* for the name servers, and by looking in the *Internet Assigned Numbers Authority* (IANA) *whois* data, among others. I did lookups against an anycast root server on my own network, because that seemed easiest to automate. My script then did a lookup for the address of each name server, stripped off the last octet, and produced a list of TLDs hosted in each /24 subnet.

There are 635 /24s containing name servers for TLDs; 142 of them host multiple TLDs; the rest host just one. I assumed that all DNS servers in a given /24 were likely to be in the same or nearby locations. This situation appears not to be the case for the UUNet name servers, and there are probably a few other exceptions that will show up as errors in my data.

I looked at a few automated geolocation systems to attempt to attach locations to the DNS servers, but none of them appeared to be producing accurate information. Instead, I guessed at the locations of the 600 subnets, using *traceroutes* from a variety of locations, paying attention to DNS, latency, and the results of whois queries for address space along the way. I also asked lots of questions of DNS operators and others and am particularly grateful to several anycast DNS operators, whose locations would not have all been found by my *traceroutes*. Some of my guesses are likely incorrect, and corrections are appreciated.

I may be missing some information about the UltraDNS TLD servers, because UltraDNS has locations it regards as confidential. This information about UltraDNS servers is from Afilias's **.net** application, *traceroutes* from a variety of locations, and UltraDNS.[7]

Locations of root servers are easier to find; they are listed at **http://www.root-servers.org**. Some supplemental information about **j.root-servers.net** was supplied by Verisign. If there are operational root servers not included on **www.root-servers.org** other than the J-roots, I did not count them.

The full lists of locations of all TLDs and TLD servers are in the appendices to this article, at:
http://www.pch.net/resources/papers/infrastructure-distribution/dns-distribution-appendices.pdf.

STEVE GIBBARD is a Network Architect for the nonprofit organization, Packet Clearing House (**www.pch.net**), based in Berkeley, California. He runs an anycast DNS network that hosts the top-level domains for several countries and several of the "I" root anycast DNS servers, maintains PCH's network of route collectors and route servers at exchange points around the world, and researches the interconnection of Internet networks. In addition, Steve carries out network architecture and peering work as a consultant for several ISPs in the San Francisco Bay Area and elsewhere. Steve is a former Senior Network Engineer at Cable & Wireless, and has held network engineering positions at Digital Island and World Wide Net. E-mail: **scg@pch.net**

Writing Internet Drafts and RFCs Using XML

by Marshall T. Rose, Dover Beach Consulting, Inc. and Carl Malamud, Public Resource, Inc.

What is the work product of the *Internet Engineering Task Force* (IETF)? Some cynical observers might suggest "many fine lunches or dinners," but we argue that those niceties are merely the means to an end. The goal of the IETF is to provide open standards for the Internet community, and those standards are memorialized as written documents called *Request For Comments* (RFCs).

In general, two organizations control the publication of documents as RFCs:

- The *Internet Engineering Steering Group* (IESG) determines which documents are suitable for publication as RFCs—typically by chartering working groups, reviewing their progress (through reading the work-in-progress *Internet Drafts*)—and ultimately approving their documents for publication.
- The RFC Editor strives for "quality, clarity, and consistency of style and format," and has developed a particular editorial style. The latest RFC that documents this style, RFC 2223[1], is about a decade old. A somewhat more current version can be found in a text file maintained by the RFC Editor.[4]

For a more detailed discussion of the interaction between these two organizations, consult RFC 3932[2].

As an organization, the IETF excels at "eating its own dog food," including its work product: just as a protocol specification describes interactions on the wire but does not dictate the programming language used for implementation, so too, the IETF has not really cared which document preparation tools are used. The IESG worries about technical quality, and the RFC Editor worries about stylistic consistency (and, to be fair, technical quality as well). This policy works because of the careful choices made by the early Internet community, and in particular the RFC Editor, with respect to the "final form" footprint of the documents. (A discussion of these design decisions is far beyond the scope of this short article—for now, we note that it is hard to argue with success.)

An unfortunate side effect of this focus on stylistic consistency is that, for many years, the RFC Editor has had to recode documents for consistent formatting. Internally, the RFC Editor used *nroff*[5] for this purpose, and sophisticated authors wishing to minimize RFC Editor "downtime" tended to use the same *nroff* boilerplate. The *nroff* text-formatting program has many strengths, but it can also be fairly viewed as a textual "assembly language," with the result that authors spent a lot of time dealing with low-level formatting concerns.

In some limited cases, the high degree of formatting-specific expertise is warranted, but for the vast majority of documents, the high entry cost is not.

From Assembly Language to Markup

In early 1999 we were working at a startup company, and we needed a way to organize, search, and retrieve information from documents. We decided to use a markup language for this purpose. We also decided to use the RFC series as one of the testing grounds for the technology, because this series was one we were familiar with. Although today everyone knows what the *Extensible Markup Language* (XML) is, then there were only two widely known markup languages for authoring: SGML and HTML.

The "SG" in SGML is an abbreviation for *Standard Generalized* and not *Simple Generic*. SGML is used for the formatting of a great many books; further, it is used in large projects with long lifetimes. Although truly excellent from an "enumerate every possibility" standpoint, it has a very high cost of entry, making it difficult to use for anything other than specialized applications.

In contrast, the *Hypertext Markup Language* (HTML) embodies elegance of design, but (in the absence of *Cascading Style Sheets* [CSS]), is a presentation language, not unlike *nroff* in many respects. In other words, we needed something with the structural richness of SGML and the elegant simplicity of HTML. The newly invented XML seemed to meet the requirements.

This process led us to develop a language based on XML, which captured high-level RFC constructs (for example, authorship information) and largely ignored presentational concerns. The result is called the *2629 format*[3] (also known as the "xml2rfc format," named after the initial processor for this language).

The Advantages of Markup

To understand the advantages of this approach, let's look at one example: references. Like most archival series, the RFC Editor has a very rigorous, yet unstructured, syntax for citations. Although this consistency is good for readers of RFCs, achieving consistency of references using tools such as *nroff* was often the hardest part of creating a new document. With the 2629 format, the **`<reference>`** element contains a small number of subordinate elements that capture all the semantics of the reference. The XML processor takes this information and produces a properly formatted document.

Further, because this information is structured, it is possible to develop automated bibliographic databases for a wide range of data sources. In fact, using the XML "include" mechanism, a document author usually includes just a pointer to the reference, and lets the processor do all the complicated work.

A second advantage is that processors can produce different kinds of output. Some people prefer to view their documents in HTML rather than the canonical textual format. Julian Reschke has written a library of XSLT files that convert to various HTML formats (Strict, Transitional, XHTML, and so on). For example, references are hyperlinked in line, allowing for easy traversal of citations. Still others prefer the *Portable Document Format* (PDF) for printing. By using one of Julian's XSLT scripts and the truly excellent Prince[6] XML/CSS processor, the result is high-quality, printer-ready output.

However, the primary advantage is that the "high-level" approach allows the author to focus more on content and less on format: a processor can enforce the vast majority of the esoterica associated with the RFC Editorial style, including:

- Inserting required boilerplate (and in particular, the desired revision of the boilerplate)
- Checking for mandatory sections such as "Security Considerations" or "Normative References"
- Generating a specialized table of contents, etc.

To Infinity and Beyond

After publishing RFC 2629, an unexpected result occurred: people outside the IETF started using the 2629 format for their projects. Most credit for this side effect goes to the universality of the canonical textual format. However, some authors are using the 2629 format when writing books (they convert the 2629 format to SGML, which is sent to the publisher), business plans, and software documentation—and even to create a new series of non-IETF technical documents. The constituency here seems to revolve around having a simple yet structured way to author documents.

For the last few years, a large number of XML editing programs have been deployed, and many of these support the 2629 format. These editors offer two advantages: first, they provide a natural paradigm for editing nested content; and, second, sophisticated editors can be integrated into an automated work flow. (Having said that, the authors still use *Emacs* and *vi* for their XML editors.)

A good example of the use of XML editors is a "plug-in" for the *XMLMind* Editor[7]. This plug-in, written by Bill Fenner, provides a variety of services to the author, such as graphical editing of sections, templates for common constructs, and validation of references.

Over the last 10 years, the 2629 format has evolved in true IETF fashion, based on running code and a rough consensus. Originally created by the authors for our own convenience, we have been more than pleased to see this format used first by an informal community of developers and writers, and more recently by the IETF secretariat, tools team, and administrative entity and by the RFC Editor.

Today, many people use a common high-level markup language for writing RFCs. The next step in this natural evolution will be making the repository of XML-tagged RFCs available to those involved in document distribution, so that RFC repositories will be able to take advantage of the meta-data in the creation of search engine, alternative formats, and any other value-added constructs that would be of use to the community. (At present the RFC Editor prefers input in the 2629 format, but ultimately runs a processor that generates *nroff* for "tweaking"—in the near future, we hope that the xml2rfc textual output can be tuned to avoid this final step.)

To find out more, go to the xml2rfc Website[8] or visit the official directory of IETF authoring tools[9].

ICANN Board Rejects .xxx Domain Application

On March 30th, 2007 the Board of the *Internet Corporation for Assigned Names and Numbers* (ICANN) voted to reject the **.xxx** *sponsored Top Level Domain* (sTLD) application from ICM Registry, Inc.

"This decision was the result of very careful scrutiny and consideration of all the arguments. That consideration has led a majority of the Board to believe that the proposal should be rejected," said Dr Vint Cerf, Chairman of ICANN. "I thank my fellow Board members and the community for their input," Dr Cerf said.

A copy of the resolution from the Board meeting is available at:

http://www.icann.org/minutes/minutes/resolutions-30mar07.htm

A transcript of the Board meeting is also available at:

http://icann.org/meetings/lisbon/transcript-board-30mar07.htm

ISOC Fellowship to the IETF

The *Internet Engineering Task Force* (IETF) is the world's premier Internet standards setting organization. It operates as a large, open international community of network designers, operators, vendor experts, researchers, and other interested technologists. While much of the IETF's work takes place over mailing lists, the in-person experience promotes a stronger understanding of the standardization process, encourages active involvement in IETF work, and facilitates personal networking with others that have similar technical interests.

Presently, there is limited participation at the IETF by technologists from developing countries. There are, however, many talented individuals in developing regions that have an interest in and follow IETF work and would benefit from the opportunities that attending an IETF meeting presents. As such, the main purposes of the Internet Society (ISOC)'s *IETF Fellowship Program* are to:

- Raise global awareness about the IETF and its work
- Foster greater understanding of and participation in the work of the IETF by technologists from the developing world
- Provide an opportunity for networking with individuals from around the world with similar technical interests
- Identify and foster potential future leaders from developing regions
- Demonstrate the Internet community's commitment to fostering greater global participation in Internet Forums such as the IETF

ISOC successfully piloted the IETF Fellowship program at the 66th IETF meeting in Montreal in June 2006. Two individuals from Africa participated in this first pilot. Three individuals from the Pacific and Latin America participated in a second pilot phase at the 67th IETF meeting in San Diego in November 2006. All found the experience highly beneficial. Based on the success of the pilots, ISOC decided to formalize the program beginning in 2007.

The ISOC Fellowship pays for the Fellow's IETF meeting registration and social event fees, a round-trip economy class airfare to the meeting, hotel accommodation, and a small stipend to offset incidental expenses.

The program provides fellowships for up to five individuals per IETF meeting. ISOC will be putting out a call for candidates, including through ISOC chapters, at least 3 months before an IETF meeting. A small selection committee comprised of individuals knowledgeable about the IETF will evaluate the applicants against selection criteria and make their fellowship recommendations.

Fellowship recipients will have an obligation to present or otherwise share their experiences at the IETF meeting they attend with their local community and to provide feedback on their experience to ISOC so that the program can be continuously improved. An *ISOC Fellowship Alumni Network* will be established to extend the fellows IETF experience and relationship-building opportunities after the meeting.

For further information on the specifics of the program and how to apply for an ISOC Fellowship see:

`http://www.isoc.org/educpillar/fellowship/application.shtml`

BGP: The Movie

Statistics on Internet resources have been animated to provide a high-level overview of the consumption and use of IPv4 addresses and AS numbers since 1983. The animated video also clearly shows the effect of *Classless Interdomain Routing* (CIDR) and *Regional Internet Registries* (RIR) allocation policies on consumption rates and routing. This animation was developed by *Asia Pacific Network Information Centre* (APNIC) staff members, Geoff Huston and George Michaelson. You can download the 58MB movie from:

`http://www.apnic.net/news/hot-topics/docs/bgp-movie.mpg`

Internet Governance Articles and References

APNIC is also maintaining a collection of articles and references on Internet governance to help the community understand the issues and stay abreast of developments. You can find these at:

`http://www.apnic.net/news/hot-topics/internet-gov/index.html`

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

A Quarterly Technical Publication for Internet and Intranet Professionals

In This Issue

From The Editor

Part One of a two-part article on *Authentication, Authorization, and Accounting* (AAA) was published in our previous issue. This time Sean Convery presents Part Two—subtitled "Protocols, Applications, and the Future of AAA."

Interest in *IP Version 6* (IPv6) is growing in many parts of the Internet technical community; see, for example, the announcement from ARIN on page 39 of this issue. Transition to IPv6 is likely to be one of the greatest technical challenges in the history of the Internet. Several groups are developing parts of the overall solution by creating IPv6-capable versions of protocols such as the *Dynamic Host Configuration Protocol* (DHCP) or including support for IPv6 in the *Domain Name System* (DNS). Although not yet widely deployed, IP *Network Mobility* is expected to play an important part in the Internet of the future. For this reason the IETF is working on IP mobility with an eye toward IPv6. Our second article looks at the *Network Mobility* (NEMO) *Basic Support Protocol,* which is being developed by the NEMO working group in the IETF.

Depletion of IPv4 address space is not the only concern for network operators and developers these days. Questions about the long-term viability of today's routing protocols and the associated addressing systems center around a basic concern about how we can scale our networks to a size orders of magnitude larger than what we have today. A recently formed *Routing and Addressing Problem Directorate* (ROAP) is tasked to examine these problems in detail. Several ROAP-related sessions took place during the most recent IETF meeting, and Geoff Huston reports on these sessions and gives his analysis and commentary. Incidentally, Geoff was not present in person at this IETF meeting, but the facilities to follow an IETF meeting remotely are now of such a quality that he was able to participate from the other side of the world.

Protocol replacement or enhancement is also the theme in our final article. Dave Crocker asks the question "Is it time to replace SMTP?" Since this is an opinion piece, we invite your feedback or rebuttals.

New on our Website is a linked article index. Visit **cisco.com/ipj** and click on "Index Files" to explore this feature.

Network Authentication, Authorization, and Accounting
Part Two: Protocols, Applications, and the Future of AAA

by Sean Convery, Identity Engines

Network *Authentication, Authorization,* and *Accounting* has been used since before the days of the Internet as we know it today. Authentication asks the question, "Who or what are you?" Authorization asks, "What are you allowed to do?" And finally, accounting wants to know, "What did you do?" These fundamental security building blocks are being used in expanded ways today. The first part of this two-part series focused on the overall concepts of AAA, the elements involved in AAA communications, and high-level approaches to achieving specific AAA goals. It was published in IPJ Volume 10, No. 1[0]. This second part of the series discusses the protocols involved, specific applications of AAA, and considerations for the future of AAA.

AAA Protocols

Although AAA is often thought of as the exclusive province of the *Remote Authentication Dial-In User Service* (RADIUS) protocol, in reality a range of protocols is involved at various stages of the AAA conversation. This section introduces these AAA protocols, organized according to the parties involved in the communication. We divide AAA communications into the following categories: Client to *Policy Enforcement Point* (PEP), PEP to *Policy Decision Point* (PDP), Client to PDP, and PDP to *Policy Information Point* (PIP). For easy reference, the AAA flow diagram from Part One of this article is reproduced here. Please refer to Part One[0] for the explanatory text associated with the diagram.

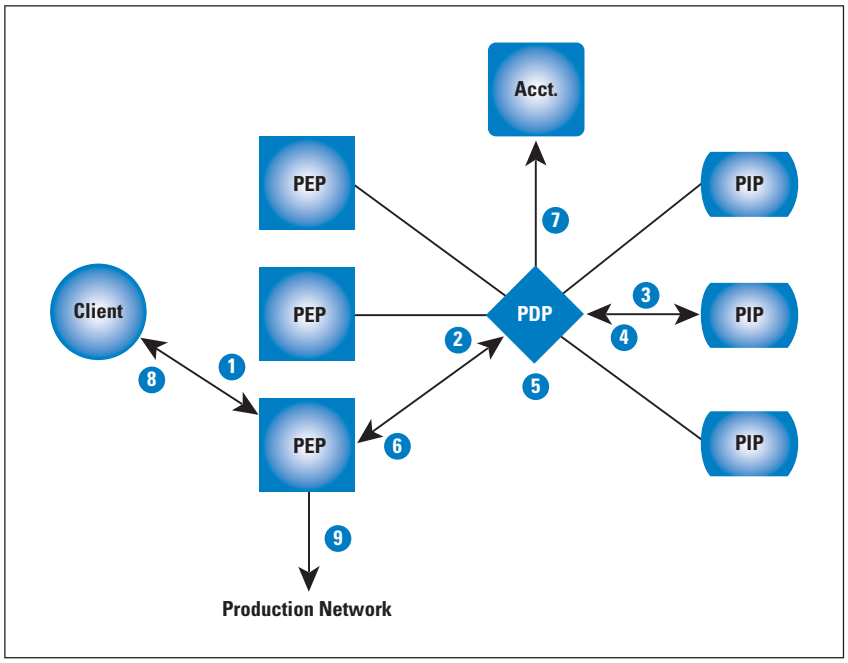

Figure 1: A Client Connects to a AAA-Protected Network (from Part One)

Client to PEP

AAA communications between the client and the PEP can travel at Layer 2 of the OSI model, or they can run at higher layers, relying on lower layers as essentially dumb transport. The most common protocols for client-to-PEP communication are the *Point-to-Point Protocol* (PPP)[1], *PPP over Ethernet* (PPPoE)[2], IEEE 802.1X[3], *IP Security* (IPsec), *Secure Sockets Layer* (SSL) VPN, and *Hypertext Transfer Protocol* (HTTP), each of which is discussed in this article.

PPP, the standard protocol for communicating across point-to-point links, includes an optional authentication step—the point at which the AAA element is introduced. During this authentication phase, protocols such as the *Challenge Handshake Authentication Protocol* (CHAP) can be used to identify the client to the PEP. (These protocols were discussed in the credential section of Part One of this article.) PPP is extensively used in dialup access but is otherwise not found in modern AAA. PPPoE, an adaptation of PPP to run over Ethernet, is used by many service providers rolling out broadband services.

PPPoE allows the broadband endpoint to authenticate itself to the service provider's network when making the initial connection. Because many broadband networks use shared Ethernet mediums, PPPoE allows *Internet Service Providers* (ISPs) to maintain the per-user accounting they were familiar with from dialup. The 802.1X protocol is an IEEE standard specifying a way to provide network access control at the port level for wired and wireless networks. The 802.1X standard specifies a way for the client to communicate with the PDP using the *Extensible Authentication Protocol* (EAP)[4], which is discussed in more detail later in this section. The 802.1X standard requires that the endpoint support 802.1X through a "supplicant" or client sign-on application. This application authenticates the client to the network through the PEP. (See the EAP section later in this article for an explanation showing how EAP and 802.1X can work together.)

For wireless networks, 802.1X has become the standard way of authenticating clients because it supports communicating unique key material to the client to secure its use of the wireless infrastructure. In wired Ethernet networks, 802.1X is rising in popularity as a way to authenticate clients as well. These applications are more fully described in the "AAA Applications" section, later in this article.

At a more generic level, the IPsec protocol has established a standard for securing IP communications, and this approach has become another common method of communicating from a client to a PEP (referred to as a *VPN Gateway* from an IPsec perspective). The initial authentication for IPsec communications uses the *Internet Key Exchange* (IKE) protocol. Version 1[5] of the IKE protocol had no built-in method for authenticating users with credentials such as passwords, so an extension to IKE called *XAUTH*[6] was proposed.

XAUTH never became an official standard (though it certainly was a de facto one) because the IETF IPsec working group created a second version of IKE[7] that used EAP as a transport for credentials such as passwords. Finally, in the areas of HTTP and VPN communications, the SSL and *Transport Layer Security* (TLS)[28] standards are two closely related protocols for securing, among other things, Web communications. SSL/TLS VPNs use these protocols to create a secure session from the client to the PEP (VPN Gateway). Client authentication with SSL and TLS can be done with client-side certificates, but more commonly they use passwords or *One-Time Passwords* (OTPs).

PEP to PDP

The three main protocols for communicating between a PEP and a PDP are *TACACS+*[9], *RADIUS,* and *Diameter*[10]. First, consider TACACS+: Developed by Cisco, TACACS+ is a proprietary protocol that is used primarily in communicating administrator authorizations for network devices. TACACS+ uses TCP port 49 and features payload encryption for the entire TACACS+ message. Though developed by Cisco, TACACS+ is supported by other companies as well, including Juniper.

Although TACACS+ excels at command-level authorizations and accounting for administrator control, another protocol has become far more common for client AAA: RADIUS. Thanks to nearly ubiquitous support for this protocol in network hardware, RADIUS is the primary protocol for communication between a PEP and a PDP in most environments. RADIUS uses the *User Datagram Protocol* (UDP) port 1812 for authentication and authorization and UDP port 1813 for accounting[8] (early deployments used ports 1645 and 1646, which are still used sometimes today). RADIUS supports numerous different attributes for communicating information back and forth from the PEP to the PDP, such as client MAC address, username, filter information for enforcement, and so on. It also supports an extensible framework for *Vendor-Specific Attributes* (VSAs), which allow extensions of the functions of RADIUS to support whatever elements a given PEP might need to best serve its role on the network. For example, a PEP manufacturer might support VSAs that allow the assignment of a user to a particular enforcement profile. RADIUS in its default implementation encrypts only the Password field of RADIUS messages, making the RADIUS protocol more prone to leaking information that could be used by an adversary. Both RADIUS and TACACS+ are secured by only a shared secret that is configured on both the PEP and the PDP.

Finally, consider the Diameter protocol. Diameter (the name is a play on words from RADIUS) is the next-generation, de jure standard for AAA. It supports stronger security through either IPsec or TLS and greater extensibility than RADIUS. It uses port 3868 for either TCP or the *Stream Control Transmission Protocol* (SCTP)[11]. The strongest use of Diameter to date is in the carrier space, where it provides AAA for call processing and *third-generation* (3G) mobile networks.

However, the corporate market has been fairly reluctant to embrace Diameter, and that reluctance has translated into a lack of support for Diameter in corporate network infrastructure equipment.

At this point in the discussion, it makes sense to compare RADIUS and Diameter. Although Diameter is an obvious alternative, RADIUS continues to be used in both new and existing deployments, so the IETF has a working group specifically formed to extend RADIUS in the future. The relationship between RADIUS and Diameter is a little like the relationship between IPv4 and IPv6. IPv6 had IPsec as a standard feature, IPv4 integrated IPsec as well, and today, by a large margin, most IPsec deployments are on IPv4 networks. The situation is similar with AAA. RADIUS certainly had limitations, but since Diameter entered the picture, RADIUS has been extended to address some of those shortcomings, particularly with both protocols using EAP as a transport. The result is that RADIUS today does what most people want. Therefore, given the significant added complexity of Diameter, many organizations have elected not to migrate to Diameter. Both RADIUS and Diameter will be around for many years to come.

Client to PDP

Although most of the protocols in this article handle communication from one component to the next component in the AAA chain (that is, client to PEP, PEP to PDP, etc.), there is one protocol that deals with communication from the client to the PDP directly: the *Extensible Authentication Protocol* (EAP). As mentioned earlier, EAP is a flexible mechanism for communicating almost any kind of credential over almost any lower-layer transport. Each technique for authenticating a client is referred to as an *EAP Method*. Originally conceived as an extension to PPP, EAP can now use many transports, including IKEv2 and 802.1X. Cisco's proprietary *Network Admission Control* (NAC) solution offers a deployment option that puts EAP inside UDP. When using 802.1X, for example, EAP uses LAN transport, referred to as *EAPoL* (EAP over LAN). This transport is only for the connection between the client and the PEP though. From the PEP to the PDP, EAP rides inside RADIUS[12, 13]. The actual conversation, however, takes place between the client and the PDP, with the PEP acting as a relay.

The major benefit of this approach is that the PEP does not need to understand the specifics of the EAP method selected—only the client and the PDP do. The EAP specification in the IETF specifies several different EAP methods, including *EAP Message Digest Algorithm 5* (EAP-MD5, very similar in security to CHAP), *EAP-OTP* (which supports an IETF-defined OTP solution[14]), and *EAP Generic Token Card* (EAP-GTC). Of the methods explicitly called out in the EAP standard, EAP-GTC is the only one in much use today in production networks. EAP-GTC allows the use of OTP token cards within an EAP context.

Beyond the methods defined in the EAP standard, EAP by its nature can be extended to support additional methods. EAP *Subscriber Identity Module* (EAP-SIM)[15] specifies a method for authentication using SIM elements in the *Global System for Mobile Communications* (GSM). EAP-SIM was developed by the *Third Generation Partnership Project* (3GPP) as a solution for these second-generation (GSM) mobile networks. EAP-AKA[16] is the 3GPP's EAP authentication technique for third-generation (*Universal Mobile Telecommunications Service* [UMTS] or *Code Division Multiple Access 2000* [CDMA2000]) mobile networks. Both EAP-SIM and EAP-AKA support authenticating a mobile phone to a Wi-Fi network without using passwords. The problem is that without some sort of user identity federation solution in place, SIM-based authentication can work only with the mobile provider's network that supplied the SIM card. EAP-TLS[17] specifies a technique for mutual certificate authentication. Although it is widely supported, EAP-TLS is not commonly deployed because of its requirement for client-side certificates.

Though none of the following EAP methods are standards, they—somewhat confusingly—represent the vast majority of EAP deployments. Each of them is referred to as a *Tunneled EAP Method* because it establishes one outer EAP method as a base secure channel and then runs another method (one that may be less secure) over that secure channel. *Protected EAP* (PEAP)[18], well supported in Microsoft's Windows operating system, has become a de facto standard for EAP methods. Most clients and PDPs support PEAP today. PEAP works by establishing a TLS session authenticated by the server certificate, and then an inner authentication method rides inside that TLS session. The inner method is almost always *Microsoft CHAP Version 2* (MS-CHAPv2), but other methods can be used as well. Another popular tunneled protocol is *EAP Tunneled TLS* (EAP-TTLS)[19]. This protocol is similar to PEAP except it supports a more arbitrary exchange of information inside the TLS tunnel. For example, one of the primary uses for EAP-TTLS is using the *Password Authentication Protocol* (PAP) as the inner authentication method, allowing an EAP-TTLS-capable PDP to authenticate clients against older password stores (such as those that support only PAP authentication).

Finally, in settings that use primarily Cisco equipment, a common tunneled protocol is *EAP Flexible Authentication via Secure Tunneling* (EAP-FAST)[20]. This protocol uses TLS to authenticate the PDP, and then a shared key is distributed to allow faster subsequent authentication. An inner EAP method such as MS-CHAPv2 can then be used to authenticate the client to the server. EAP-FAST is used extensively in Cisco products for wireless deployments.

PDP to PIP

The final set of AAA protocols we consider are the ones that govern the communication between the PDP and the PIP. The primary protocol of interest is the *Lightweight Directory Access Protocol* (LDAP)[21]. From a AAA context, LDAP allows a PDP to query a PIP (typically an X.500 directory[22]) for information about a client. This information is exposed through a series of group and attribute identifiers, which can include information about a client's home location, organizational role, job title (if referring to a user), and so on. LDAP includes several different authentication options[23]. This client information learned from the PIP enables the PDP to better make its policy decision. Also useful in the PDP-PIP communications context is the RADIUS protocol. Some large organizations or inter-organization federations use a hierarchy of RADIUS-speaking PDPs where one RADIUS PDP can act as a PIP for another RADIUS PDP further down the AAA hierarchy.

Finally, Microsoft *Active Directory* (AD) uses the LDAP protocol when acting as a PDP but also has its own extension, called *Netlogon,* for validating Microsoft credentials such as MS-CHAPv2. This means that integrating a PDP with Microsoft AD generally involves using LDAP to find information about the client and using Netlogon to validate the client's credential. Other options for PDP-to-PIP interaction—though less often used—include *Structured Query Language* (SQL) databases, *Network Information Service* (NIS), and Kerberos.

AAA Applications

This section surveys the different applications of AAA technology throughout networking. It is divided into three sections covering consumer, enterprise, and carrier applications, with a final section covering emerging applications of AAA technology.

Consumer-Managed Applications

Most consumer network deployments do not perform any advanced AAA beyond a shared key for authentication to a wireless network. In this example, the client is the consumer's host and the wireless access point acts as PEP, PDP, and PIP by validating that any client connecting to the access point presents the correct shared key.

Enterprise-Managed Applications

AAA has numerous enterprise applications, including remote access, wireless security, *Voice over IP* (VoIP), guest access, *Role-Based Access Control* (RBAC), and endpoint posture validation (also known as NAC). This section discusses each of these applications. Remote-access security is the original enterprise AAA application. In the remote-access scenario, remote users connect over a dialup connection or a VPN and authenticate themselves (and optionally their hosts) to the organization's network.

The client's credential is almost always a password, expressed in one of the forms discussed in the credential section of Part One of this article. The main purpose of AAA in the remote-access case is to validate that the client is a valid user of the organization's network.

Wireless security is similar in some respects to remote-access security. The goals of AAA in wireless security are twofold: first it must validate that the wireless client is an authorized user, and second, it must provide the client with a session key for cryptographic protection of the client's traffic. Given these goals, 802.1X using EAP are the ideal protocols to use because they support both client authentication and dynamic keying. Older wireless security approaches relied on an open wireless network and a VPN Gateway separating that network from the rest of the organization's network. In that example, the wireless-security approach mimics the remote-access application just discussed. Other types of networking require different applications of AAA. For example, VoIP deployments have authentication requirements as well. The *Session Initiation Protocol* (SIP)[24] is used extensively for, well, session initiation in VoIP networks (for example, authenticating the calling parties prior to initiating a new call). Authentication can be handled natively within SIP using HTTP digest authentication, or the same request can be sent to a PDP using RADIUS. AAA for VoIP allows handsets to authenticate themselves to the network and gain access to call-processing services.

Another, very popular application of AAA is guest-access management for networks. This application has grown quickly with the recent growth of wireless networks. Guest access is a method by which guests can be granted temporary access to a network with a full audit trail[27]. Guest access generally involves creating a distinct PIP, which houses short-term user accounts, and a technique for creating and, after a configurable period of time, automatically deactivating those user accounts. The PIP is often co-resident with the PDP and allows this temporary access without having to provision these users into the organization's more permanent directory. The guest can communicate with the PEP using any of the client-PEP protocols discussed earlier, though HTTP is the most common. The PEP is told by the PDP that the client (because it is a guest) should have restricted access—typically access only to the Internet at large and not any communication with an organization's internal network.

Also growing in popularity as a AAA application is RBAC, an application of AAA that allows customization of the network session based on the role of the client. In fact, guest access is a simple form of RBAC whereby two classes of clients are created: guest and permanent. However, RBAC can be extended to include more levels of delineation, including guest, contractor, and specific classes of permanent users such as sales, human resources, and engineering.

This classification can be done with all forms of AAA-enabled network infrastructure, including wired, wireless, and remote access. Current scalability limitations of VLAN technology and *Access Control Lists* (ACLs) make creating large quantities of roles difficult, but a significant business benefit in audit and regulatory compliance can be realized with usually fewer than five roles.

To implement RBAC, most organizations choose a mix of 802.1X and HTTP authentication for wired and wireless access, combined with VPN technology for remote access. This approach is the most common one to RBAC, though others are used.

Finally, another important AAA application is *Endpoint Posture Validation,* also referred to as *Network Access Control* (NAC). Unfortunately NAC is an inappropriate name because of its almost complete overlap with the more general AAA term—leading to a fair amount of confusion in the market. Endpoint posture validation refers to many different parameters in the industry as it is an emerging technology. These parameters range from very narrow device-centric posture checking to a more identity-centric approach for secure mobile computing. Because this entire article is concerned with the latter, we will consider NAC in its narrow context of endpoint posture checking. With this label, NAC simply acts as another PIP for the PDP to use.

This time, though, instead of checking the client's credential, NAC checks the client's software configuration. This checking generally focuses on security-sensitive configuration details of the endpoint security software and the operating system itself, such as the revision, configuration, and current operating status. This client configuration data is gathered by a host agent on the client and then sent to the PDP or PIP for evaluation. The host agent is either permanent on the client or downloaded dynamically to acquire the information. Some NAC applications rely exclusively on external scanning of the client, although this scanning generally yields far less granular information than an agent would.

The challenge with NAC today is deploying a system built on standards. The IETF and the *Trusted Computing Group* (TCG) are both pursuing standards in this space. Meanwhile Cisco, Microsoft, and a host of smaller companies have offerings not currently based on any standard. Recent announcements from the TCG and Microsoft are changing this. The TCG recently standardized the as-implemented NAC protocol used by Microsoft's NAC approach. Though there is much more work to do, this should allow the beginnings of standards-based interoperability in NAC solutions since a core protocol in Microsoft's NAC is now a standard from the TCG. There is a great base in standards at a low enough layer in all the NAC approaches though, as the emerging standards use the protocols discussed in this article including 802.1X, IPsec, RADIUS, and LDAP.

Carrier-Managed Applications

Some carrier-managed AAA applications are similar to those for the enterprise and others are different. The common distinctions for almost all carrier applications are their large scale and their emphasis on accounting. Carrier applications include dialup, DSL or cable PPPoE, mobile or 3G, wireless hotspot, and metro wireless. Dialup is similar to the remote-access application in the enterprise section, but on a massive scale. *Network Access Servers* (NASs) for a large ISP are geographically dispersed, as are the PDP and PIP systems that support them. Clients communicate with the PEP (NAS) with PPP using one of the password credential techniques discussed in Part One of this article, and the PEP communicates with the PDP using RADIUS or Diameter.

Now consider DSL or cable PPPoE. Though PPPoE-based broadband access seems to be on the decline, many ISPs are still using PPPoE for the enhanced audit trail it provides compared with an unauthenticated connection. In the realm of mobile telephone networks, service providers are increasingly providing data services in mobile phones, and these services require AAA for security and billing. Such data services come in several varieties on both the second- and third-generation mobile networks. Additionally, smartphones are increasingly supporting 802.11-based wireless access as well, creating a complex relationship between the smartphone, mobile voice network, mobile data network, 802.11 data network, and VoIP-based voice services. Previously discussed standards such as EAP-SIM and EAP-AKA are trying to bridge some of these worlds, but there is much work to be done. Ideally, any smartphone should take advantage of the network with the fastest and richest set of services, and callers trying to reach a smartphone user as well as the user himself, should be shielded from this discovery and association process. Business motivators and detractors within the carrier space may affect this convergence.

The next carrier-managed AAA application to discuss is the *wireless hotspot*. Hotspots work much like dialup providers in that regular users get a password-based credential that lets them authenticate to the hotspot. In this context, the 802.1X protocol is less commonly used because the required client software is not yet ubiquitous in the client install base. More common is Web-based authentication much like that used to access broadband in a hotel. A critical security consideration for a hotspot operator is the ability to ensure that a given client is not connected to two hotspots at the same time—a situation that would indicate an account was shared between two or more users. This stipulation places an increasing burden on the accounting aspect of AAA, as with any carrier-based AAA application.

Finally, the last AAA application we examine is the metropolitan wireless network, known as "metro wireless." In metro wireless, an 802.11 network is deployed throughout a metropolitan area, and access is provided free of charge or for a fee. I live in Mountain View, California, which is home to Google's headquarters, and is where Google has installed its free, citywide metro wireless network.

Although the service is free, AAA is still required: to sign on to the wireless network, you must authenticate to Google using an ID. This step, much like signing on to a wireless hotspot, allows Google to trace network use to an individual (if necessary) and switch to a fee-based model later on if desired. HTTP authentication is most common in metro wireless environments, and, because of the on/off nature of access, little sophistication in policy decision is required other than validating the client's credential.

Emerging Applications

Several interesting applications of network AAA are emerging. The first is in building just-in-time networks, such as when establishing an on-scene emergency operations center after a disaster. In this situation, emergency workers often need to communicate in a protected environment, and the press that covers the disaster needs network access to send in its reports. The AAA application required here is a cross between wireless security, guest access, and RBAC.

Another emerging application is what we call "granular RBAC." As opposed to RBAC, which associates users into coarse-grained classes of users, granular RBAC knows much more about the users and makes a more sophisticated access decision.

One example of the use of granular RBAC is for classroom control in higher education. Increasingly, classrooms are wireless-enabled as a convenience feature for faculty and students. However, during exam time it is often useful to disable this access to the students taking an exam. Without a granular understanding of which clients are connecting to the network, this setup is very difficult to achieve without physically disabling large portions of the wireless network during exam time. By using AAA, a school could put class schedules inside an LDAP store along with the rest of the students' information. Professors could also register exam times by time and location. AAA could then prevent students from getting on the network inside the classroom during their exam period, while still letting them connect to the network when inside their dorm room.

Finally, the last application we consider is what I call "punitive access restrictions." As networks become more and more an integral part of our lives, it is natural to want as fast a network connection as we can find, creating the situation where denying access to the network based on past behavior (network related or not) can be used as a punitive action. Today, your driver's license can be revoked based on your behavior while on the road. Punitive access restrictions on the network could mirror the same technique (for example, punishing people who propagate a virus by restricting their network access for a time) or could be used even if the infraction is not related to the network. Imagine a university that has trouble getting students to return overdue library books. Fines are one way to get the books back quickly, but if the student's parents are paying the bill, this consequence may not be as effective as the university desires.

However, imagine if the student's account record (in the PIP) had a directory attribute containing a count of the student's overdue library books. The network could then use RBAC or *Quality-of-Service* (QoS) techniques to provide degraded access to the student until the books were returned.

The Future of AAA

AAA as a concept has remained relatively unchanged since its inception. However, as this article has demonstrated, the techniques and applications of AAA continue to evolve. This section discusses some of the ways AAA may change more fundamentally in the future.

Security and Identity Convergence

Today the security and identity services provided by physical building access, network access, and application access are completely distinct. Security can be improved by communicating among these layers. Imagine a user executing a $10 million purchase order in a financial application. The chance of fraud would be reduced if the application could know that the user was coming from an authorized client with an up-to-date antivirus configuration. The chance of fraud could be further reduced by checking that the same user had accessed the badge access system of the building that day, and that the point of badge-access entry was consistent with the location where the application request originated. Within computer security, the notion of *defense-in-depth* has been around for a long time and is considered a best practice. Security and identity convergence adds new layers to this defense, and can potentially make all the layers more intelligent in their interaction.

User-Centric AAA

In the Web application world, the notion of user-centric identity is gaining ground. Kim Cameron's "Laws of Identity"[25] makes a compelling case that identity information housed in silos to be used by one organization is problematic. Several circles in the Web and e-commerce communities are beginning to look at identity differently. One change, consistent with the notion of user-centric identity, is that users should own their own identity information and should control how that information is used. The simplest example I can offer is shopping preferences at an online store. Most online stores make suggestions to you based on prior purchases. This data is owned by the online store, though, and not you, the consumer. If you wanted to take your purchasing profile from Amazon.com and transfer it to Barnes and Noble, it would not work. With user-centric identity, this kind of process is possible.

Another example is asserting a user's age. Depending on what you are trying to do on the Internet, you may need to validate that you are above a certain age. To do that, you are often asked to enter your date of birth, but that is more information than the site really needs.

If you could assert, with an identity you control but that is validated by a trusted party, that you are over the required age, it would not be necessary to disclose your date of birth (a process that is sometimes used as an authentication factor when you call places such as your credit card company).

The idea here is that you control your own information and limit what you need to share with others. This is very beneficial for privacy. One user-centric identity approach is included in Windows Vista through an application called "Card Space." Other approaches include OpenID and the Higgins Project. All of these approaches are somewhat consumer-focused, but if they take hold, it seems natural that there will be pressure for similar identity approaches in the enterprise and carrier space.

Federation

One of the natural evolutions of AAA infrastructure is to start federating access between multiple organizations. Imagine if visiting professors at another university's campus could access the network as guests using their password from their home location? Federation promises to make this possible, but the most challenging hurdles are political and logistical rather than technological. Protocols such as the *Security Assertion Markup Language* (SAML)[26] combined with RADIUS and LDAP can overcome this hurdle. The challenge is how to set up the trust relationships between the organizations to make it work. Eduroam based on RADIUS is an early effort delivering federation in Europe today.

Summary

This article, with its companion piece, has explored all aspects of AAA. Part One described the overall approach of AAA, how it works, and the elements that provide authentication, authorization, and accounting. Part Two has explored all the protocols used in the communication between the various AAA elements, the applications of AAA, and some thoughts about the future of AAA. AAA is a giant topic, and each of these sections, protocol descriptions, and applications could be expanded into a paper all by itself. The information in this article, combined with the references provided, should be a good starting point for your own examination of the specific aspects of AAA that are of interest to you.

IPv6 Network Mobility

by Carlos J. Bernardos, Ignacio Soto, and María Calderón, Universidad Carlos III de Madrid

The *Internet Protocol* (IP) is currently accelerating the integration of voice and data communications. The Mobile IP protocol enables host mobility support, but several scenarios exist today, such as the provision of Internet access from mobile platforms (for example, planes, trains, cars, etc.), making it necessary to also support the mobility of complete networks. In response to this demand, the *Internet Engineering Task Force* (IETF) has developed the *Network Mobility* (NEMO) *Basic Support Protocol*[1], enabling IPv6 network mobility.

This article explains the Network Mobility Basic Support Protocol, by first providing a general overview and then examining the details.

Why Network Mobility?

Accelerated by the success of cellular technologies, mobility has changed the way people communicate. As Internet access becomes more and more ubiquitous, demands for mobility are not restricted to single terminals anymore. It is also needed to support the movement of a complete network that changes its point of attachment to the fixed infrastructure, maintaining the sessions of every device of the network: what is known as *network mobility* in IP networks. In this scenario, the mobile network has at least a (mobile) router that connects to the fixed infrastructure, and the devices of the mobile network connect to the exterior through this mobile router.

Support of the roaming of networks that move as a whole is required in order to enable the transparent provision of Internet access in mobile platforms, such as the following:

- *Public transportation systems:* These systems would let passengers in trains, planes, ships, etc. access the Internet from terminals onboard (for example, laptops, cellular phones, *Personal Digital Assistants* [PDAs], and so on) through a mobile router located at the transport vehicle that connects to the fixed infrastructure.
- *Personal networks:* Electronic devices carried by people, such as PDAs, photo cameras, etc. would connect through a cellular phone acting as the mobile router of the personal network.
- *Vehicular scenarios:* Future cars will benefit from having Internet connectivity, not only to enhance safety (for example, by using sensors that could control multiple aspects of the vehicle operation, interacting with the environment and communicating with the Internet), but also to provide personal communication, entertainment, and Internet-based services to passengers.

However, IP networks were not designed for mobile environments. In both IPv4[2] and IPv6[3, 4], IP addresses play two different roles. On the one hand, they are *locators* that specify, based on a routing system, how to reach the node that is using that address. The routing system keeps information about how to reach different sets of addresses that have a common network prefix. This address aggregation in the routing system satisfies scalability requirements. On the other hand, IP addresses are also part of the *endpoint identifiers* of a communication, and upper layers use the identifiers of the peers of a communication to identify them. For example, the *Transmission Control Protocol* (TCP), which is used to support most of the Internet applications, uses the IP address as part of the TCP connection identifier.

This dual role played by IP addresses imposes some restrictions on mobility, because when a terminal moves from one network (IP subnet) to another, we would like to *maintain* the IP address of the node that moves (associated to one of its network interfaces) in order not to change the identifier that upper layers are using in their ongoing sessions. However, we also would like to *change* the IP address to make it topologically correct in the new location of the terminal, allowing in this way the routing system to reach the terminal.

Protocols such as the *Dynamic Host Configuration Protocol* (DHCP)[5, 6] facilitated the portability of terminals by enabling the dynamic acquisition of IP configuration information without involving manual intervention. However, this automation is not enough to achieve real and transparent mobility because it requires the restarting of ongoing transport sessions after the point of attachment changes. The IETF has studied the problem of terminal mobility in IP networks for a long time, and IP-layer solutions exist for both IPv4 (Mobile IPv4[7, 8]) and IPv6 (Mobile IPv6[9]) that enable the movement of terminals without stopping their ongoing sessions.

If we focus on IPv6[3] networks, Mobile IPv6 does not support, as it is now defined, the movement of complete networks. One way of achieving the transparent mobility of all the nodes of a network moving together (for example, in a plane) could be enabling host mobility support in all of them, so they independently manage their mobility. However, this approach has the following drawbacks:

- Host mobility support (for example Mobile IP[7, 8, 9]) is required in *all* the nodes of the network. This support might not be possible, for example, because of the limited capacities of the nodes (such as in sensors or embedded devices) or because it is not possible to update the software in some older devices. By having a single entity (the mobile router) that manages the mobility of the complete network, nodes of the network do not require any special mobility software to benefit from the transparent mobility support provided by the (mobile) router.

- The signaling exchanged because of the roaming of the network is limited to a single node sending only one message (avoiding "storms" of signaling messages every time the network moves).
- Nodes of the network must be able to attach to the access technology available to connect to the Internet. This requirement might mean that all the nodes of the network should have *Universal Mobile Telecommunications Service* (UMTS) or WiMAX interfaces, for example. On the other hand, by putting this requirement on a single node (the mobile router), nodes of the network can gain access to the Internet through the mobile router, using cheaper and widely available access technologies (for example, *wireless LAN* [WLAN] or Bluetooth).

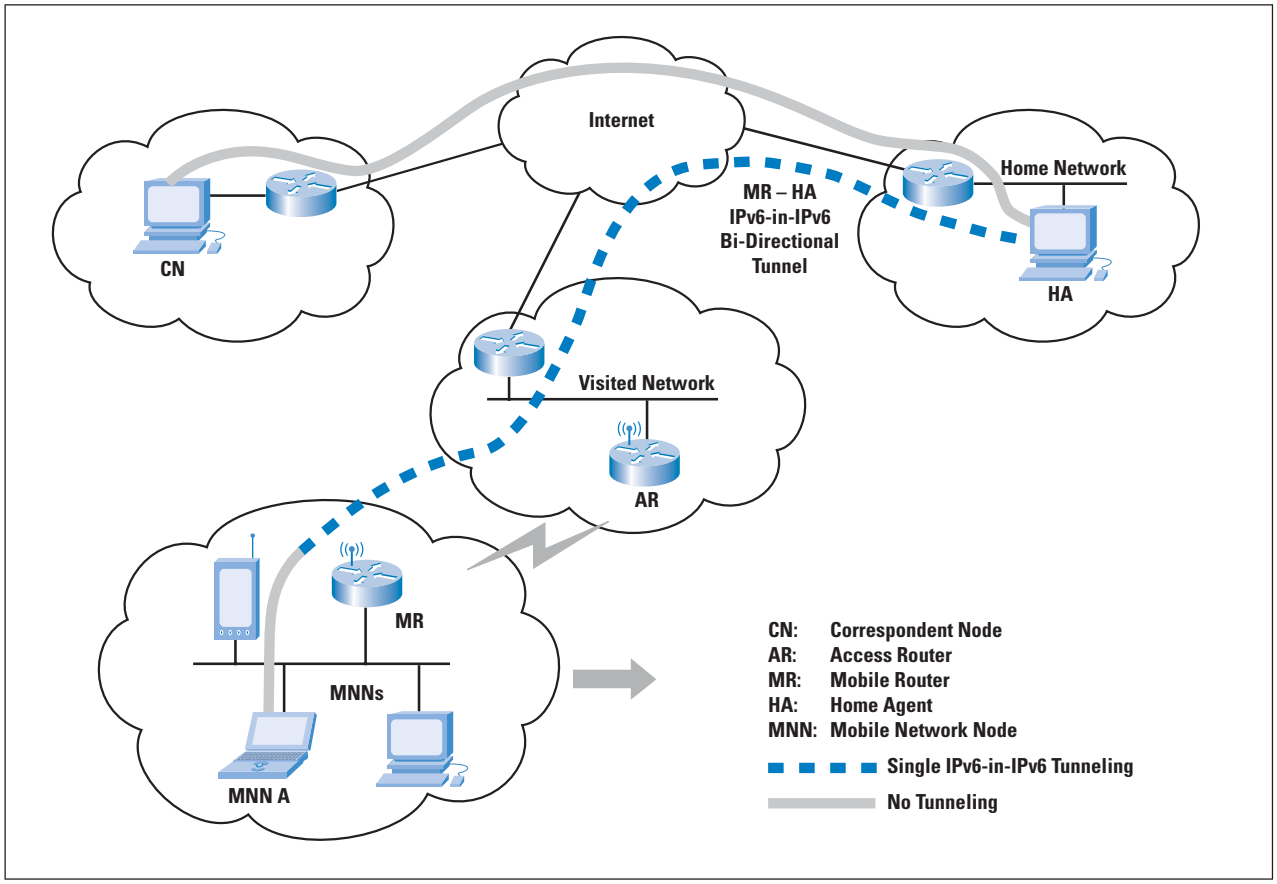
Because of these problems, the IETF *NEMO Working Group* was created to standardize a solution enabling network mobility at the IPv6 layer. The current solution, called the Network Mobility Basic Support Protocol, is defined in RFC 3963[1].

Operation of the NEMO Basic Support Protocol

A mobile network (known also as a "network that moves," or *NEMO*) is defined as a network whose attachment point to the Internet varies with time. Figure 1 depicts an example of a network-mobility scenario. The router within the NEMO that connects to the Internet is called the *Mobile Router* (MR). It is assumed that the NEMO is assigned to a particular network, known as its *Home Network,* where it resides when it is not moving. Because the NEMO is part of the home network, the mobile network has configured addresses belonging to one or more address blocks assigned to the home network: the *Mobile Network Prefixes* (MNPs). These addresses remain assigned to the NEMO when it is away from home. Of course, these addresses have topological meaning only when the NEMO is at home. When the NEMO is away from home, packets addressed to the nodes of the NEMO, known as *Mobile Network Nodes* (MNNs), are still routed to the home network. Additionally, when the NEMO is away from home, the mobile router acquires an address from the visited network, called the *Care-of Address* (CoA), where the routing architecture can deliver packets without additional mechanisms.

When any node located at the Internet, known as a *Correspondent Node* (CN), exchanges IP datagrams with a *Mobile Network Node* (MNN; A in Figure 1), the following operations are involved in the communication:

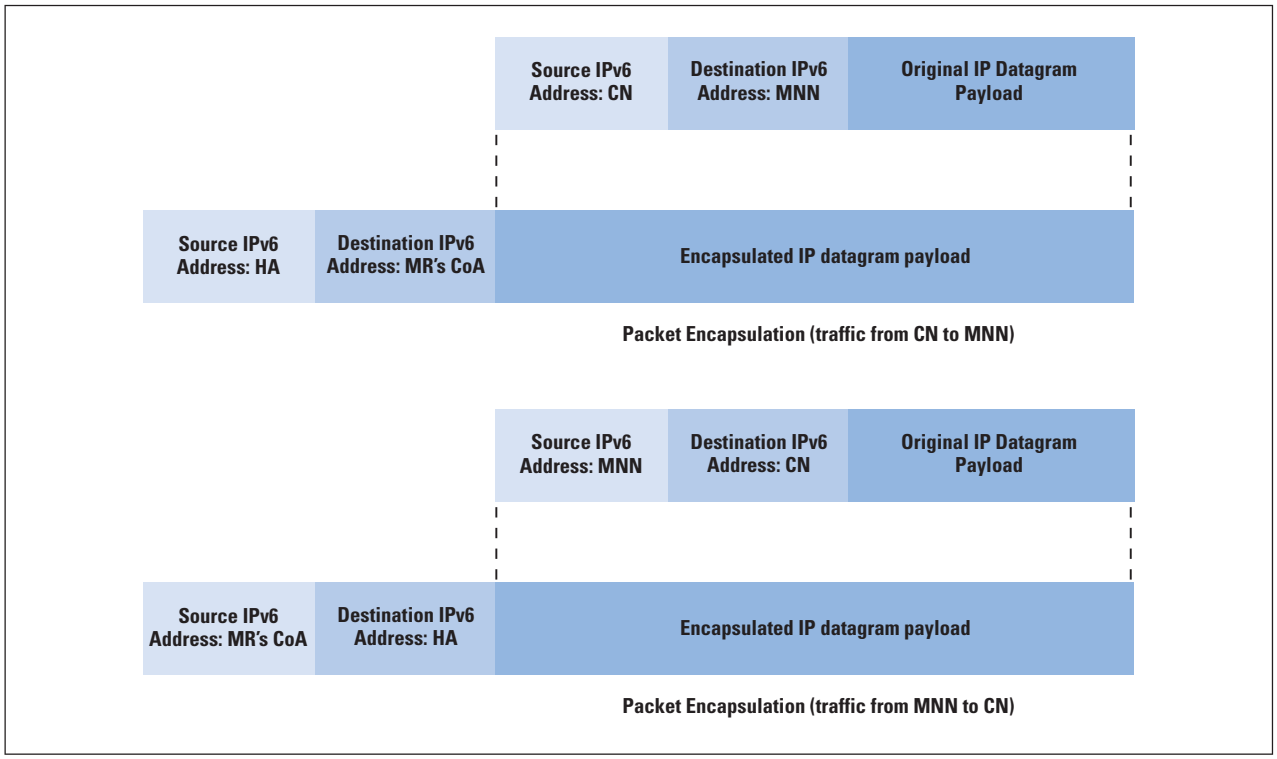
Figure 1: Example of NEMO Basic Support Protocol Operation



1. The correspondent node transmits an IP datagram destined for MNN A. This datagram carries as its destination address the IPv6 address of MNN A, which belongs to the MNP of the NEMO.
2. This IP datagram is routed to the home network of the NEMO, where it is encapsulated inside a new IP datagram by a special node located on the home network of the NEMO, called the *Home Agent* (HA). The new datagram is sent to the CoA of the mobile router, with the IP address of the home agent as source address. This encapsulation (as shown in Figure 2) preserves mobility transparency (that is, neither MNN A nor the correspondent node are aware of the mobility of the NEMO) while maintaining the established Internet connections of the MNN.
3. The mobile router receives the encapsulated IP datagram, removes the outer IPv6 header, and delivers the original datagram to MNN A.

4. In the opposite direction, the operation is analogous. The mobile router encapsulates the IP datagrams sent by MNN A toward its home agent, which then forwards the original datagram toward its destination (that is, the correspondent node). This encapsulation is required to avoid problems with ingress filtering, because many routers implement security policies that do not allow the forwarding of packets that have a source address that appears topologically incorrect.

Figure 2: Overview of NEMO Basic Support Protocol Encapsulation

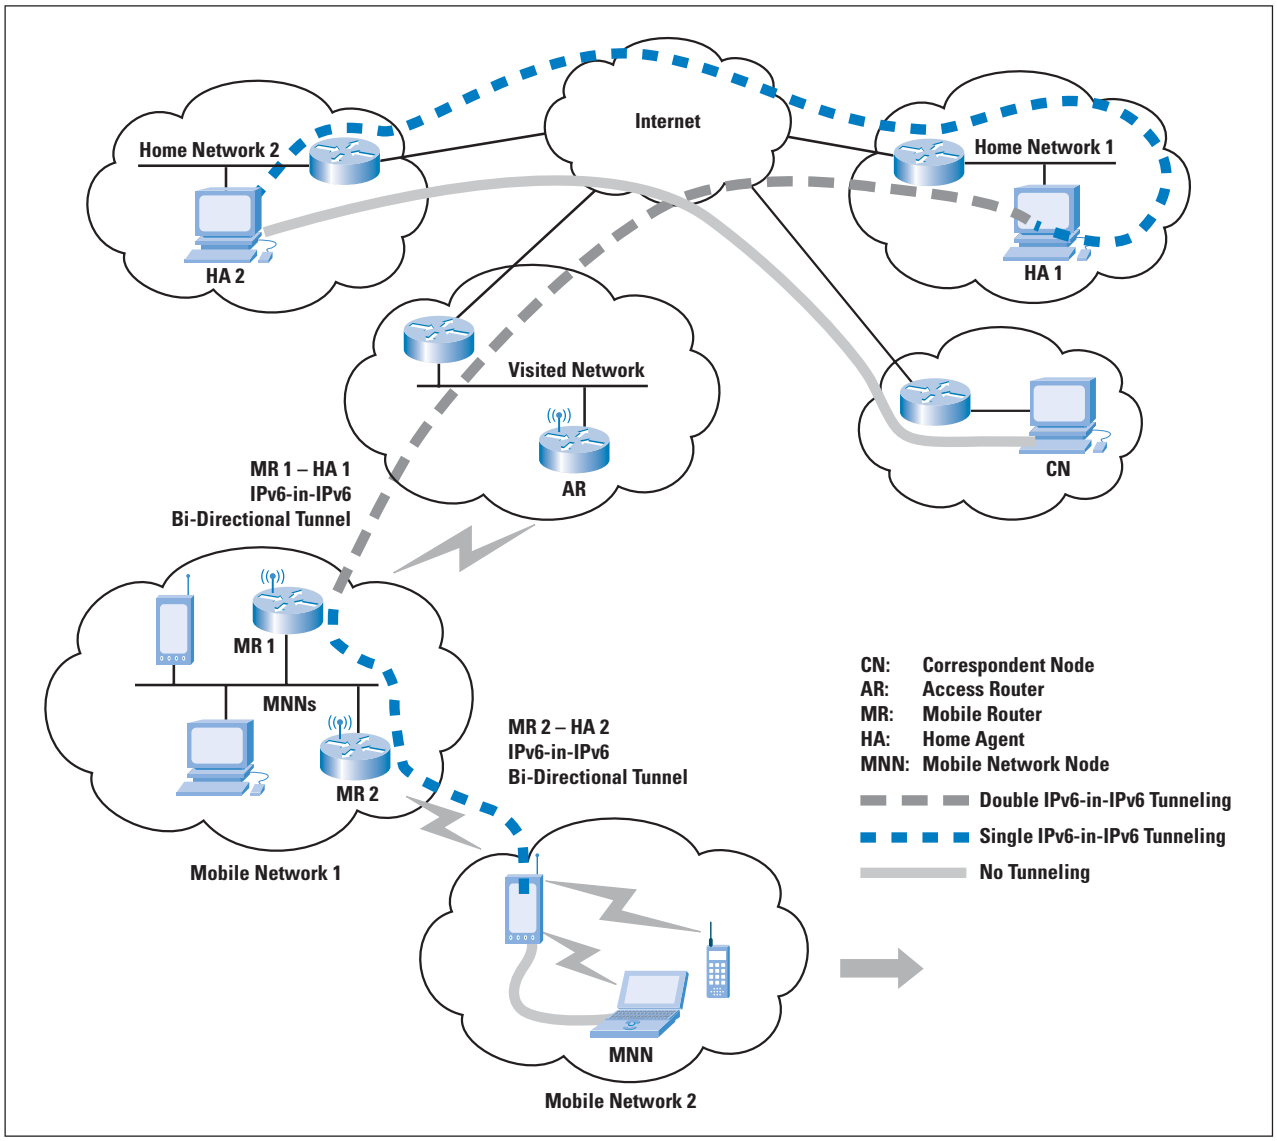


Following are different types of MNNs:

- *Local Fixed Node* (LFN): This node has no mobility-specific software and therefore cannot change its point of attachment while maintaining ongoing sessions. Its IPv6 address is taken from a MNP of the NEMO to which it is attached.
- *Local Mobile Node* (LMN): This node implements the Mobile IPv6 protocol; its home network is located in the mobile network. Its *home address* (HoA) is taken from an MNP.
- *Visiting Mobile Node* (VMN): This node implements the Mobile IP protocol (and therefore, it can change its point of attachment while maintaining ongoing sessions), has its home network outside the mobile network, and it is visiting the mobile network. A VMN that is temporarily attached to a mobile subnet (used as a foreign link) obtains an address on that subnet (that is, its CoA is taken from an MNP).

Additionally, mobile networks can be *nested*. A mobile network is said to be nested when it attaches to another mobile network and obtains connectivity through it (refer to Figure 3). An example is a user who enters a vehicle with his personal area network (mobile network 2) and connects, through a mobile router—like a Wi-Fi enabled PDA—to the network of the car (mobile network 1), which is connected to the fixed infrastructure.

Figure 3: Nested Mobile Network: Operation of the NEMO Basic Support Protocol (multiangular routing)



Protocol Details: NEMO Versus Mobile IPv6

The NEMO Basic Support Protocol is an extension of the solution proposed for host mobility support, *Mobile IPv6* (MIPv6)[9].

In Mobile IPv6, three mechanisms support the mobility of a host: movement detection, location registration, and traffic tunneling. The NEMO Basic Support Protocol extends some of these mechanisms to support the movement of complete networks. These mechanisms are described next, with those parts that are different from the Mobile IPv6 protocol highlighted.

Movement Detection

In Mobile IPv6, the host needs to discover its own movement, so it can proceed with the required signaling and operations that allow its transparent mobility. Mobile IPv6 defines a generic movement-detection mechanism based on the *Neighbor Discovery Protocol*[10], which basically consists of listening to *Router Advertisements* (RAs). Routers send these router-advertisement messages, both periodically and in response to a *Router Solicitation* message issued by a host. By looking at the information contained in the router advertisements, a host can determine whether or not it has moved to a new link.

The NEMO Basic Support Protocol does not introduce any change on the movement-detection mechanisms that a mobile router can use.

Location Registration

When a host moves to a new network, it has to configure a new IPv6 address on the visited link (belonging to the IPv6 address space of that visited network): the CoA, and inform the home agent of the movement. In Mobile IPv6, the mobile node (that is, a mobile host) informs its home agent of its current CoA using a mobility message called the *Binding Update* (BU). This message is carried in an IPv6 datagram using a special extension header defined by Mobile IPv6 to encapsulate all messaging related to the creation and management of mobility bindings, called the *mobility header.* The binding-update message contains information required by the home agent to create a mobility binding, such as the home address of the *Mobile Node* (MN) and its CoA, where the home agent should encapsulate all the traffic destined to the mobile node. The home agent replies to the mobile node by returning a *Binding Acknowledgement* (BA) message.

The NEMO Basic Support Protocol extends the binding-update message to convey the following additional information:

- *Mobile Router Flag* (R): The mobile router flag is set to indicate to the home agent that the binding update is from a mobile router. A mobile router can behave as a mobile host: by setting this flag to 0, the home agent does not forward packets destined for the mobile network to the mobile router, but forwards only those packets destined to the home address of the mobile router.

- *Mobile Network Prefix Option:* This option is in the binding update to indicate the prefix information for the mobile network to the home agent. There could be multiple mobile network prefix options if the mobile router has more than one IPv6 prefix in the mobile network and wants the home agent to forward packets for each of these prefixes to the current location of the mobile router.

When the NEMO Basic Support Protocol is used to provide mobility to a complete network, only one binding-update or binding-acknowledgement signaling messages exchange is performed, whereas if the Mobile IP protocol were used by all the nodes of an *N*-node network, *N* × (Binding-update or Binding-acknowledgement) signaling messages synchronized exchanges would be required—usually referred to as a "binding-update signaling storm."

Mobile IPv6 defines a route-optimization mechanism that enables direct path communication between the mobile node and a correspondent node (avoiding traversal of the home agent). This route optimization is achieved by allowing the mobile node to send binding-update messages also to the correspondent nodes. In this way the correspondent node is also aware of the CoA, where the home address of the mobile node is currently reachable. A special mechanism—called the *Return Routability* (RR) procedure—is defined to prove that the mobile node has been assigned (that is, "owns") both the home address and the CoA at a particular moment in time[11], and therefore provides the correspondent node with some security guarantees.

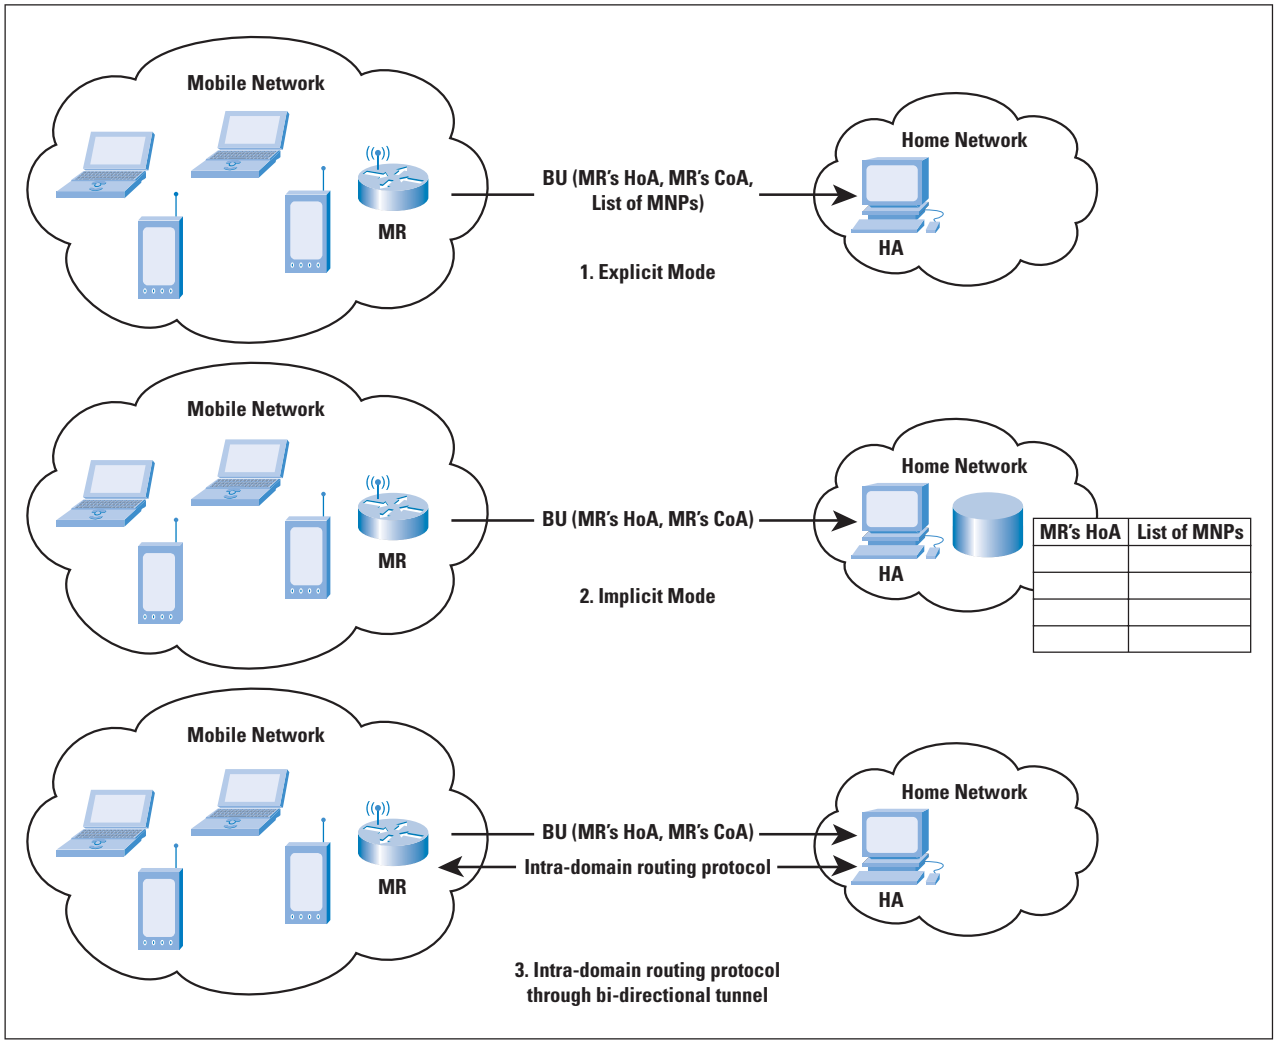
Because of the nature of the network-mobility scenario, the task of providing mobile networks with route-optimization support becomes more complex. The IETF is currently working on this topic[12, 13, 14].

Traffic Tunneling

In Mobile IPv6, after the mobile node has successfully registered its current location, the home agent starts encapsulating the data traffic destined to the mobile node toward its CoA.

In a NEMO scenario, the home agent forwards not only those IP datagrams arriving at the home network that are destined to the home address of the mobile router, but also all the traffic addressed to any of the mobile-network prefixes managed by the mobile router. The home agent can determine which prefixes belong to the mobile router in three different ways (refer to Figure 4):

Figure 4: NEMO Basic Support Modes of Operation



- *Explicit mode:* The mobile router includes one or more mobile network prefix options in the binding-update message that it sends to the home agent. These options contain information about the mobile-network prefix(es) configured on the mobile network.
- *Implicit mode:* The mobile router does not include prefix information in the binding-update message it sends to the home agent. The home agent determines the mobile-network prefix(es) owned by the mobile router by using any other mechanism (the NEMO Basic Support Protocol does not define any, leaving this prefix determination open to be implementation-specific).

  One example would be manual configuration at the home agent mapping the home address of the mobile router to the information required for setting up forwarding for the mobile network.

- *Intradomain Dynamic Routing Protocol through the bidirectional tunnel:* Alternatively to the previous two modes of operation, the home agent and the mobile router can run an intradomain routing protocol (for example, *Routing Information Protocol next generation* [RIPng] or *Open Shortest Path First* [OSPF]) through the bidirectional tunnel. The mobile router can continue running the same routing protocol that it ran when attached to the home link.

Fragmentation may be needed to forward packets through the tunnel between the mobile router and the home agent. In this case, the other end of the tunnel (the home agent of the mobile router) must reassemble the packet before forwarding it to the final destination. This requirement does not contradict the fact that *intermediate* IPv6 routers do not fragment (as opposed to IPv4), because the mobile router and home agent are the actual *ends* of the tunnel.

Performance of the NEMO Basic Support Protocol

The NEMO Basic Support Protocol relies on the creation of a bidirectional tunnel between the mobile router and the home agent to provide transparent mobility support to a complete network. The use of this tunnel causes an additional overhead of 40 bytes per packet, because of the extra IPv6 header added by the encapsulation. The effect of this overhead might be relevant for applications that generate small packets, such as *voice-over-IP* (VoIP) packets, because the 40-byte added overhead may be even bigger than the actual VoIP payload.

The end of the bidirectional tunnel at the side of the mobile router needs to be updated each time the mobile network moves (and also periodically to refresh the binding at the home agent), to reflect the current location of the mobile router. This updating is achieved by the binding-update or binding-acknowledgement signaling exchange between the mobile router and the home agent. As stated previously, only one exchange (two packets, one in each direction) is required per movement, regardless of the number of MNNs that are attached to the mobile router—one of the main advantages of using the NEMO Basic Support Protocol on the mobile router instead of Mobile IPv6 on every node of the mobile network, because the signaling generated by a complete moving network (composed of numerous nodes) is the same as the one generated by a single moving node.

Conclusions

The NEMO Basic Support Protocol[1] extends the functions of Mobile IPv6 to support the mobility of complete networks. The current specification supports basic mobility, and the IETF is currently working on new enhancements and extensions to provide route-optimization support, multihoming capabilities, and IPv4 support.

Some implementations of the NEMO Basic Support Protocol are already available. For example, the latest Cisco IOS® Software releases provide network mobility support. Open-source implementations also exist, such as the *NEMO Platform for Linux* (NEPL) (**http://www.mobile-ipv6.org/**) and SHISA (**http://www.mobileip.jp/**), for Linux and *Berkeley Software Distribution* (BSD) operating systems, respectively.

More ROAP: Routing and Addressing at IETF68

by Geoff Huston, APNIC

Over the past year or so we have seen a heightened level of interest in Internet routing and addressing. Speculation regarding the future role of the Internet raises the possibility of the Internet supporting as many as hundreds of billions of chattering devices. What does such a future imply in terms of the core technologies of the Internet? Consideration of this topic has prompted a critical examination of the architecture of the Internet, including the scaling properties of routing systems, the forms of interdependence between addressing plans and routing, and the roles of addresses within the architecture.

The March 2007 meeting of the IETF, IETF68, saw some further steps in analysing these topics, and many sessions addressed aspects of routing and addressing. This article reports on these sessions, and includes some conjecture as to what lies ahead.

Plenary ROAP – The Plenary Session on Routing and Addressing

The plenary session presented an overview of the topic, looking at the previous initiatives in routing and addressing, as well as providing some perspectives on the current status of work in this area. There are concerns that the technology platform cannot scale by further orders of magnitude without some changes. Also of concern are the scalability of routing, the "transparency" of the network, renumbering questions, provider-based addressing, and service and traffic engineering and routing capabilities—and these concerns are potentially even more relevant and challenging for tomorrow's Internet.

Our routing technology does not localize the external effects of local configuration choices. Far from being a protocol that damps instability, the *Border Gateway Protocol* (BGP) is a highly effective amplifier of noise components of routing events. So although it is a remarkably useful information-dissemination protocol, the properties of BGP in an ever-more connected world with ever-finer granularity of information raise some questions about its scaling properties. Will the imposed "noise" of the behaviour of the protocol completely swamp the underlying information content? Will we need to deploy disproportionately larger routers to support a larger network? The prospect here is that routing may become far less efficient because as we simultaneously increase the degree of interconnection and the information load, the inability to effectively localize information creates a far greater load on network routing.

In addition to these observations about routing, there is the continuing suspicion that the semantic load of addresses in the Internet architecture, where an address simultaneously conveys the concepts of "who," "where," and "how," contributes to routing load.

To what extent the semantic intent of endpoint identity (or "id") can be separated from the semantic intent of network location and forwarding lookup token (or "loc") is a question of considerable interest. Although the current IP address semantics removes the need to support an explicit mapping operation between identity and location, the cost lies in the inability to support an address plan that is cleanly aligned to network topology, and the inability to cleanly support functions associated with device or network mobility. In the end it is the routing system that carries the consequent load. The questions in this area include an evaluation of the extent to which identity can be separated from location, and the effect of such a measure on the operation of applications. How much of today's Internet architecture would be affected by such a change, and what would be the resultant benefits if this measure were deployed? Are we necessarily looking at a single model of such an id/loc split, or should we think about this scenario in a more general manner with numerous potential id/loc splits?

Obviously this study of routing and addressing, and the related aspects of name space attributes and mapping and binding properties, has a very broad scope. The larger question posed here is whether we can defer resolution of this problem to a comfortably distant future, or whether its effect on the present network is imminent. Are we accelerating toward some form of near-term technical limit that will cause a significant disruptive event within the deployed Internet, and will volume-based networks economics hold or will bigger networks start to experience disproportionate cost bloat—or worse? Is it time to be alarmed?

The unallocated IPv4 address pool will certainly be exhausted in the coming years, but this sense of alarm over routing and addressing is more about whether there are real limits in the near future in the capability to continue to route the Internet within the deployed platform, using the current technologies, and working within current cost-performance relationships irrespective of whether the addresses in the packet headers are 32 or 128 bits in size. There was a strong sense of "Don't panic!" in the plenary presentation, with the relatively confident expectation that BGP will be able to carry the routing load of the Internet over the next 3 to 5 years without the need for major protocol "surgery," and that Moore's Law will continue to ensure that the capacity and speed of hardware will track the anticipated growth rates. Expectations are that the current technologies and cost-performance parameters will continue to prevail in this time frame.

The *Internet Engineering Steering Group* (IESG) has followed the *Internet Architecture Board's* (IAB's) initiative and has begun working with a focus group, the *Routing and Addressing Problem Directorate* (ROAP), to refine the broad space into many more specific work areas, and has assumed a role of coordination and communication across the related IETF activities.

In addition, because a relatively significant research agenda is posed by such long-term questions, the *Routing Research Group* of the *Internet Research Task Force* (IRTF) has been rechartered and, judging by the participation at its most recent meeting, effectively reinvigorated to investigate various approaches to routing that take us well beyond tweaking the existing routing toolset.

Internet ROAP – The Internet Area Meeting

The Internet Area meeting concentrated on aspects of this approach of supporting an identifier/locator split within the architecture of the Internet, and gathering some understanding as to whether this approach would assist with routing scaling. One of the important considerations in this area is working through what could be called boundary conditions of the study. For example, is this matter purely one for protocol stacks within an endpoint, or should distributed approaches that have active elements within the network also be considered? To what extent should a study consider mobility, traffic engineering, *Network Address Translation* (NAT), and *Maximum Transmission Unit* (MTU) behaviour? What appears to be clear at the outset is that this network is not a "clean-slate" network, and any approach should be deployable on the existing infrastructure, should use capability negotiation to trigger behaviours so that deployment can be incremental and piecemeal, should allow existing applications and their identity referential models to operate with no changes, and, hopefully, should have a direct benefit to those parties who decide to deploy the technology.

From the routing perspective, the overall desire is to reduce the growth rates of the interdomain routing space. The desired intent is to reduce the amount of information associated with locators so that locators reflect primarily network topology in such a way that the locators can be efficiently aggregated within the routing system that attempts to maintain a highly stable view of the network topology.

More detailed consideration of the implications of disambiguating aspects of identity from those of network location involves many dimensions—including the structure of the spaces—the mapping functions, and the practicalities of any form of deployment of such a technology.

A critical topic appears to be how an identity-mapping function relates to the forwarding-mapping function. Assuming that the existing name spaces remain unaltered, then the resultant framework appears to require distinct "name-to-identifier" and "identifier-to-locator" mappings and a "locator-to-forwarding" mapping. Where these mapping functions should be performed, who should perform them, when they should be performed, the duration of the validity of the outcomes, whether the mapping function outcomes are relative or universal, the scope and level of granularity in time and space of the map elements, the security of these mapping functions, and whether there is a simple operation in each mapping function or multiple operations all remain undefined at this point.

Other questions include whether the mapping is explicit or implicit, what evidence of a previous mapping operation is held in a packet in a visible manner, and what is occluded from further inspection after the mapping operation has been performed. In addition, what level of state is required in each host, and is there true end-to-end transparency—at what level?

It is likely, at least at this stage of the study, that such a split can have a variety of approaches, both in the intended roles of identifier and location tokens and in their binding. The expectation at this stage of the study is that further ideas will surface, and such ideas will be helpful rather than distracting. It is unclear if a single solution can emerge from this activity, or whether different actors have a sufficiently different set of relative priorities that multiple approaches—each of which expresses different prioritization of functions—are viable longer-term outcomes.

The critical consideration here is that it is unlikely that scaling routing over the longer term to a much larger network is simply a matter of just changing the operation of the routing system itself. Real improvement in this area appears to also require an understanding of the meaning of the objects, or "addresses," that are being passed within the routing system. The motivation for opening up the identifier or locator space within the Internet area appears to be strongly tied to the notion that if you can unburden some of the roles of the addresses used in routing, and treat these routed tokens as unadorned network locality tokens, then you can gain some additional capability in routing.

Routing ROAP – The Routing Area Meeting

The first part of the Routing ROAP session looked at the trends in the routing system over 2005 and 2006. The overall trend appears to be a system that is increasingly densely interconnected, carrying more information elements, each of which expresses finer levels of granularity in reachability. There appears to be two forms of dynamic BGP load: the BGP "supernova" that burst with an intense BGP update load over some weeks and then disappear, and "background radiation" generators that appear to be unstable at a steady update rate for months or even the entire year.

In looking at scaling the BGP routing environment, one response is that of behavioural changes in local instances of BGP that reduce the potential for unnecessary updates to be propagated beyond a "need-to-know-now" radius. Another response is to consider changes to BGP in terms of additional attributes to BGP updates—such as a "withdrawal-at-origin" flag, or selective advertisement of "next best path"—both of which are intended to limit the span of advertised intermediate transitions while the BGP distance vector algorithm converges to a stable state.

It appears that we could improve our understanding of the operational profile of the routing space, looking particularly at the various forms of pathological routing behaviours and comparing these behaviours against the observations of known control points. Such a study may also lead to some more effective models of projections of the size of the routing space in the near- and medium-term future, and allow some level of quantification as to what "scaling of the routing space" actually implies.

The second part of the Routing ROAP session considered the current status of the routing world, updating some of the observations made at the IAB Routing Workshop and outlining some further perspectives on this space. One critical perspective on BGP is the behaviour of BGP under load. It was noted that most BGP implementations use adaptive responses to peer load, so that BGP attempts to ensure that its peer receives only the most current state information when the peer signals that it is not keeping pace with the update rate.

Another critical factor is the nature of "convergence" in BGP. The claim was made that this problem was the biggest, yet least important, problem with BGP. Convergence delays can be mitigated by *Graceful Restart, Nonstop Routing,* and *Fast Reroute*. One of the measures that exacerbates convergence is the use of *Route Reflectors*. The model of information hiding or Route Reflectors is intended to reduce the number of BGP peer sessions and the update load, but the benefits they do achieve are at the cost of slower convergence with a higher message rate during the intermediate-state transitions. Perhaps it is appropriate to consider small-scale changes to BGP behaviour to mitigate the transient BGP update bursts caused by path hunting, including those already mentioned of "withdrawal-at-origin" notification and propagation of backup paths.

The approach advocated here is based on the perspective that BGP is not in danger of imminent collapse, and there is still considerable "headroom" for BGP operation in today's Internet.

More ROAP?

The routing space is a classic example of the commons, where each party can use routing to solve a multitude of business problems. This includes, for example, using routing to perform load balancing of traffic over a set of transit providers, using a "spot market" in Internet transit services, creating differentiated transit offerings using more specific routes and selective advertisements. The ultimate cost of these local efforts in optimising local business outcomes lies in the increasing bloat in the routing system and the consequent escalation in costs across the entire network in supporting the routing system. There is no way to impose administrative controls on the global routing system, nor have we been able to devise an economic model of routing where the incremental costs of local routing decisions are visible to the originator as true economic costs for the business, and the benefit of a conservative and prudent use of the routing system reaps economic dividends in terms of relatively lower costs for the business.

Like the commons, there are no effective feedback mechanisms to impose constraint on actors in the routing space. Also, like the commons, there is the distinct risk that the cumulative effect of local actions in routing creates a situation that pushes the routing system, either as a whole or in various locales, into a nonfunctioning state.

Whether it needs a sense of urgency to motivate the work, or a sense that there can and should be a better way to plan a future than crude crisis management, the underlying observation is that the routing and address world is fundamental to tomorrow's Internet. Unless we make a concerted effort to understand the various interdependencies and feedback systems that exist in the current environment, and understand the interdependences that exist between network behaviours and routing and addressing models, then I'm afraid that the true potential of the Internet will always lie within our vision—but frustratingly just beyond our grasp.

Opinion: Is It Time to Replace SMTP?

by Dave Crocker, Brandenburg InternetWorking

The first Internet (ARPANET) e-mail, sent 35 years ago, was remarkably similar to a basic text e-mail of today: From, To, CC, Subject, Date, followed by lines of text, and the familiar @-sign in addresses. The right side of the address changed from a simple string into the multilevel domain name that we now use. The body can now be a set of multimedia attachments rather than just lines of text, but it can still be in its original, simpler form. The means of moving mail was the *File Transfer Protocol* (FTP) in the early 1970s. The current mechanism, the *Simple Mail Transfer Protocol* (SMTP)[1a, 1b], was not created until 10 years later, but a mere 25 years of use is not bad, either.

All of the technical specifications for e-mail have undergone many changes over the years, but a core requirement has been to protect the installed base of users and operators by incrementally adding features as options, rather than by performing wholesale replacement of any infrastructure service component. E-mail has changed the way we communicate, yet it is also now viewed as having a serious problem: As the Internet grew, it acquired the full mixture of participants, some of whom do not make nice neighbors.

Frustration with the effect of abusive users is often expressed as a belief that the solution lies in replacing some or all of the core technology of the e-mail service, or even by moving to an entirely different paradigm, such as querying Webpages using *Really Simple Syndication* (RSS)[2]. Although different paradigms make sense for some forms of human communications, what is forgotten in these pleas for massive change is the power of the classic mail model, whether by paper or by electrons: Spontaneous or occasional communication requires the ability to "push" the message to the recipient, without prior arrangement. This ability is, of course, also what leaves the door open for abuse—anyone may walk in, uninvited and unwanted.

The alternative proposals might work well enough for ongoing, regular communication among people who already know each other. And for most of us, that is probably 80 percent of our exchanges, or more. Unfortunately, as soon as anyone starts worrying about the remaining 20 percent, these alternative approaches require cascading hacks, producing a design that looks no better that what we have today, except that it based strictly on theory rather than decades of practice. It is easy for a paper proposal to beat a deployed system; making it work as promised is, of course, more difficult.

Mantra

I have developed a simple mantra, in response to calls for replacing today's Internet mail:

0. The basic problems we are experiencing with e-mail are really based on undesirable social behaviors, long popular outside the Internet. The Internet enables broader reach, to more victims, and in much shorter time spans, but the core misbehaviors have existed for all of recorded human history. We should not assume that there are technical solutions to social problems.
1. The beginning of changing a human service is to gain community consensus about the change that is needed, because a mechanism will not be successful unless it is perceived as needed. Only then can the engineers work on designing the change.
2. When there is community consensus about the way that e-mail needs to be changed, the folks who are currently contributing to its 35-year evolution need to try to find a way to add the desired features to the existing service. Given the record of accomplishment of e-mail, the odds seem favorable that any new requirement can also be satisfied without disrupting the installed base.
3. When that effort fails, it will be time to create a replacement infrastructure.

Alas, as those who track e-mail abuse technical discussions are well aware, we have not completed Step 1. As soon as we try to formulate community consensus about basic messaging communication policies, discussion devolves into cacophony or marginalized community fragments. It is certain that there will eventually be a change required for e-mail, which we cannot fit into the current service, but we do not yet have any evidence that e-mail abuse is going to produce that requirement.

Trust Models

One hopeful sign is that we do have a solid set of efforts to evolve e-mail to support mechanisms that are based on trust. This evolution begins with the ability to associate a validated identity to a message and then requires assessing the "safety" of that identity's owner. Until recently, only the IP address of the last-hop sending SMTP server could be used as an identifier. Using addresses as identifiers sounds reasonable at first glance, but turns out to have long-term scaling and administrative problems. As a result, there has been a broad effort to find ways to use domain names, which are more stable, and they align better with organizational boundaries. This process is well under way, with the recent IETF standardization of the *Domain Keys Identified Mail* (DKIM)[3] message-signing specification, as well as path-based registration schemes, such as Sender-ID[4] and SPF[5].

That took about 5 years. And now comes the hard part: developing a range of *assessment mechanisms*—sometimes generically called *reputation services*—that satisfy requirements for quality, strength, convenience, and stability. Assessment services tell recipients whether the author of the message, or the service that sent it, can be trusted. Some mechanisms need to work for small groups, others need to work for mass-market business-to-consumer mailings, and others need to work among business partners. A few startup companies have recently joined the few, surviving volunteer services, to satisfy this need. It is too early to tell whether they will suffice, or whether additional services will be needed. What is important is that these services are generally regarded as producing good results.

For the long term it seems likely that this capability will result in an Internet mail service that is logically split into two types of traffic. One has substantial trust associated with its messages, so that they can be delivered with a reasonable degree of comfort. The other is the current, open-to-all service that requires heavy filtering and the use of various heuristics, to reduce the effect of abuse mail. If the first traffic flow is sufficiently successful, filters for the second can become much more stringent. The aggregate effects of these changes will be that wanted mail is likely to be received and identified much more reliably, and unwanted mail is more likely to be rejected.[8, 9]

So the current Internet mail technical infrastructure is safe, right? Well, maybe.

Enhancements?

What gets less attention, but perhaps should worry us more, is the general lack of user-level functional enhancement for e-mail. What users can do with e-mail, today, is pretty much the same as they could do 25 years ago. The evolution of Internet mail has been primarily in support of performance, reliability, and scaling. Although important, they have not produced functional changes that are apparent to end users. Human communication is a very rich space, yet most e-mail is limited to a narrow range of styles: person-to-person informal communications, and informal, unstructured group communications. Toss in some very basic, one-way "transactional" mail, such as order confirmations from businesses to their customers, and that about covers it.

Instead, new functions for human collaboration have tended to appear in new services. *Instant Messaging* (IM), blogging, and wikis are the most popular examples. In each case, they rely on a centralized service, rather than the highly distributed model that e-mail uses. Users must all go to a single, centralized address to obtain a given service. Most of the IM world does not even know that there are two (!) Internet standards for distributed IM—*Extensible Messaging and Presence Protocol* (XMPP)[6] and SIMPLE[7]. Even for these standards, most of their production use tends to be within noninteroperable, centralized services.

Is there something about e-mail that is a barrier to functional enhancements for end users?

For these new services, the interservice relaying that is at the core of e-mail is absent. Indeed, centralized services are easier to create and operate than are distributed services, but they also carry scaling, administration, and control challenges. So the issue is not so much what is easier, but who will do the work—and when? With a centralized service, all the interesting work is done by the single provider. For a distributed model, like e-mail, the work is shared across participating organizations. The Internet was designed to avoid single points of failure (and failure), so it is ironic that these new services risk exactly these problems.

For a distributed model, like e-mail, to add end-user functions, useful adoption is required by all user software that participates, and possibly by all the intermediate, relaying services. The adoption is in three parts: agreeing on the enhancement, modifying existing software, and making it available to users. These are daunting barriers, so the appeal of centralized services is clear: a single organization decides what to change, changes it, and makes it available to end users with, at most, a natural software upgrade.

Interorganization partnerships provide the best argument for adoption of distributed services, because they do not naturally permit agreement on a central point of control. The counterforce is, again, the simplification (for the partners) that comes from agreeing to use independent third-party services. The scaling problem here is with end users having to juggle a large number of independent services. Note the emergence of IM clients that support a variety of independent IM services.

Perhaps the real danger to e-mail is not its wholesale and traumatic replacement, stemming from frustration about abuses, but a gradual attrition, as portions of its traffic move to services that evolve more quickly, but leave end users with a complicated array of narrow, specialized, and noninteroperable venues.

ARIN Board Advises Internet Community on Migration to IPv6

The *American Registry for Internet Numbers* (ARIN) and the other *Regional Internet Registries* (RIRs) have distributed Internet Protocol version 6, IPv6, alongside IPv4 since 1999. To date, ARIN has issued both protocol versions in tandem and has not advocated one over the other. ARIN has closely monitored trends in demand and distribution for both protocol versions with the understanding that the IPv4 available resource pool would continue to diminish.

The available IPv4 resource pool has now been reduced to the point that ARIN is compelled to advise the Internet community that migration to IPv6 is necessary for any applications that require ongoing availability from ARIN of contiguous IP number resources. On 7 May 2007, the ARIN Board of Trustees passed the following resolution:

"Whereas, community access to *Internet Protocol* (IP) numbering resources has proved essential to the successful growth of the Internet; and,

Whereas, ongoing community access to *Internet Protocol version 4* (IPv4) numbering resources can not be assured indefinitely; and,

Whereas, *Internet Protocol version 6* (IPv6) numbering resources are available and suitable for many Internet applications,

Be it Resolved, that this Board of Trustees hereby advises the Internet community that migration to IPv6 numbering resources is necessary for any applications which require ongoing availability from ARIN of contiguous IP numbering resources; and,

Be it Ordered, that this Board of Trustees hereby directs ARIN staff to take any and all measures necessary to assure veracity of applications to ARIN for IPv4 numbering resources; and,

Be it Resolved, that this Board of Trustees hereby requests the ARIN Advisory Council to consider Internet Numbering Resource Policy changes advisable to encourage migration to IPv6 numbering resources where possible."

Implementation of this resolution will include both internal and external components. Internally, ARIN will review its resource request procedures and continue to provide policy experience reports to the Advisory Council. Externally, ARIN will send progress announcements to the ARIN community as well as the wider technical audience, government agencies, and media outlets. ARIN will produce new documentation, from basic introductory fact sheets to FAQs on how this resolution will affect users in the region. ARIN will focus on IPv6 in many of its general outreach activities, such as speaking engagements, trade shows, and technical community meetings. For more information, visit ARIN's IPv6 Information Center at:

From The Editor

For the last 10 or so years I have been involved with the organization of APRICOT, the *Asia Pacific Regional Internet Conference on Operational Technologies*. APRICOT has at its core a set of workshops featuring expert instructors with years of operational network experience. A recent addition to the APRICOT workshop program is a course focusing on Internet security in a multivendor environment. Our first article, written by Kunjal Trivedi from Cisco Systems, Inc., and Damien Holloway from Juniper Networks, is based on this workshop. It's not every day that you see an article co-authored by instructors from competing companies, but this is exactly the type of cooperation that is needed in order to deploy security in a multivendor network.

The rest of this issue is mostly devoted to IPv4 depletion and the transition to IPv6. The first article, by Geoff Huston, summarizes many of the concerns related to IPv4 depletion and IPv6 transition, and gives numerous pointers to further articles and documents of interest. Our second addressing-related article, by Iljitsch van Beijnum, looks more closely at the numbers relating to address allocation by the *Regional Internet Registries* (RIRs). The final article concerns some address blocks that are currently unassigned but actually in use. Leo Vegoda explains the potential problems that may arise when these blocks eventually become part of the RIR assignment pool.

We are pleased to announce a new online addition to this journal. *The Internet Protocol Forum* (IPF) available at **www.ipjforum.org** is designed to allow discussion of any article published in the printed edition of IPJ. In addition to article discussions, the forum will be used to provide updates and corrections, downloads, expanded versions of some articles, configuration and programming examples, and news and analysis that does not fall into our quarterly publication schedule. The IPF's editor and moderator is Geoff Huston, long-time contributor to this journal and chief scientist at APNIC. I am confident that IPF will become an important addition to IPJ, and I hope you will take the time to participate in the online discussions. Of course, you can always contact us at the usual e-mail address: **ipj@cisco.com**

A Standards-Based Approach for Offering a Managed Security Service in a Multivendor Network Environment

By Kunjal Trivedi, Cisco Systems and Damien Holloway, Juniper Networks

As transport becomes a commodity, service providers are seeking new revenue sources and new ways to differentiate themselves. Managed security services address a growing market because business customers are struggling to comply with regulatory requirements such as the *Payment Card Industry-Data Storage Standards* (PCI-DSS), the *Sarbanes-Oxley Act,* the *Gramm-Leach Bliley Act, Health Insurance Portability and Accountability Act* (HIPAA), *Directive 2002/58/EC,* and the *Asia-Pacific Economic Cooperation-Organization for Economic Cooperation and Development* (APEC-OECD) initiative on regulatory reform. Increasingly, business customers recognize that outsourcing network security is less costly than staffing with highly specialized security personnel who can provide 24-hour incident detection and response. Another incentive for outsourcing is to free existing IT resources to focus on the core business.

A standards-based approach helps service providers take best advantage of the managed security service opportunity because it increases the potential breadth and depth of the service offering. Multivendor solutions are becoming the norm when deploying services on an integrated backbone. Therefore, standards simplify deployment and management, helping control operational costs and accelerating time to market.

Service providers are experiencing a growing need for skilled engineers who understand multivendor environments—the motivation for conducting a multivendor security workshop at the 2006 *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT 2006)[15], held in Perth, Australia, in February 2006. During the workshop (which was repeated again at APRICOT 2007 in Bali), participants successfully deployed and tested a multivendor service environment using *IP Security* (IPsec)-based Layer 3 *Virtual Private Networks* (VPNs)[1, 2, 3] over a *Border Gateway Protocol/ Multiprotocol Label Switching* (BGP/MPLS) core[4].

Technical Challenges

To offer managed security services, service providers need the following:

- A secure network infrastructure, including tools and techniques for risk mitigation
- Technical solutions for the customer's business needs, such as VPNs based on BGP/MPLS, IPsec, or both

- Web-based reporting tools that business customers can use to monitor the security service in accordance with *Service-Level Agreements* (SLAs). Service providers can scale cost-effectively by offering customers a secure, Web-based portal that shows open trouble tickets, security incident-handling detail, SLAs, and access reports that customers need to comply with regulations.

An effective managed security service requires tools and techniques to address the following challenges:

- *More sophisticated threats, and less time between vulnerability and exploitation:* In addition to worms and viruses, the service provider needs to protect its own and its customers' networks against *Denial-of-Service* (DoS) attacks. Today's botnets can launch thousands or even a million bots that carry out outbound DoS attacks. New varieties of worms have side effects similar to those of DoS attacks. These threats can take down the service provider infrastructure, thereby violating SLAs and eroding revenue.
- *A need for proactive rather than reactive threat response:* Many service provider security groups are stuck in reactive mode. Every network device and security system produces voluminous event logs every day, and vendors use different formats. Therefore, identifying security incidents in order to react to them can take hours or days—or not happen at all. The connection between two separate events in different parts of the network can easily escape human detection, especially when the clues are buried among tens of thousands of harmless events that took place around the same time.
- *Multivendor networks:* Network security and reporting are easier to achieve in single-vendor networks. Realistically, however, many service providers and business customers have multivendor networks, sometimes because of mergers and acquisitions. Even if the service provider itself has a single-vendor network, some of its customers will use other vendors' equipment.
- *Slow progress toward adopting IP Next-Generation Networks (IP NGNs):* When service providers complete the migration to IP NGN, they will achieve greater control, visibility, and operational efficiency. Until then, service providers will incur higher costs and labor requirements for support and migration.
- *A need to comply with industry standards from IETF and ITU:* Standards facilitate security in multivendor networks. MPLS helps ensure infrastructure security, whereas IPsec provides secure connectivity among the customer's branches and remote offices. By using industry standards, the service provider can select best-of-class products based on performance, features, or cost.

- *Scalability challenges:* The security operations center for a managed services provider cannot cost-effectively scale to process several million events for each customer. However, it can scale to process a few security-incident trouble tickets. Scalability hinges on the ability to minimize false positives. Products such as Cisco *Security Monitoring, Analysis and Response System* (MARS), IBM Micromuse, and NetIQ provide analysis and correlation of events from multiple elements in the IT infrastructure. They process events using consolidation, filtering, normalization, enrichment, correlation, and analysis techniques, and also notify IT staff about critical events.

Infrastructure Security in Multivendor Environments

Securing the service provider infrastructure requires the following common best practices:

- Point protection
- Edge protection
- Remote-triggered black-hole protection
- Source-address validation on all customer traffic
- Control-plane protection
- Total visibility into network activity

Point Protection

Before offering a managed security service, providers need to protect the backbone; security operations center or network operations center; *Authentication, Authorization, and Accounting* (AAA)[10, 11] server; and remote-access networks. Securing individual network devices requires enforcing AAA, controlling the type of packets destined to network devices, and performing regular configuration audits to ensure that no unauthorized changes have been made. Best common practices include:

- *Protect the backbone by locking down the vty and console ports:* This protection helps prevent unauthorized access to network devices.
- *Encrypt management commands that staff send to devices:* Use of the *Secure Shell* (SSH) protocol helps prevent hackers from obtaining passwords that they could later use to compromise the network. Service providers that use out-of-band management for device configuration should also encrypt this management traffic and restrict access to authorized personnel.
- *Deploy a AAA server:* Using a AAA server is preferable to relying on local authorization on the devices themselves because it enables centralized policy control. The AAA server controls a user's access to the device, or even the specific commands that the user is authorized to execute.

It is strongly recommended that service providers use TACACS+[13] authentication rather than *Remote Authentication Dial-In User Service* (RADIUS)[12] authentication. With RADIUS, traffic is sent in the clear between the AAA servers and network devices using the *User Datagram Protocol* (UDP), which defeats the use of SSH to encrypt logins and passwords. Open-source implementations of TACACS+ are available.

- *Use one-time passwords (OTPs):* To distribute one-time passwords, service providers can provide authorized users with a token card, soft token, or soft key. One-time passwords ensure that the user was authorized at the time of login, and was not an attacker who used a packet-sniffer program to intercept a password.
- *Protect the AAA infrastructure from DoS attacks:* Some service providers set up local accounts on routers and switches so that staff can log in if the AAA infrastructure is down, creating vulnerability. If the service provider does not secure management-plane access to the device, hackers can use SSH or Telnet and attempt a brute-force attack to crack the local account. The local account is often not as secure as an OTP because it is changed only once every 30 days, providing a longer window of opportunity for hackers to gain device access. It is strongly advised to not use default or easy-to-guess passwords. To prevent attacks against the AAA infrastructure, service providers should harden the infrastructure and consider placing the server behind a firewall with stateful inspection. Use *Access Control Lists* (ACLs), which are packet filters, on the firewall to restrict traffic between the AAA server and network devices only. Also be sure to distribute the AAA servers so that they do not create a single point of failure.
- *Regularly audit device configurations:* Frequently, the first indications of an attack, often unnoticed, are unauthorized commands executed on routers that change the configuration. An easy way to monitor configurations is using RANCID *(Really Awesome New Cisco Config Differ)*[14], a UNIX or Linux freeware tool that logs into each of the devices in the device table file, runs various show commands, processes the output, and sends e-mail messages reporting any differences from the previous collection to staff. RANCID works with routers from Cisco and other vendors. Another tool for auditing device configurations, the *Router Audit Toolkit* (RAT) assigns security scores to ACLs and other security best practices to show the relative security of routers.

Traditionally, service providers enforced policy at the process level, using vty ACLs, *Simple Network Management Protocol* (SNMP) ACLs, and others. Some service providers used ingress ACLs when possible. Today, it is far preferable to stop DoS traffic at ingress points: the peer edge, downstream and upstream routers, colocated network devices, and the customer access edge, enabling central policy enforcement and more granular protection schemes.

In addition, many network devices at the network edge have hardware acceleration, which provides far more robust resistance to attack than the process level.

Edge Protection

In many service provider networks, each core router is individually secured but still accessible to outsiders using SNMP or Telnet. Now service providers can supplement individual router protection with infrastructure protection that prevents undesired traffic from ever touching the infrastructure.

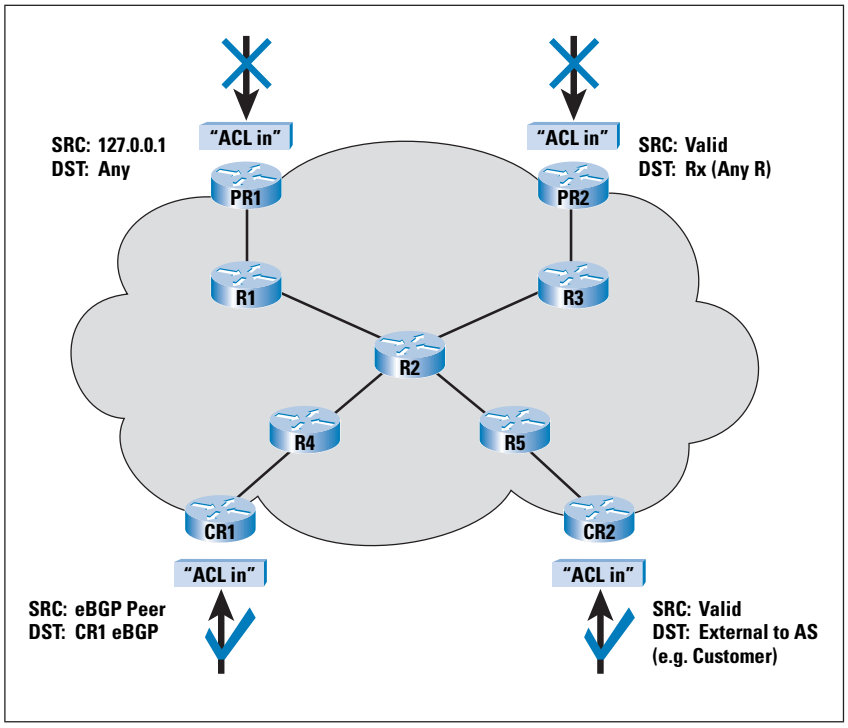

Figure 1: Protecting the Network Edge

The following steps help protect the network edge (Figure 1):

1. Classify the required protocols that are sourced from outside the *Autonomous System* (AS) access core routers, such as *external BGP* (eBGP) peering, *Generic Routing Encapsulation* (GRE)[5], and IPsec. (Examples of nonrequired protocols are SNMP and Telnet.) Classification can be performed using a classification packet filter or Cisco *NetFlow* telemetry. The classification packet filter comprises a series of permit statements that provide insight into required protocols. Gradually narrow down the list, keeping in mind that very few protocols need access to infrastructure equipment, and even fewer are sourced from outside the autonomous system. Summarize the IP address space as much as possible, for simpler and shorter ACLs. Be cautious: just because certain types of traffic appear in a classification packet filter or NetFlow telemetry data does not mean they should be permitted to pass through to the routers.

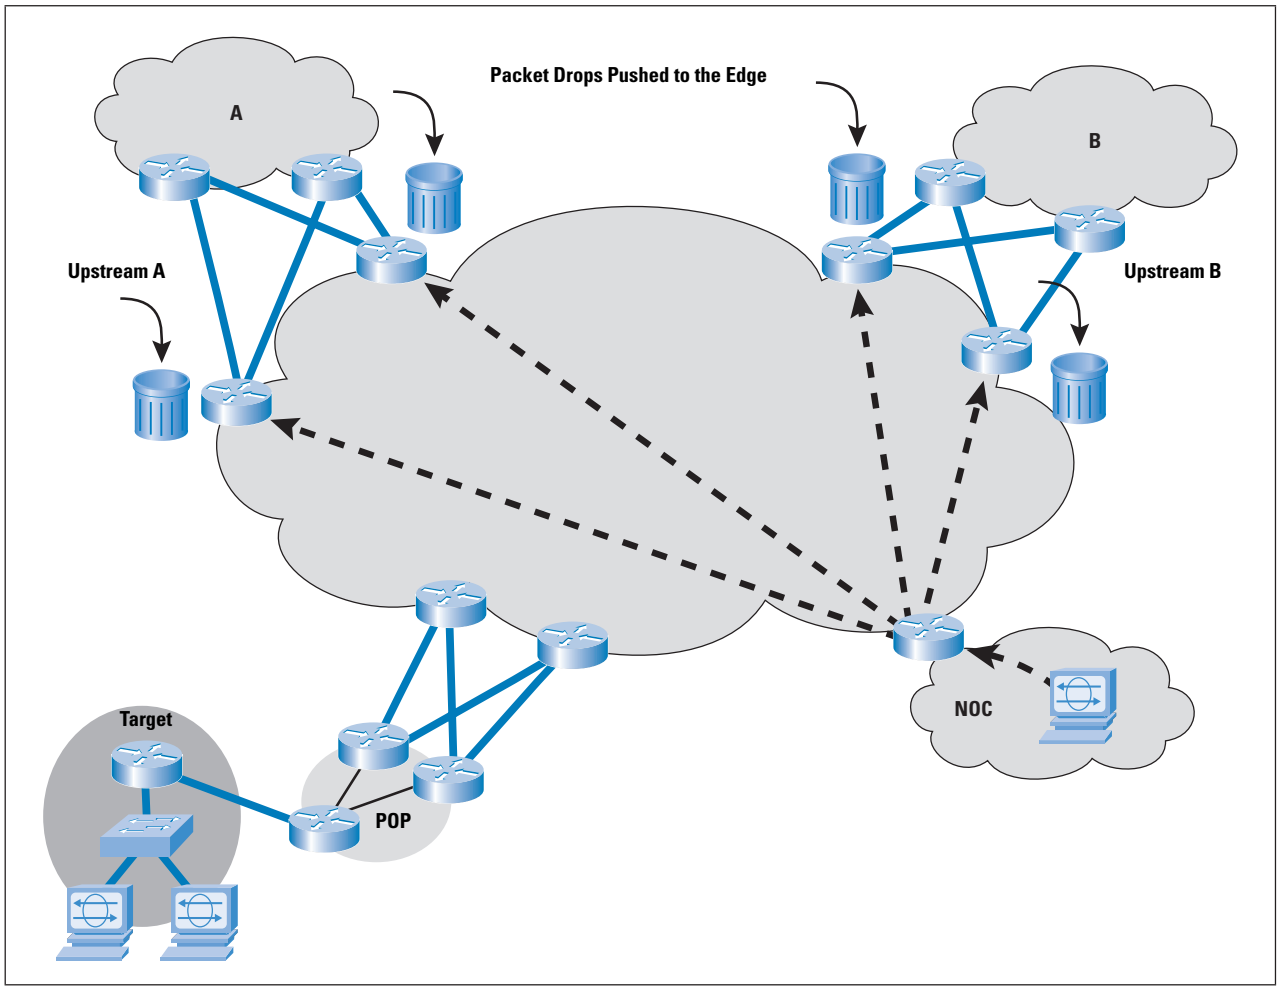
2. Begin filtering. Use an infrastructure packet filter to permit only the required protocols to access infrastructure-only address blocks, denying all other protocols. It is important to monitor the packet filter entry counters, because a high volume of hits, whether or not a protocol has been identified as required, might signal an attack. To permit transit traffic, use the following as the final line of the *Infrastructure ACL* (iACL): **`permit ip any any`**, protecting the core network with a basic iACL that admits only the required protocols. Note that iACLs also provide antispoof filtering by denying access to the space from external sources, denying the RFC 1918 space[6], and denying multicast source addresses. RFC 3330[7] defines special-use IPv4 addressing.
3. Further protect the core by identifying legitimate source addresses for the required protocols, such as external BGP peers and tunnel endpoints.
4. Deploy destination filters when possible.

Infrastructure packet filters at the edge of the network protecting the infrastructure are an effective first layer of defense. Service providers need additional forms of infrastructure protection for their older routers that do not support infrastructure packet filters and for packets that cannot be filtered with infrastructure packet filters.

Remote Triggered Black Hole Filtering

Remote Triggered Black Hole Filtering (RTBH) is among the most effective reaction and mitigation tools for DoS, *Distributed DoS* (DDoS), and backscatter tracebacks. It enables service providers to quickly drop DoS traffic at the network edge (Figure 2). Rather than sending commands to every router to drop DoS or other problem traffic, the service provider can deploy a trigger router that uses BGP to signal all other routers—just as fast as iBGP can update the network. In destination-based RTBH, all traffic headed to the destination under attack is dropped—the good traffic as well as the bad. In source-based RTBH, traffic from all or certain sources are blocked. The advantage of sourced-based RTBH is that service providers can whitelist certain addresses, such as the *Network Operations Center* (NOC) or route-name servers, so that they can continue providing services.

Figure 2: DoS Packets Dropped at the Network Edge



Source Address Validation on all Customer Traffic

Source address validation, defined in *Best Current Practices* (BCP) 38[8], prevents service provider customers from spoofing traffic—that is, sending IP packets out to the Internet with a source address other then the address allocated to them by the service provider. Best practices from BCP 38 are to filter as close to the edge as possible, filter precisely, and filter both the source and destination address when possible.

Every access technology has antispoofing mechanisms derived from BCP 38:

- Packet filters
- Dynamic packet filters that are provisioned to be AAA profiles; when a customer signs in with RADIUS, a packet filter is set up for the customer
- *Unicast Reverse Path Forwarding* (URPF)
- Cable-Source Verify and packet cable multimedia (cable)
- IP Source Verify and DHCP Snooping (Metro Ethernet)

To gain operational confidence in BCP 38, service providers can take a phased approach—for example, implementing it first on one port, then on a line card, then on an entire router, and then on multiple routers.

Control-Plane Protection

Protecting the infrastructure control plane helps prevent an attacker from taking down a BGP session and thereby causing denial of service. The exploits a service provider needs to prevent include saturating the receive-path queues so that BGP times out, saturating the link so that the link protocols time out, dropping the *Transmission Control Protocol* (TCP) session, and dropping the *Interior Gateway Protocol* (IGP), which causes a recursive loop-up failure.

Following are techniques for control-plane protection.

- *Generalized Time-to-Live (TTL) Security Mechanism (GTSM):* This technique protects BGP peers from multihop attacks. Routers are configured to transmit their packets with a TTL of 255, and to reject all packets with a TTL lower than 254 or 253. Therefore, a device that is not connected between the routers cannot generate packets that either router will accept.
- *Configuring routing authentication:* The *Message Digest Algorithm 5* (MD5) peer authentication feature instructs the router to certify the authenticity of its neighbors and the integrity of route updates. MD5 peer authentication can also prevent malformed packets from tearing down a peering session, and unauthorized devices from transmitting routing information. Be aware that MD5 peer authentication does not protect the router if an attacker compromises the router and begins generating bogus routing updates. Although it is not a panacea, MD5 peer authentication does raise the level of protection.
- *Customer ingress prefix filtering:* Prefix hijacking is an exploit in which a service provider customer announces an address space that belongs to another customer. The remedy is customer ingress prefix filtering, which enables service providers to accept only those customer prefixes that have been assigned or allocated to their downstream customers. For example, if a downstream customer has a **`220.50.0.0/20`** block, customers can announce this block only to their peers, and upstream peers accept this prefix only. Service providers can apply ingress prefix filtering to and from customers, peers, and upstream routers.

Visibility into Network Activity

To gain visibility into the network for early detection of security incidents, service providers can use open-source tools to analyze flow-based telemetry data, which is retrieved from routers and switches. Open-source tools for visibility into security incidents include RRDTool, FlowScan, Stager, and NTOP *Remote Monitoring* (RMON).

These tools provide information such as packets per second, bits per second, and traffic types. For example, RRDTool shows the number of *Domain Name System* (DNS) queries per second, according to record type. A spike in *Mail Exchange* (MX) Record queries might indicate that a customer's router has been compromised and is being used as a spam proxy. Similarly, a sharp increase in round-trip-time latency might indicate a DoS attack.

MPLS Security in a Multivendor Environment

In addition to securing the infrastructure, managed security service providers need to secure packets as they travel from one customer-edge router to another—regardless of the equipment the customer uses at the edge. Layer 3 VPNs meet this need. RFC 4364, which replaced RFC 2547bis, defines a BGP/MPLS IP VPN that creates multiple virtual routers on a single physical router: one virtual router for each customer.

In BGP/MPLS VPNs, *Customer Edge* (CE) routers send their routes to the *Service Provider Edge* (PE) routers. Customer edge routers at different sites do not peer with each other, and the customer's routing algorithms are not aware of the overlay. Data packets are tunneled through the backbone so that the core routers do not need to know the VPN routes. BGP/MPLS IP VPNs support either full mesh or partial mesh, although full mesh is more cost-effective.

A unique advantage of BGP/MPLS VPNs is that two service provider customers with overlapping IP addresses can connect across the service provider backbone. The router distinguishes between traffic from different companies by examining the label at the beginning of the packet, and then instantly forwards the traffic based on the *Label Switching Path* (LSP) that has been established for each customer's VPN. Eliminating the need to look at the packet in depth enables faster forwarding. That is, the service provider core does not impose any latency as packets pass between the provider edge routers.

IPsec Security in a Multivendor Environment

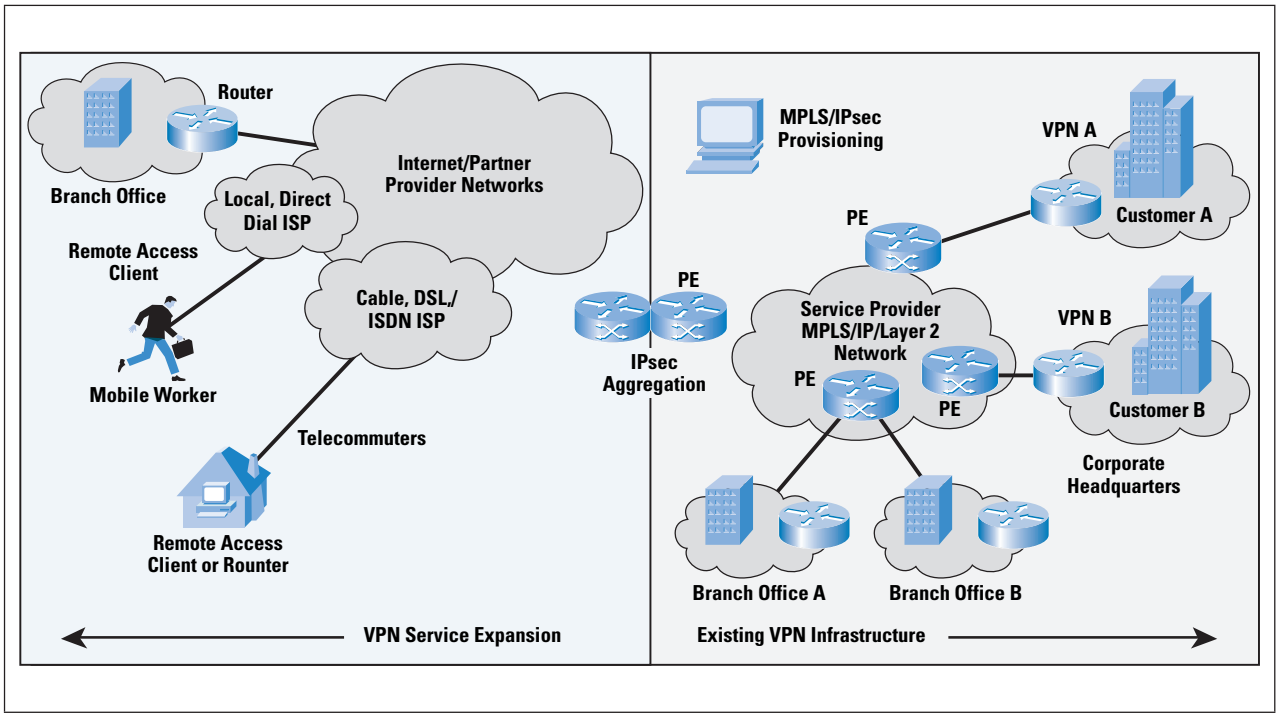
In addition to or instead of deploying a BGP/MPLS IP VPN, the service provider can extend its service to other partner provider networks using IPsec. The options are to use MPLS alone, IPsec alone, or a combination (Figure 3 on page 12). A retail customer that needs to comply with PCI-DSS, for example, needs IPsec or *Secure Sockets Layer* (SSL) encryption for payment card transaction data as part of its managed security service.

Table 1 summarizes the process based on the option the service provider selects. In the table, VPNA refers to one customer's VPN on a router that hosts VPNs for multiple customers.

Table 1: Comparing Packet Flow in IPsec VPNs, BGP/MPLS VPNs, and Combination VPNs

IPsec	BGP/MPLS VPN	BGP/MPLS VPN and IPsec
1. Host A in site 1 of VPNA sends packets to host B in site 2 of VPNA. 2. Routers A and B negotiate an Internet Key Exchange (IKE) [9] phase-one session in aggressive or main mode to establish a secure and authenticated channel between peers. 3. Routers A and B negotiate an IKE phase-two session to establish security associations on behalf of IPsec services. 4. Information is exchanged securely through an IPsec tunnel. 5. The tunnel is terminated.	1. Host A in site 1 of VPNA sends packets to host B in site 2 of VPNA. 2. Packet arrives on a VPN Route-Forwarding (VRF) VPNA interface on the PE1 router. 3. The PE1 router performs an IP lookup, determines the label stack and the outgoing core-facing interface, and forwards the packet to the MPLS core. 4. The packet is label-switched at each hop in the core until it reaches the penultimate hop router. At this point, the top label is popped before the packet is forwarded to the egress provider edge router. 5. The egress PE2 router performs a MPLS lookup and determines that it should remove the label before forwarding the packet to host B in site 2. 6. Router B in site 2 receives a regular IP packet and forwards it to host B.	1. Router A in site 1 and the associated PE1 router negotiate an IKE phase-one session in aggressive or main mode to negotiate a secure and authenticated channel between peers. 2. Router A and the PE1 router negotiate an IKE phase-two session to establish security associations on behalf of IPsec services so that information is exchanged securely through an IPsec tunnel. 3. Host A in site 1 of VPNA sends packets to host B in site 2 of VPNA. 4. The PE1 router, which is enabled with VRF-aware IPsec, creates a direct association through the IPsec tunnel that connects site 1 and the corresponding VRF ID (VPNA) on the provider edge router over the Internet. 5. Encrypted traffic arrives on an Internet-facing interface on the provider edge router A, which terminates the IPsec tunnel, decrypts the incoming packet, and forwards the plaintext packet to the VRF VPNA for further processing. 6. The PE1 router performs an IP lookup, determines the label stack and the outgoing core-facing interface, and forwards the packet to the MPLS core. 7. The packet is label-switched at each hop in the core until it reaches the penultimate hop router. At this point, the top label is popped before the packet is forwarded to the egress provider edge router. 8. The egress PE2 router performs a MPLS lookup and determines that it should remove the label before forwarding the packet to host B in site 2. Router B in site 2 receives a regular IP packet and forwards it to host B. 9. If site 2 is also reachable over the Internet and the egress PE2 router is enabled with VRF-aware IPsec, the packet is encrypted and sent to site 2 across the Internet over an IPsec tunnel. 10. Router B in site 2 terminates the IPsec tunnel, performs a regular IP lookup, and forwards the packet to host B.

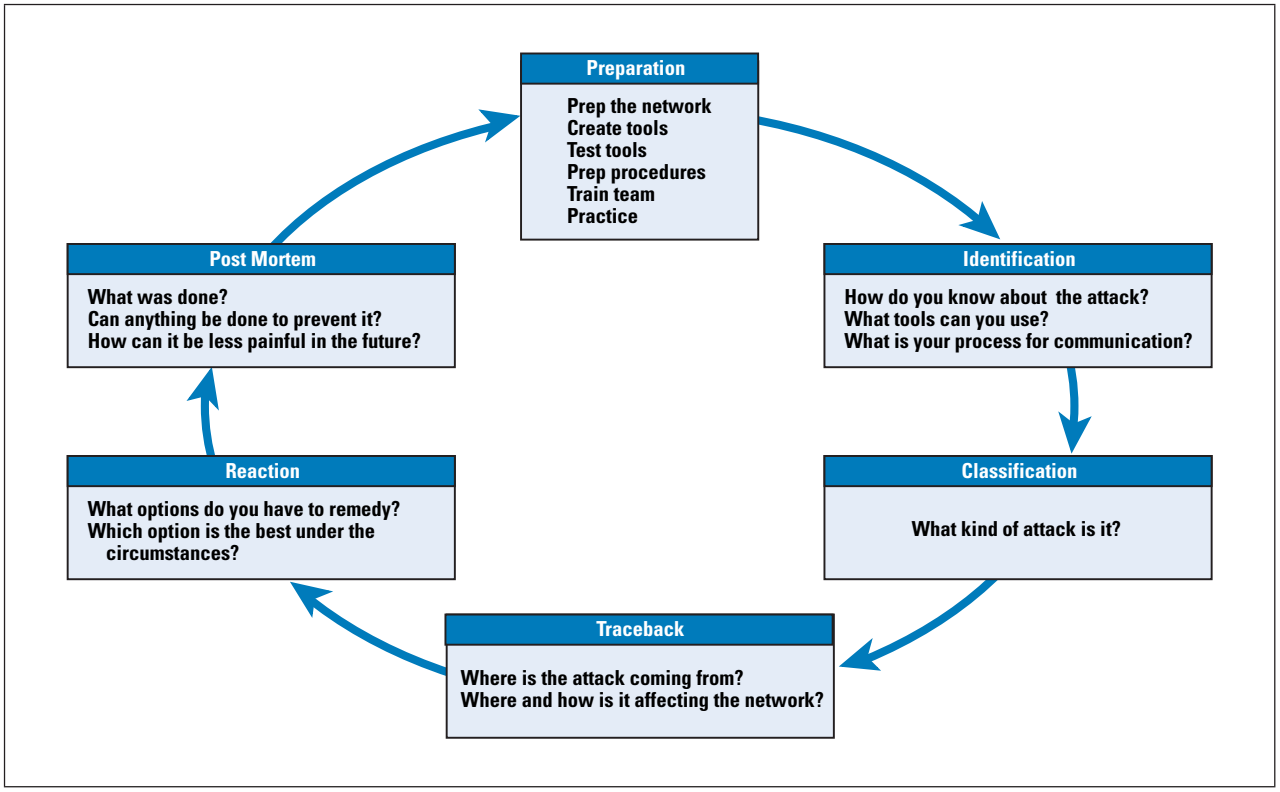
Figure 3: Managed IP VPN Security Services: IP MPLS, IPsec, or MPLS plus IPsec



Six-Step Methodology

Service providers can detect and mitigate attacks on the infrastructure using a six-step incident-response methodology (Figure 4).

Figure 4: Six Phases of Incident Response



- *Preparation:* The service provider needs to prepare the network, acquire the needed tools, develop and document a security plan, implement security procedures, and train NOC staff to use tools and procedures. *It is vital that security be a practice; the first time that the NOC staff follows its incident-response procedures should not be during an actual attack.*
- *Identification:* Unfortunately, service providers sometimes learn about a security incident from their customers. It is far better to be able to identify the threat before it becomes a problem, using NetFlow telemetry data and analysis tools, for example.
- *Classification:* The service provider needs to be able to quickly assess the nature of the threat and its scope: single customer, multiple customers, or entire infrastructure.
- *Traceback:* After classifying the threat, the IT staff needs to identify the point of ingress: peer, upstream server, downstream server, or compromised network device in the data center.
- *Reaction:* Following classification and traceback, the IT team applies the tools and processes needed to mitigate the attack. Success requires visibility into the network and well-defined procedures. Adherence to standard operating procedures helps prevent the service provider from inadvertently making the problem worse.
- *Post-mortem:* After the incident, the security team should analyze the root causes and integrate new insights into the security incident-handling procedures for use during the next incident.

Real-Life Observations About Interoperability from the APRICOT Workshops

Cisco and Juniper conducted a multivendor security workshop at APRICOT 2006 in Perth, Australia, and again at APRICOT 2007 in Bali, Indonesia. The workshops were offered in response to the fact that service providers often deploy a multivendor network for reasons ranging from financial to political.

Hands-on workshops were conducted in a lab using 12 routers running the Cisco IOS Software and another 12 running JUNOS software. Topics included:

- Password protection
- Packet filtering at the network edge
- Protecting the control plane
- Securing routing protocols
- Network monitoring techniques: NetFlow, syslog, SNMP, and *Network Time Protocol* (NTP)
- BGP MPLS Layer 3 VPNs
- IPsec VPNs

The goal of the workshops was to achieve a working configuration that interoperated with JUNOS and the Cisco IOS Software, resulting in consistent technology implementation, as well as common security policy enforcement. The workshops underscored the fact that interoperability is not automatic—even among standards-based network products. The reason is that standards bodies such as IETF, ITU, IEEE, and others define some aspects of protocols but leave others to vendor discretion. Standards do define *protocol format,* which is a syntactical structure identifying bit-field definition, length, and more. They also define *protocol behavior,* which specifies when actions occur, such as sending Hello and Keepalive timer probes and handling retransmission and reset packets. For purposes of analogy, a spoken language such as English is like a protocol format, and polite conversation conventions, such as beginning with a greeting and concluding with goodbye, is like a protocol behavior.

What standards do *not* cover are vendor-specific internal implementations, such as software coding techniques, hardware acceleration for performance, *command-line interface* (CLI) structure, and so on. Therefore, even though the APRICOT workshops involved deploying standards-based technology such as BGP-based MPLS VPNs and IPsec, vendor-specific differences had to be accounted for in the workshop materials and were noticed by participants. Following are examples noted at the APRICOT workshop:

- *Label Distribution Protocol:* With BGP MPLS VPN, JUNOS and Cisco IOS Software did not interoperate in their default configurations. However, routers from the same vendor did establish *Label Distribution Protocol* (LDP) sessions. The explanation, which participants found by troubleshooting with debug commands and referring to the manual, is that Cisco IOS Software uses the *Tag Distribution Protocol* (TDP) by default, whereas JUNOS uses LDP. After the Cisco IOS Software was changed to use LDP, the BGP-based MPLS VPN configuration succeeded.
- *IPsec tunnel establishment:* To simplify IPsec configuration, the workshop employed a *Graphical User Interface* (GUI) that prompted the user to choose source and destination IP addresses for the tunnel endpoints, a shared key, and the prefixes that defined the "interesting" traffic that was to use the IPsec tunnel. On the first attempt, the IPsec tunnel was not established. Workshop participants used the CLI to determine the problem, which was that the default encryption being negotiated was incompatible. The root cause for this mismatched encryption standard was that some routers were using an export version of software and needed an upgrade to support a higher encryption standard. Furthermore, even with common encryption capabilities, the two operating systems used different criteria to identify the interesting traffic that would be encrypted. Using the GUI, JUNOS defined interesting traffic as sourced from "ANY" network and destined to **`192.168.1.0/24`**.

In contrast, the Cisco IOS Software defined interesting traffic as sourced from **10.1.1.0/24** and destined to **192.168.1.0/24**. Following a discussion about whether the JUNOS default was too permissive or the Cisco IOS Software default was too restrictive, workshop participants agreed to disallow traffic that did not require encryption in the IPsec tunnel. The consensus was that the customer's security policy would provide a more conclusive answer to how permissive the policy should be, and that it was reasonable to require use of the CLI to tweak the configuration because the GUI performed most of the more difficult parts of the configuration on both platforms.

- *Loopback interface cost with Open Shortest Path First (OSPF):* During the OSPF deployment, participants noticed that the OSPF cost associated with interfaces was the same for each vendor. The OSPF cost is based upon a reference bandwidth of 100 Mbps. However, the loopback interfaces had different values: a default OSPF cost of 1 for the Cisco IOS Software and 0 for JUNOS. It is advisable to change one of the defaults to make them the same.

Although these subtle differences in protocols are documented by the vendors, service provider operational teams often have little time to research them. Therefore, it can be valuable for them to participate in multivendor hands-on workshops. Anecdotal evidence suggests that operators who are comfortable with multiple vendors understand the protocols, helping them design networks that can support new, revenue-generating services.

It is hoped that events such as the APRICOT workshops will help build a community of professionals who can add value for their employers, each other, and the broader Internet community. The result will be a secure and trusted networking environment that people and industry can rely on and use to connect in new and innovative ways.

Summary

Managed security services represent a growing revenue opportunity for service providers. Most service providers operate in a multivendor environment, either because of mergers and acquisitions or because their customers use other vendors' equipment. Therefore, a standards-based approach positions providers to capitalize on the managed security service opportunity. Providers can secure their infrastructure in a multivendor environment by following best practices for point protection, edge protection, RTBH protection, source-address validation, control-plane protection, and total visibility into network activity.

IPv4 Address Depletion and Transition to IPv6

by Geoff Huston, APNIC

At the recent APNIC meeting in New Delhi, the subject of IPv4, IPv6, and transition mechanisms was highlighted in the plenary session[1]. This article briefly summarizes that session and the underlying parameters in IPv4 address depletion and the transition to IPv6.

IPv4 Status

As of September 2007 we have some 18 percent of the unallocated IPv4 address pool remaining with the *Internet Assigned Numbers Authority* (IANA), and 68 percent has already been allocated to the *Regional Internet Registries* (RIRs) and through the RIRs to *Internet Service Providers* (ISPs) and end users. The remaining 14 percent of the IPv4 address space is reserved for private use, multicast, and special purposes. Another way of looking at this situation is that we have exhausted four-fifths of the unallocated address pool in IPv4, and one-fifth remains for future use. It has taken more than two decades of Internet growth to expend this initial four-fifths of the address space, so why shouldn't it take a further decade to consume what remains?

At this point the various predictive models come into play, because the history of the Internet has not been a uniformly steady model. The Internet began in the 1980s very quietly; the first round of explosive growth in demand was in the early 1990s as the Internet was adopted by the academic and research sector. At the time, the address architecture used a model where class A networks (or a /8) were extremely large, the class B networks (/16) were also too large, and the class C networks (/24) were too small for most campuses. The general use of class B address blocks was an uncomfortable compromise between consuming too much address space and consuming too many routing slots through address fragmentation. The subsequent shift to a classless address architecture in the early 1990s significantly reduced the levels of IPv4 address consumption for the next decade. However, over the past five years the demand levels for addresses have been accelerating again. Extensive mass-market broadband deployment, the demand for public non-*Network Address Translation* (NAT) addresses for applications such as *Voice over IP* (VoIP), and continuing real cost reductions in technology that has now brought the Internet to large populations in developing economies all contribute to an accelerating IPv4 address consumption rate.

Various approaches to modeling this address consumption predict that the IANA unallocated address pool will be fully depleted sometime in 2010 or 2011[2, 3, 4, 5].

Transitioning to IPv6

The obvious question is "What then?", and the commonly assumed answer to that question is one that the *Internet Engineering Task Force* (IETF) started developing almost 15 years ago, namely a shift to use a new version of the Internet Protocol: what we now know as IP Version 6, or IPv6. But if IPv6 really is the answer to this problem of IPv4 unallocated address-pool depletion, then we appear to be leaving the transition process quite late. The uptake of IPv6 in the public Internet remains extremely small as compared to IPv4[6]. If we really have to have IPv6 universally deployed by the time we fully exhaust the unallocated IPv4 address pools, then this objective appears to be unattainable during the 24 months we have to complete this work. The more likely scenario we face is that we will not have IPv6 fully deployed in the remaining time, implying a need to be more inventive about IPv4 in the coming years, as well as inspecting more closely the reason why IPv6 has failed to excite much reaction on the part of the industry to date.

We need to consider both IPv4 and IPv6 when looking at these problems with transition because of an underlying limitation in technology: *IPv6 is not "backward-compatible" with IPv4*. An IPv6 host cannot directly communicate with an IPv4 host. The IETF worked on ways to achieve this through intermediaries, such as a protocol to translate NATs[7], but this approach has recently been declared "historic" because of technical and operational difficulties[8]. That decision leaves few alternatives. If a host wants to talk to the IPv4 world, it cannot rely on clever protocol translating intermediaries somewhere, and it needs to have a local IPv4 protocol stack, a local IPv4 address, and a local IPv4 network and IPv4 transit. And to speak to IPv6 hosts, IPv6 has the same set of prerequisites as IPv4. This approach to transition through replication of the entire network protocol infrastructure is termed "Dual Stack." The corollary of Dual Stack is continued demand for IPv4 addresses to address the entire Internet for as long as this transition takes. The apparent contradiction here is that we do not appear to have sufficient IPv4 addresses in the unallocated address pools to sustain this Dual Stack approach to transition for the extended time periods that we anticipate this process to take.

What Can We Expect?

So we can expect that IPv4 addresses will continue to be in demand well beyond any anticipated date of exhaustion of the unallocated address pool, because in the Dual Stack transition environment all new and expanding network deployments need IPv4 service access and addresses. But the address distribution process will no longer be directly managed through address allocation policies after the allocation pool is exhausted.

Ideas that have been aired in address policy forums include encouraging NAT deployment in IPv4, expanding the private use of IPv4 address space to include the last remaining "reserved-for-future-use" address block, various policies relating to rationing the remaining IPv4 address space, increased efforts of address reclamation, the recognition of address transfers, and the use of markets to support address distribution.

Of course the questions here are about how long we need to continue to rely on IPv4, how such new forms of address distribution would affect existing notions of fairness and efficiency of use, and whether this effect would imply escalation of cost or some large-scale effect on the routing system.

On the other hand, is IPv6 really ready to assume the role of the underpinning of the global Internet? One view is that although the transition to a universal deployment of IPv6 is inevitable, numerous immediate concerns have impeded IPv6 adoption, including the lack of backward compatibility and the absence of simple, useful, and scalable translation or transition mechanisms[9]. So far the business case for IPv6 has not been compelling, and it appears to be far easier for ISPs and their customers to continue along the path of IPv4 and NATs.

When we contemplate this transition, we also need to be mindful of what we need to preserve across this transition, including the functions and integrity of the Internet as a service platform, the functions of existing applications, the viability of routing, the capability to sustain continued growth, and the integrity of the network infrastructure.

It appears that what could be useful right now is clear and coherent information about the situation and current choices, and analyzing the implications of various options. When looking at such concerns of significant change, we need to appreciate both the limitations and the strengths of the Internet as a global deregulated industry and we need, above all else, to preserve a single coherent networked outcome. Perhaps this topic is far broader than purely technical, and when we examine it from a perspective that embraces economic considerations, business imperatives, and public policy objectives, we need to understand the broader context in which these processes of change are progressing[10].

It is likely that some disruptive aspects of this transition will affect the entire industry, and this transition will probably be neither transparent nor costless.

IPv4 Address Space: 2.46 Billion Down, 1.25 Billion to Go

by Iljitsch van Beijnum

In September 2005, *The Internet Protocol Journal* published an article about the IPv4 address space consumption[1]. At that time, projections done by Geoff Huston and Tony Hain varied widely, because the number of /8 address blocks in use had gone up sharply in early 2005. So what has happened since then, and what can we expect for the not-too-distant future?

Address Assignment and Allocation

The *Internet Assigned Numbers Authority* (IANA, part of the *Internet Corporation for Assigned Names and Numbers* [ICANN]) has authority over the IPv4 address space. In the past, IANA gave out address blocks directly to end users, but now IANA distributes address space in the form of /8 blocks, each holding 24 bits worth of address space, or 16,777,216 addresses, to five *Regional Internet Registries* (RIRs). There are a few exceptions, but AfriNIC[2] gives out address space in Africa; APNIC[3] in the Asia-Pacific region; ARIN[4] in North America; LACNIC[5] in Latin America and the Caribbean; and RIPE NCC[6] in Europe, the former Soviet Union, and the Middle East. These RIRs sometimes assign address space to end users, but mostly allocate it to *Internet Service Providers* (ISPs), who then assign it to their customers, meaning that there are two pools of available address space: the global pool of /8 blocks that IANA has not delegated to anyone[7], and the address space held by the RIRs that they have not given out yet. The article in the September 2005 issue of *The Internet Protocol Journal*[1] looked at the depletion of the IANA global pool, whereas this article mostly looks at the amounts of address space given out by the RIRs, providing a more granular view. The RIRs publish daily reports of their address assignments and allocations on their respective FTP servers. According to these reports as downloaded on January 1, 2007, the amounts of address space shown in Table 1 were given out over the past seven years.

Table 1: Address Space Allocated 2000–2006 [January 2007 data]

	2000	2001	2002	2003	2004	2005	2006
AfriNIC	0.56	0.39	0.26	0.22	0.51	1.03	2.72
APNIC	20.94	28.83	27.03	33.05	42.89	53.86	51.78
ARIN	30.83	28.55	21.08	22.32	34.26	47.57	38.94
LACNIC	0.88	1.61	0.65	2.62	3.77	10.97	11.50
RIPE NCC	24.79	25.36	19.84	29.61	47.49	62.09	56.53
Total	78.00	84.73	68.87	87.82	128.92	175.52	161.48

However, if we compare these totals to the totals seen on January 1, 2006, we see some differences (Table 2).

Table 2: Address Space Allocated 2000–2006 [January 2006 data]

	2000	2001	2002	2003	2004	2005	2006
Total	78.35	88.95	68.93	87.77	128.45	165.45	–

For the years 2000 to 2002, the number of addresses registered as given out is slightly lower, as seen in the January 1, 2007 data compared to the January 1, 2006 data—a result that is to be expected because address space given out in that year that is no longer used is returned. However, for the later years, and especially for 2005, there is a retroactive *increase* in the number of addresses given out. The reason: When ARIN suspects an address space user may come back for more space relatively soon, it takes a larger block than requested, and then fulfills the request from part of that block and keeps the rest in reserve. So an organization requesting a /16 may get the first half of a /15. When that organization then requests another /16 one or two years later, ARIN gives the organization the second half of the /15. ARIN subsequently records this as a /15 given out on the date when the original /16 was requested.

For instance, ARIN's January 1, 2006, data shows that a block of 12.6 million addresses was given out within **`73.0.0.0/8`** block:

```
arin|US|ipv4|73.0.0.0|12582912|20050419|allocated
```

In the January 1, 2007, data, this number had changed to 13.6 million addresses:

```
arin|US|ipv4|73.0.0.0|13631488|20050419|allocated
```

This change means that simply looking at the registration date does not provide very good information. It also does not account for address space given out in earlier years that is returned. An alternative approach is to count the amount of address space given out based on the RIR records published on a certain date (Table 3).

Table 3: RIR Records for Address Space Allocation

	IANA (/8)		RIRs (millions)			Total	
	Delegated	Free	Received	Delegated	Free	Free	Delta
Jan. 1, 2004	133	88	1509.95	1245.63	264.32	1740.71	
Jan. 1, 2005	142	79	1660.95	1351.66	309.30	1634.69	106.02
Jan. 1, 2006	155	66	1879.05	1517.74	361.31	1468.61	166.08
Jan. 1, 2007	166	55	2063.60	1685.69	377.90	1300.65	167.96
May 1, 2007	172	49	2181.04	1754.68	426.36	1248.44	52.21

(Note that block **`7.0.0.0/8`** shows up as unused in the IANA global pool and is counted as available in the table, but this block is in fact used by the U.S. Department of Defense.)

The jump in address consumption between 2004 (106 million) and 2005 (166 million) is even more dramatic in this light, while consumption numbers of 2005 and 2006 (168 million) are now almost identical. The figure for the first four months of 2007 seems rather modest at 52 million addresses, but the reason lies in the fact that Bolt, Beranek and Newman returned **`46.0.0.0/8`** to IANA in April. So the number of addresses given out from January to April was 69 million, a rate that puts the RIRs on track to give out more than 200 million addresses in 2007.

The size of address blocks given has been increasing steadily. Table 4 shows the number of requests for a certain range of block sizes: equal or higher than the first, lower than the second value (2005 and earlier values from the January 1, 2006 data, 2006 values from the January 1, 2007 data).

Table 4: Number of Requests for Ranges of Block Sizes

	2000	2001	2002	2003	2004	2005	2006
< 1,000	326	474	547	745	1022	1309	1526
1,000 – 8,000	652	1176	897	1009	1516	1891	2338
8,000 – 64k	1440	868	822	1014	1100	1039	1133
64k – 500k	354	262	163	215	404	309	409
500k – 2M	19	39	29	46	61	60	56
> 2M	3	5	5	6	7	18	13

The number of blocks in the two smallest categories has increased rapidly, but not as fast as the number of blocks in the largest category, in relative numbers. However, the increase in large blocks has a very dramatic effect whereas the small blocks are insignificant, when looking at the millions of addresses involved (Table 5).

Table 5: Millions of Addresses Given Out

	2000	2001	2002	2003	2004	2005	2006
< 1,000	0.10	0.16	0.18	0.25	0.35	0.44	0.52
1,000 – 8,000	2.42	4.47	3.23	3.45	4.49	5.07	6.10
8,000 – 64k	18.79	12.81	11.35	14.00	15.99	15.46	17.17
64k – 500k	35.98	32.19	20.28	25.51	42.01	34.23	49.64
500k – 2M	12.68	24.64	21.30	31.98	44.63	41.63	46.64
> 2M	8.39	14.68	12.58	12.58	20.97	68.62	41.42

The increase in the 2M+ blocks was solely responsible for the high number of addresses given out in 2005. In 2006, there was growth in all categories except the 2M+ one (even the 500k – 2M category increased in number of addresses if not in number of blocks). When the 2M+ blocks are taken out of the equation, 2005 had a total of 96.83 million addresses (January 1, 2006) and 2006 had 119.06 million given out, even without fully correcting for the ARIN reporting particularities. Apparently there is still an underlying upward trend.

Figure 1 shows the amounts of address space given out by IANA and by the RIRs every year from 1994 to 2006.

Figure 1: IPv4 Address Space Given Out from 1994 to 2006

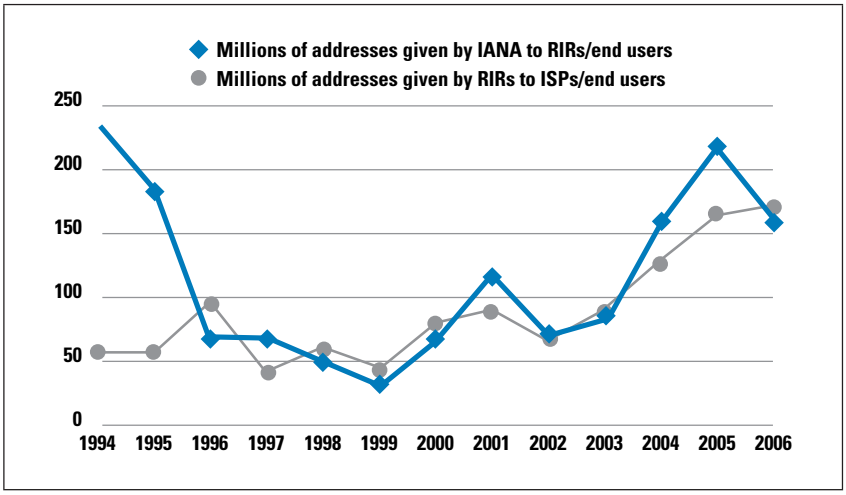

Figure 2 shows the amounts of address space marked as "in use" by IANA and by the RIRs. The difference between the two numbers is what the RIRs hold in order to satisfy day-to-day address space requests. This amount is usually two years' worth of address space.

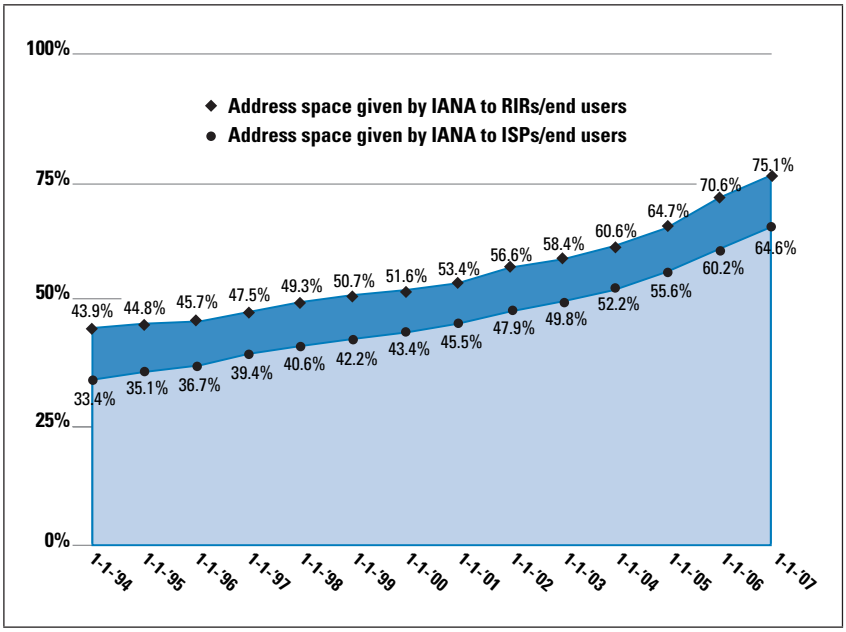
Figure 2: IPv4 Address Space in Use from 1994 to 2006



Depletion

The exact moment when the IPv4 address space will be depleted depends on numerous factors. Since 1997, the three-year period with the largest growth in yearly address use was from 2003 to 2005 relative to the 2002 figure: a factor 2.4, or 34 percent per year. If this growth repeats itself in the next three years, we will be out of IPv4 addresses in the second half of 2010.

Interestingly, the period with the lowest growth also includes the year 2003: from 2001 to 2003 relative to 2000. In 2003, 12 percent more addresses were given out than in 2000, for an average increase in yearly use of 4 percent. If this is the new trend for the coming years, we can expect to run out of IPv4 addresses in mid-2013. There is of course no reason to assume that future IP address use will conform to patterns seen in earlier years, but we really have nothing else to base our projections upon.

So anyone expecting to obtain new IPv4 address space more than three years from now is taking a big risk. With the IPv4 reserves visibly diminishing each year, the question is: What can we, as a community, do to make the IPv4 address depletion as painless as possible? IPv4 addresses are useful only if the people who need them can obtain them, meaning that using up addresses unnecessarily fast or locking up the still-available reserves are both suboptimal solutions. It has been suggested that turning IPv4 address space into a tradable commodity would allow a free market to form, aiding the efficient distribution of address space from those who have it to those who need it.

This scenario has several problems. First, when supply is limited and demand is high, prices rise and hoarding becomes lucrative. So the effect of making address space tradable could be a reduction of available address space rather than an increase. And certainly, as trading IPv4 space becomes more likely, holders of large address blocks will be less inclined to return them. Finally, more than half of the IPv4 address space in use is held by organizations in the United States, whereas the developing world has comparatively little address space. The prospect of having to buy address space from American companies that got the space for free is not likely to be popular in the rest of the world.

Address Reclamation a Solution?

There are two large classes of potentially reclaimable address space: the class E reserved space (**`240.0.0.0 – 255.255.255.255`**) and the class A blocks given out directly to end users by IANA. The class E space has 268 million addresses and would give us in the order of 18 months worth of IPv4 address use. However, many TCP/IP stacks, such as the one in Windows, do not accept addresses from class E space and will not even communicate with correspondents holding those addresses. It is probably too late now to change this behavior on the installed base before the address space would be needed. There are currently 42 class A blocks and another two /8s from class C space listed as given out to end users—738 million addresses. The U.S. government uses about 10 of those blocks; 21 of them are not present in the *Border Gateway Protocol* (BGP) routing table.

Although harsh judgments about the need for so much address space are easily made from the outside without having all the pertinent information, it seems reasonable to try to reclaim some of this space. I would consider getting back half of this space a big success, but that would give us only 2 years worth of additional address space. There are also 645 million addresses of older class B assignments, but reclaiming those will be extremely difficult because nearly 8,000 individual assignments are involved. Reclaiming a class B block is probably not much easier than reclaiming a class A block, but the amount of address space returned is less than half a percent.

Planning for the End Game

So what should we do? In my opinion: promote predictability. The situation where we run out of IPv4 address space much faster than expected would be very harmful as organizations struggle to adjust to the new circumstances. On the other hand, if the IPv4 space unexpectedly lasts longer, people may be disinclined to believe space is really running out and then would be unprepared when it does. Artificially delaying running out of IPv4 address space also prolongs the situation in which it is difficult to get IPv4 space, but not enough people feel the pain to initiate IPv6 deployment. One solution worthy of consideration would be to impose a worldwide moratorium on the change of IPv4 address allocation and assignment policies after a certain date to aid this predictability. If some kind of encouraged or forced reclamation of older class A blocks is desired, this process should be instigated sooner rather than later, both for the sake of predictability and because it gives the address holders involved time to reorganize their networks. Another small but useful step would be to limit the size of address blocks given out. This scenario would be like the agreement between the RIRs and IANA that the RIRs will receive two /8s at a time in the future. The situation where a single /9 or /8 allocation constitutes 5 or even 10 percent of the address space given out in that year makes adequate predictions extremely difficult, and also runs the risk that a good part of the address block in question will never be used as circumstances change. Limiting individual allocations to a /11 or /12 would be better, even if it requires the requesting organization to come back for more address space several times per year.

Finally, it seems prudent for all organizations using public IPv4 address space to start planning for the moment that they themselves, or third parties that they communicate with over the public Internet, can no longer obtain additional IPv4 address space.

Used but Unallocated: Potentially Awkward /8 Assignments

by Leo Vegoda, ICANN

IPv4 has proven to be exceedingly popular, so it should be no surprise that the time is rapidly approaching when the last /8 block will be allocated and the *Internet Assigned Numbers Authority's* (IANA's) free pool of address space will be empty. At the time of writing, Geoff Huston of the *Asia Pacific Network Information Centre* (APNIC) is projecting[1] the IANA free pool will run out in mid-2010. Unfortunately, it is possible that some of these remaining /8s may cause problems for enterprise and *Internet Service Provider* (ISP) network operators when they are put back into use. These blocks are not the /8s that have been returned to IANA by the original registrants; they are previously unassigned address blocks.

Concerns

There are many concerns about the IANA free pool depletion, but one of them seems particularly straightforward to identify and fix. Many organizations have chosen to use unregistered IPv4 addresses in their internal networks and, in some cases, network equipment or software providers have chosen to use unregistered IPv4 addresses in their products or services. In many cases the choice to use these addresses was made because the network operators did not want the administrative burden of requesting a registered block of addresses from a *Regional Internet Registry* (RIR)[2, 11]. In other cases they may not have realized that RFC 1918[3] set aside three blocks of address space for private networks, so they just picked what they believed to be an unused block, or their needs exceeded the RFC 1918 set-aside blocks. Other organizations used the default address range suggested by their equipment vendor, or supplied in example documentation, when configuring *Network Address Translation* (NAT) devices. Regardless of the reason, these uses of unregistered addresses will conflict with routed addresses when the /8s in question are eventually assigned to ISPs or enterprise users.

A few examples of /8s where problems are likely to occur follow:

`1.0.0.0/8` Widely used as private address space in large organizations whose needs exceed those provided for by RFC 1918[4]

`5.0.0.0/8` Used by one of numerous zero-configuration Internet applications (including the Hamachi VPN service [5, 6])

`42.0.0.0/8` Default range used in the NAT configuration of at least one Internet appliance (the HP Procurve 700wl[7])

Organizations using these address ranges in products or services may experience problems when more specific Internet routes attract traffic that was meant for internal hosts, or alternatively find themselves unable to reach the legitimate users of those addresses because those addresses are being used internally. The users of unregistered networks may also find problems with reverse *Domain Name System* (DNS) resolution, depending on how their DNS servers are configured. These problems are likely to result in additional calls to helpdesks and security desks at both enterprises and ISPs, with unexpected behavior for end users that might be hard to diagnose. Users of unregistered address space may also experience problems with unexpected traffic being received at their site if they leak internal routes to the public Internet. Many ISPs have already had experience with this type of routing inconsistency as recent /8 allocations reach routing tables and bogon filters are updated.

Alternatives

There are several alternatives to using unregistered IPv4 address space:

- Use RFC 1918 IPv4 address space (no need to obtain this space from an RIR)
- Use IPv4 address space registered with an RIR
- Use IPv6 address space registered with an RIR
- Use IPv6 Unique Local Address[8] space (no need to obtain this space from an RIR)

Obviously, all of these efforts will involve renumbering networks, a sometimes painful and time-consuming process. Those using unregistered unique IPv4 address space should look at renumbering their networks or services before the previously unallocated /8s are allocated to avoid address clashes and routing difficulties.

Additionally, vendors and documentation writers can clean up their configurations to ensure they use RFC 1918 addresses, or make it clear to their users that they must use registered addresses to avoid routing conflicts.

All RIRs provide free telephone helpdesks that can advise you on obtaining unique IPv4 or IPv6 address space. But if you want to continue using unregistered space and can transition to IPv6, the prefix selection mechanism described in RFC 4193 makes the probability of a clash a mere 1 in 550 billion. Ultimately, transitioning to IPv6 is most likely the best solution, and this approach offers an opportunity for those having to renumber parts of their network to avoid a subsequent renumbering later into IPv6.

About IANA and ICANN

IANA allocates address space to RIRs according to the global IPv4 [9] and IPv6[10] policies. Enterprise and ISP networks need to obtain IP addresses from their upstream provider or from the appropriate RIR.

The *Internet Corporation for Assigned Names and Numbers* (ICANN) is an internationally organized, nonprofit corporation that has responsibility for *Internet Protocol* (IP) address space allocation, protocol identifier assignment, *generic* (gTLD) and *country code* (ccTLD) *Top-Level Domain* name system management, and root server system management functions. These services were originally performed under U.S. government contract by IANA and other entities. ICANN now performs the IANA function.

Book Review

Uncommon Sense

Uncommon Sense: Out of the Box Thinking for An In the Box World, By Peter Cochrane, ISBN 1-84112-477-x, Published by Capstone, 2004, **http://www.wileyeurope.com**

A series of articles published in **silicon.com** form the basis for this book, which looks at the effect that new technology has on business and its implications for society. In many ways it attacks conventional wisdom and forces a reevaluation of the effect of technology, often exposing flaws in the business logic that lead to many investments and decisions.

The book is aimed at technologists, managers, and professionals who are interested in change and progress, offering them a glimpse of the future. It is easy to read, with liberal use of figures and tables to aid understanding.

Organisation

Cochrane begins by looking at the communication of ideas, particularly fairly complex and novel concepts. He notes the lack of agreement on the major concerns of the future and bemoans the handling of complex business and political topics–and the lack of engineering type rigour applied to their assessment. He suggests a much more rigorous modeling of complex business problems is required, especially of business processes, which are typically complex and inter-related, so treating them as isolated "stovepipes" is inappropriate and error-prone. Cochrane emphasises the need for nonlinear thinking.

Cochrane's analysis continues with an assessment of technology markets, not surprisingly beginning with the forces behind the dot-com bubble, with particular reference to the effect that the so-called new and old economies have had on each other. He suggests that short-term approaches, with their tendency to hit high-visibility symptoms and not the underlying commercial factors, are a barrier to progress. Cochrane reflects that whilst the dot-com boom is over, it is now clear that the online world has been very successful and has dragged the old world along in its wake.

The book then looks at change: considering the adoption of new technology and the impact effect of the Internet, comparing this new technology with the adoption of television. Cochrane spends a significant amount of time on both entertainment and learning. He examines topics as varied as security, the ease of movement of information across borders, and the role of specialist and general devices.

His assessment of security considers the range and rate of spread of threats and some advanced countermeasures such as biometrics. He considers the nature of change programmes and the harmful ways insensitive micromanagement can affect their progress.

Cochrane explores the role of the consumer in deciding which technical innovations survive, as exemplified by the growth of the American cable TV (CATV) market. He notes that most consumers have a fixed level of disposable income and new innovations allow them to redirect rather than increase their level of spending. Cochrane argues that this truth is reflected in the saturation within the mobile handset market and the dynamics seen between the media companies and new innovators such as Napster.

The penultimate collection of essays considers the speed of innovation. Cochrane notes that many consumers are suffering from "technology fatigue" and many products are suffering from "feature death." Here he discusses stagnation within the mobile market and disillusionment with the *Wireless Application Protocol* (WAP), *General Packet Radio Service* (GPRS), and Bluetooth. He notes that the adoption of technology is linked to the willingness of customers to pay.

Cochrane concludes by looking at leading-edge variables, including reliability, noting that this variable goes hand-in-hand with maturity, with the *Public Switched Telephone Network* (PSTN) delivering extremely high levels of reliability and most modern IT solutions delivering considerably less. He makes this comparison a critical test of the five-nines availability claims of many new technology solutions. Cochrane looks at some more less-conventional ideas such as the replication of ant logic in IT systems and the possible future use of plasma screens and voice recognition as convenient input/output devices. He notes the increasing intelligence of devices, but also acknowledges that rapid communications and minimal hierarchy can triumph over better organised structures as demonstrated by protesters in France in 2000 and 2001.

Synopsis

Cochrane takes the reader through many contemporary technology developments and concerns and in the process invites his readers to form their own views. His mission is to "communicate the implications of what we have done, are doing and are about to do." In 50 short articles, delivered in 233 pages, it is possible for the author to cover only a small portion of a rapidly growing field, providing sufficient detail to appeal to the technologist without losing the bigger picture. He examines the implications of new technology for society and notes that the progress we are seeing means that we have to take on the new, changing the way we manage, operate, and govern our businesses as a result.

The Author

Peter Cochrane is the ex-BT Chief Technologist, who with a group of ex-Apple Computer technologists founded Concept Labs, where he advises a range of companies across the world. He has published widely, holds B.Sc., M.Sc., Ph.D., and D.Sc. degrees from Nottingham (Trent) and Essex Universities, is an Apple Master, and is a visiting professor at London, Essex, and Southampton Universities. He is best known for his incisive and often provocative views on the United Kingdom and world telecommunications industries.

Read Any Good Books Lately?

Then why not share your thoughts with the readers of IPJ? We accept reviews of new titles, as well as some of the "networking classics." In some cases, we may be able to get a publisher to send you a book for review if you don't have access to it. Contact us at **ipj@cisco.com** for more information.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

The Internet Protocol Journal is published quarterly by the Chief Technology Office, Cisco Systems, Inc.

A Quarterly Technical Publication for Internet and Intranet Professionals

In This Issue

From The Editor

Identity theft is a widely reported problem in today's world. Criminals can use numerous ways to obtain private information such as Social Security Numbers, credit card details, and other information that makes it possible for the perpetrator to successfully "pretend to be" someone else. A similar concept, albeit less personal, is so-called *IP Spoofing*, wherein fake IP datagrams can be generated and sent across the network in order to compromise remote systems in a variety of ways. Farha Ali gives an overview of IP Spoofing and explains ways in which the problem can be mitigated.

Our second article looks at numerous standards for information security management being developed by organizations such as the *International Organization for Standardization* (ISO), the *National Institute of Standards and Technology* (NIST), and others. The author of the article is William Stallings.

On November 2, 2007, Vint Cerf ended his term as chairman of the *Internet Corporation for Assigned Names and Numbers* (ICANN). At the same time he released a document entitled "Looking Toward the Future," which details ICANN's history, as well as outlining its challenges ahead. We've included the document in this issue and added some pointers for those readers who may not be familiar with the workings of ICANN.

In late October, the Internet technical community received the sad news that Dr. Junichiro Hagino, universally known as "Itojun" had passed away. Itojun played a very important role in the development of IPv6 and had many friends across the world. We asked one of them, Bob Hinden, to reflect on Itojun's life and compile some comments from those who knew him well.

We would like to remind you about our online adjunct to this journal. *The Internet Protocol Forum* (IPF) available at **http://www.ipjforum.org/** is a resource you can use to discuss articles and read additional material. Please take a moment to explore IPF.

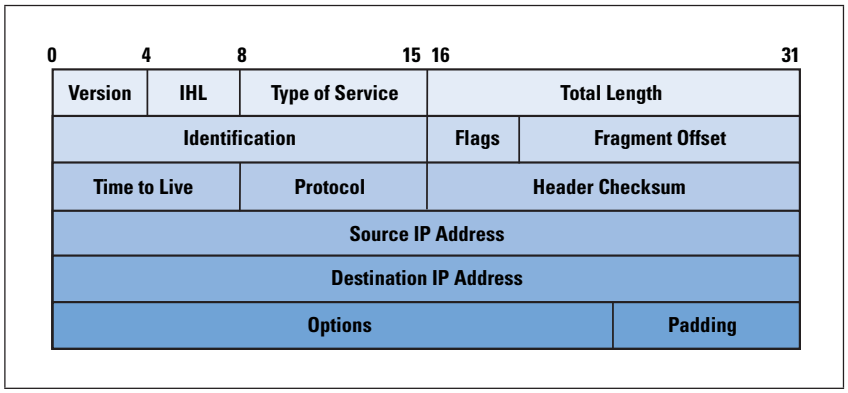
IP Spoofing

by Farha Ali, Lander University

The *Internet Protocol*, or IP, is the main protocol used to route information across the Internet. The role of IP is to provide best-effort services for the delivery of information to its destination. IP depends on upper-level TCP/IP suite layers to provide accountability and reliability. The heart of IP is the IP *datagram*, a packet sent over the Internet in a connectionless manner. An IP datagram carries enough information about the network to get forwarded to its destination; it consists of a *header* followed by bytes of *data*. The header contains information about the type of IP datagram, how long the datagram should stay on the network (or how many hops it should be forwarded to), special flags indicating any special purpose the datagram is supposed to serve, the destination and source addresses, and several other fields, as shown in Figure 1.

Figure 1: The IP Header



Layers above IP use the source address in an incoming packet to identify the sender. To communicate with the sender, the receiving station sends a reply by using the source address in the datagram. Because IP makes no effort to validate whether the source address in the packet generated by a node is actually the source address of the node, you can spoof the source address and the receiver will think the packet is coming from that spoofed address. Many programs for preparing spoofed IP datagrams are available for free on the Internet; for example, *hping* lets you prepare spoofed IP datagrams with just a one-line command, and you can send them to almost anybody in the world. You can spoof at various network layers; for example, you can use *Address Resolution Protocol* (ARP) spoofing to divert the traffic intended for one station to someone else. The *Simple Mail Transfer Protocol* (SMTP) is also a target for spoofing; because SMTP does not verify the sender's address, you can send any e-mail to anybody pretending to be someone else. This article focuses on the various types of attacks that involve IP spoofing on networks, and the techniques and approaches that experts in the field suggest to contend with this problem.

Spoofing IP datagrams is a well-known problem that has been addressed in various research papers. Most spoofing is done for illegitimate purposes—attackers usually want to hide their own identity and somehow damage the IP packet destination. This article discusses ways of spoofing IP datagrams, various attacks that involve spoofed IP packets, and techniques to detect spoofed packets and trace them back to their original source; spoofing concerns for IPv6 are briefly addressed.

Spoofing an IP Datagram

IP packets are used in applications that use the Internet as their communications medium. Usually they are generated automatically for the user, behind the scenes; the user just sees the information exchange in the application. These IP packets have the proper source and destination addresses for reliable exchange of data between two applications. The IP stack in the operating system takes care of the header for the IP datagram. However, you can override this function by inserting a custom header and informing the operating system that the packet does not need any headers. You can use raw sockets in UNIX-like systems to send spoofed IP datagrams, and you can use packet drivers such as *WinPcap* on Windows. Some socket programming knowledge is enough to write a program for generating crafted IP packets. You can insert any kind of header, so, for example, you can also create *Transmission Control Protocol* (TCP) headers. If you do not want to program or have no knowledge of programming, you can use tools such as *hping, sendip,* and others that are available for free on the Internet, with very detailed documentation to craft any kind of packet. Most of the time, you can send a spoofed address IP packet with just a one-line command.

Why Spoof the IP Source Address?

What is the advantage of sending a spoofed packet? It is that the sender has some kind of malicious intention and does not want to be identified. You can use the source address in the header of an IP datagram to trace the sender's location. Most systems keep logs of Internet activity, so if attackers want to hide their identity, they need to change the source address. The host receiving the spoofed packet responds to the spoofed address, so the attacker receives no reply back from the victim host. But if the spoofed address belongs to a host on the same subnet as the attacker, then the attacker can "sniff" the reply. You can use IP spoofing for several purposes; for some scenarios an attacker might want to inspect the response from the target victim (called "nonblind spoofing"), whereas in other cases the attacker might not care (blind spoofing). Following is a discussion about reasons to spoof an IP packet.

Scanning

An attacker generally wants to connect to a host to gather information about open ports, operating systems, or applications on the host. The replies from the victim host can help the attacker in gathering information about the system.

These replies might indicate open ports, the operating system, or several applications running on open ports. For example, a response for connection at port 80 indicates the host might be running a Web server. The hacker can then try to *telnet* to this port to see the banner and determine the Web server version and type, and then try to exploit any vulnerability associated with that Web server. In the scanning case, attackers want to examine the replies coming back from the host, so they need to see the returned packet. If the spoofed address is actually an address of a host on the attacker's subnet, then the attacker can use a sniffer to see the packets.

Sequence-Number Prediction

If you establish the connection between two hosts by using TCP, the packets exchanged between the two parties carry sequence numbers for data and acknowledgments. The protocol uses these numbers to determine out-of-order and lost packets, thus ensuring the reliable delivery to the application layer as promised by TCP. These numbers are generated pseudo-randomly in a manner known to both the parties. An attacker might send several spoofed packets to a victim to determine the algorithm generating the sequence numbers and then use that knowledge to intercept an existing session. Again it is important for the attacker to be able to see the replies.

Hijacking an Authorized Session

An attacker who can generate correct sequence numbers can send a reset message to one party in a session informing that party that the session has ended. After taking one of the parties offline, the attacker can use the IP address of that party to connect to the party still online and perform a malicious act on it. The attacker can thus use a trusted communication link to exploit any system vulnerability. Keep in mind that the party that is still online will send the replies back to the legitimate host, which can send a reset to it indicating the invalid session, but by that time the attacker might have already performed the intended actions. Such actions can range from sniffing a packet to presenting a shell from the online host to the attacker's machine.

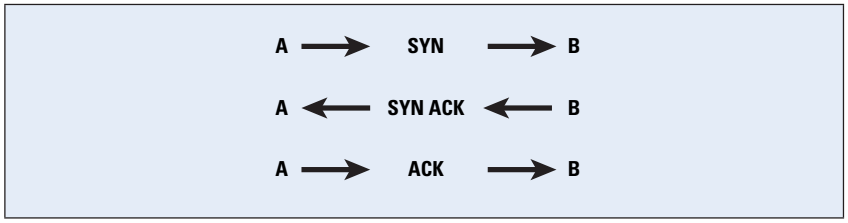
Determining the State of a Firewall

A firewall is used to protect a network from Internet intruders. Packets entering a firewall are checked against an *Access Control List* (ACL). TCP packets sent by a source are acknowledged by acknowledgment packets. If a packet seems like an acknowledgement to a request or data from the local network, then a stateful firewall also checks whether a request for which this packet is carrying the acknowledgment was sent from the network. If there is no such request, the packet is dropped, but a stateless firewall lets packets enter the network if they seem to carry an acknowledgment for a packet. Most probably the intended receiver sends some kind of response back to the spoofed address. Again, for this process to work, the attacker should be able to see the traffic returning to the host that has the spoofed address—and the attacker generally knows how to use the returned packet to advantage.

Denial of Service

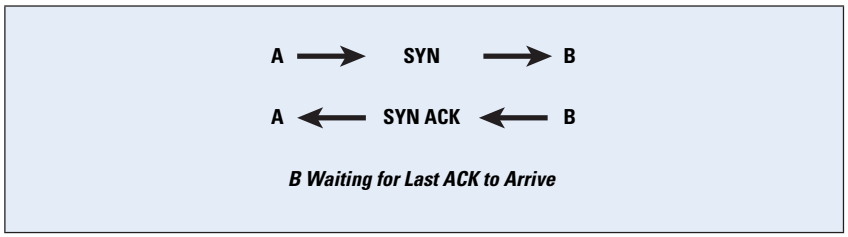
The connection setup phase in a TCP system consists of a *three-way handshake*. This handshake is done by using special bit combinations in the "flags" fields. If host A wants to establish a TCP connection with host B, it sends a packet with a SYN flag set. Host B replies with a packet that has SYN and ACK flags set in the TCP header. Host A sends back a packet with an ACK flag set, finishing the initial handshake. Then hosts A and B can communicate with each other, as shown in Figure 2.

Figure 2: A Normal TCP Connection Request from A to B



The three-way handshake must be completed in order to establish a connection. Connections that have been initiated but not finished are called *half-open connections*. A finite-size data structure is used to store the state of the half-open connections. An attacking host can send an initial SYN packet with a spoofed IP address, and then the victim sends the SYN-ACK packet and waits for a final ACK to complete the handshake. If the spoofed address does not belong to a host, then this connection stays in the half-open state indefinitely, thus occupying the data structure. If there are enough half-open connections to fill the state data structure, then the host cannot accept further requests, thus denying service to the legitimate connections (Figure 3).

Figure 3: Half-Open TCP Connection



Setting a time limit for half-open connections and then erasing them after the timeout can help with this problem, but the attacker may keep continuously sending the packets. The attacked host will not have space to accept new incoming legitimate connections, but the connection that was established before the attack will have no effect. In this type of attack, the attacker has no interest in examining the responses from the victim. When the spoofed address does belong to a connected host, that host sends a reset to indicate the end of the handshake.

Flooding

In this type of attack an attacker sends a packet with the source address of the victim to multiple hosts. Responses from other machines flood the victim. For example, if an attacker uses the IP address of source A and sends a broadcast message to all the hosts in the network, then all of them will send a reply back to A, hence flooding it. The well-known *Smurf* and *fraggle* attacks used this technique.

Countermeasures for IP Spoofing

IP spoofing countermeasures include detecting spoofed IP packets and then tracing them back to the originating source. Detection of spoofed IP packets requires support of routers, host-based methods, and administrative controls, whereas tracing of IP packets involves special traceback equipment or traceback features in routers. The following section discusses both IP spoofing detection and IP spoofing traceback techniques.

Spoofed Packet Detection

Detection of a spoofed packet can start as early as at Layer 2. Switches with the *IP Source Guard* feature[8] match the MAC address of the host with a *Dynamic Host Configuration Protocol* (DHCP)-assigned dynamic or administratively assigned static IP address. Packets that do not have the correct IP source address for that particular MAC address are dropped, thereby limiting the ability of hosts connected to such a switch to send a packet with their neighbor's address. The IP Source Guard feature works very well for interfaces with a single IP address, but one interface can be assigned multiple IP addresses, and that may cause problems. The same problems can occur with *Network Address Translation* (NAT), where hosts might get different IP addresses several times. Routers work at Layer 3 in networks, and they know which interface a network is connected to and what network addresses can be expected to come from that network. If the outgoing packet from an interface does not have the network address of that interface, then the packet is spoofed and the router can stop that packet at that point; however, if the attacker is spoofing an IP address of a host on the same network (most likely in the attacks where they will be sniffing the replies), then this technique is not really helpful. The same logic can be used for an incoming packet; if a packet destined for an interface has a source address of the same network as the interface, then it is a spoofed packet. Routers can detect spoofed packets only when the packets pass through them, and if the target and attacker are both on the same subnet then this technique does not work.

Hosts receiving a suspicious packet can also use certain techniques to determine whether or not the IP address is spoofed. The first (and easiest) one is to send a request to the address of the packet and wait for the response; most of the time the spoofed addressees do not belong to active hosts and hence no response is sent.

Another method is to check the *Time to Live* (TTL) value of the packet, and then send a request to the spoofed host. If the reply comes, you can compare the TTL of both packets. Most probably the TTL values will not match. But of course it is also possible that these TTL values are the same but the packet is coming from a different source, and conversely. Packets generated by different operating systems differ slightly in values of certain fields; for example, in *Internet Control Message Protocol* (ICMP) *ping* packets, you can examine the data payload to determine the operating system. Windows fills the packet with letters of the alphabet, whereas Linux puts numbers in the data portion. If the suspicious packet does not have the same characteristics as the legitimate packet, that is evidence it was not sent from the IP address that is in its source address field. You can also use IP identification numbers to determine whether a packet is actually coming from the said source. For legitimate packets the IP ID is close in value, but this method is not reliable because the attacker can ping the said source and determine the IP ID that it is using, and then craft packets that will seem legitimate. In all these techniques we are trying to determine only whether or not a packet is spoofed, and taking all these steps for all packets would be prohibitive from an overhead standpoint. Thus you should either randomly check packets or determine some suspicious activity that would trigger further investigation for spoofed-packet detection. The next section addresses measures you can take to trace a spoofed packet back to its real source.

Tracing Spoofed IP Packets

IP traceback technology plays an important role in discovering the source of spoofed packets. Hop-by-hop traceback and logging of suspicious packets in routers are the two main methods for tracing the spoofed IP packets back to their source.

When a node detects that it is a victim of flood attack, it can inform the *Internet Service Provider* (ISP). In flood attacks the ISP can determine the router that is sending this stream to the victim, and then it can determine the next router, and so on. It reaches either to the source of the flood attack or the end of its administrative domain; for this case it can ask the ISP for the next domain to do the same thing. This technique is useful only if the flood is ongoing.

As mentioned earlier, a router has an idea of the IP addresses that should be arriving at its interfaces. If it sees any packet that does not seem to belong to the address range for its interface, it can log the packet as suspicious. Appropriately timed broadcasts among different domains to detect spoofed packets can help administrators of different networks trace spoofed IP packets back to their source.

IP Spoofing and IPv6

IP spoofing detection, or in other words validating the source address of an IPv6 packet, is a little more complicated than the process for IPv4. A host using IPv6 may potentially have multiple addresses. Again the problem inside the Local Area Network is to associate the IPv6 address with the Layer 2 or MAC address. Among peers on the same network, you can use *Neighbor Discovery* or *Secure Neighbor Discovery* (SEND) advertisements to verify the source address in a packet. You can verify source addresses of packets arriving from nodes outside the network by using the *Authentication Header* (AH) in IPv6 datagrams. You can use agreed-upon parameters between source and destination to calculate authentication information on header fields that does not change during transit. Although this process will not prevent someone from signing a spoofed address, it does provide a means to authenticate the identity of the source.

IPv6 and IPv4 network interconnections will likely face spoofing problems. IPv6 packets are usually encapsulated in IPv4 packets to travel across the non-IPv6 supporting networks. The IPv6 interim mechanism "6to4"[10, 11] uses automatic IPv6-to-IPv4 tunneling to interconnect networks using different IP versions. This mechanism uses 6to4 routers and 6to4 *Relay Routers* that accept and decapsulate IPv4 traffic from anywhere. There are no constraints on such embedded packets. Relay routers act as bridges between IPv6 and 6to4 networks and can be tricked into sending spoofed traffic anywhere. Also, anyone can send tunneled spoofed traffic to a 6to4 router, and the router will believe that it is coming from a legitimate relay. There is no simple way to prevent such attacks, and longer-term solutions are needed in both IPv6 and IPv4 networks.

Conclusion

IP spoofing is a difficult problem to tackle, because it is related to the IP packet structure. IP packets can be exploited in several ways. Because attackers can hide their identity with IP spoofing, they can make several network attacks. Although there is no easy solution for the IP spoofing problem, you *can* apply some simple proactive and reactive methods at the nodes, and use the routers in the network to help detect a spoofed packet and trace it back to its originating source.

Standards for Information Security Managment

by William Stallings

To effectively assess the security needs of an organization and to evaluate and choose various security products and policies, the manager responsible for security needs some systematic way of defining the requirements for security and characterizing the approaches to satisfy those requirements. This process is difficult enough in a centralized data processing environment; with the use of local- and wide-area networks (LANs and WANs, respectively), the problems are compounded.

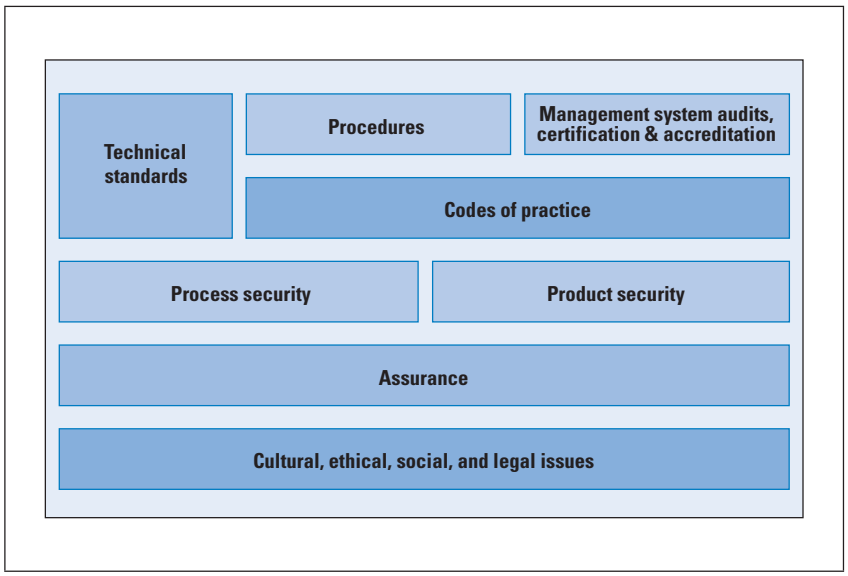
The challenges for management in providing information security are formidable. Even for relatively small organizations, information system assets are substantial, including databases and files related to personnel, company operation, financial matters, and so on. Typically, the information system environment is complex, including a variety of storage systems, servers, workstations, local networks, and Internet and other remote network connections. Managers face a range of threats always growing in sophistication and scope. And the range of consequences for security failures, both to the company and to individual managers, is substantial, including financial loss, civil liability, and even criminal liability.

Standards for providing information system security become essential in such circumstances. Standards can define the scope of security functions and features needed, policies for managing information and human assets, criteria for evaluating the effectiveness of security measures, techniques for ongoing assessment of security and for the ongoing monitoring of security breaches, and procedures for dealing with security failures.

Figure 1, based on [1], suggests the elements that, in an integrated fashion, constitute an effective approach to information security management. The focus of this approach is on two distinct aspects of providing information security: process and products. *Process security* looks at information security from the point of view of management policies, procedures, and controls. *Product security* focuses on technical aspects and is concerned with the use of certified products in the IT environment when possible. In Figure 1, the term *technical standards* refers to specifications that refer to aspects such as IT network security, digital signatures, access control, nonrepudiation, key management, and hash functions. Operational, management, and technical *procedures* encompass policies and practices that are defined and enforced by management. Examples include personnel screening policies, guidelines for classifying information, and procedures for assigning user IDs. *Management system audits, certification, and accreditation* deals with management policies and procedures for auditing and certifying information security products.

Codes of practice refer to specific policy standards that define the roles and responsibilities of various employees in maintaining information security. *Assurance* deals with product and system testing and evaluation. *Cultural, ethical, social, and legal issuers* refer to human factors aspects related to information security.

Figure 1: Information Security Management Elements



Many standards and guideline documents have been developed in recent years to aid management in the area of information security. The two most important are *ISO 17799*, which deals primarily with process security, and the *Common Criteria*, which deals primarily with product security. This article surveys these two standards, and examines some other important standards and guidelines as well.

ISO 17799

An increasingly popular standard for writing and implementing security policies is *ISO 17799* "Code of Practice for Information Security Management." (ISO 17799 will eventually be reissued as ISO 27002 in the new ISO 27000 family of security standards). ISO 17799 is a comprehensive set of controls comprising best practices in information security. It is essentially an internationally recognized generic information security standard. Table 1 summarizes the area covered by this standard and indicates the objectives for each area.

Table 1: ISO 17799 Areas and Objectives

Security Policy Provide management direction and support for information security in accordance with business requirements and relevant laws and regulations. **Organization of Information Security** Manage information security within the organization. Maintain the security of the organization's information and information processing facilities that are accessed, processed, communicated to, or managed by external parties. **Asset Management** Achieve and maintain appropriate protection of organizational assets. Ensure that information receives an appropriate level of protection. **Human Resources Security** Ensure that employees, contractors, and third-party users (1) understand their responsibilities and are suitable for the roles they are considered for; (2) are aware of information security threats and concerns; (3) exit an organization or change employment in an orderly manner. **Physical and Environmental Security** Prevent unauthorized physical access, damage, and interference to the organization's premises and information. Prevent loss, damage, theft, or compromise of assets and interruption to the organization's activities. **Communications and Operations Management** Develop controls for operational procedures, third-party service delivery management, system planning, malware protection, backup, network security management, media handling, information exchange, e-commerce services, and monitoring.	**Access Control** Develop controls for business requirements for user access, user responsibilities, network access control, OS access control, application access control, and information access control. **Information Systems Acquisition, Development, and Maintenance** Develop controls for correct processing in applications, cryptographic functions, system file security, support process security, and vulnerability management. **Information Security Incident Management** Ensure information security events and weaknesses associated with information systems are communicated in a manner that allows timely corrective action to be taken. Ensure a consistent and effective approach is applied to the management of information security incidents. **Business Continuity Management** Counteract interruptions to business activities to protect critical business processes from the effects of major failures of information systems or disasters and to ensure their timely resumption. **Compliance** Avoid breaches of any law, statutory, regulatory, or contractual obligations, and of any security requirements. Ensure compliance of systems with organizational security policies and standards. Maximize the effectiveness of and minimize interference to and from the information systems audit process.

With the increasing interest in security, ISO 17799 certification, provided by various accredited bodies, has been established as a goal for many corporations, government agencies, and other organizations around the world. ISO 17799 offers a convenient framework to help security policy writers structure their policies in accordance with an international standard.

Much of the content of ISO 17799 deals with security controls, which are defined as practices, procedures, or mechanisms that may protect against a threat, reduce a vulnerability, limit the effect of an unwanted incident, detect unwanted incidents, and facilitate recovery. Some controls deal with security management, focusing on management actions to institute and maintain security policies. Other controls are operational; they address the correct implementation and use of security policies and standards, ensuring consistency in security operations and correcting identified operational deficiencies. These controls relate to mechanisms and procedures that are primarily implemented by people rather than systems.

Finally, there are technical controls; they involve the correct use of hardware and software security capabilities in systems. These controls range from simple to complex measures that work together to secure critical and sensitive data, information, and IT systems functions. This concept of controls cuts across all the areas listed in Table 1.

To give some idea of the scope of ISO 17799, we examine several of the security areas discussed in that document. *Auditing* is a key security management function that is addressed in multiple areas within the document. First, ISO 17799 lists key data items that should, when relevant, be included in an audit log:

- User IDs
- Dates, times, and details of key events, for example, log-on and log-off
- Terminal identity or location if possible
- Records of successful and rejected system access attempts
- Records of successful and rejected data and other resource access attempts
- Changes to system configuration
- Use of privileges
- Use of system utilities and applications
- Files accessed and the kind of access
- Network addresses and protocols
- Alarms raised by the access control system
- Activation and deactivation of protection systems, such as antivirus systems and intrusion detection systems

It provides a useful set of guidelines for implementation of an auditing capability:

1. Audit requirements should be agreed upon by appropriate management.
2. The scope of the checks should be agreed upon and controlled.
3. The checks should be limited to read-only access to software and data.
4. Access other than read-only should be allowed only for isolated copies of system files, which should be erased when the audit is completed or given appropriate protection if there is an obligation to keep such files under audit documentation requirements.
5. Resources for performing the checks should be explicitly identified and made available.
6. Requirements for special or additional processing should be identified and agreed upon.

7. All access should be monitored and logged to produce a reference trail; the use of timestamped reference trails should be considered for critical data or systems.
8. All procedures, requirements, and responsibilities should be documented.
9. The person(s) carrying out the audit should be independent of the activities audited.

Under the area of communications and operations management, ISO 17799 includes *network security management*. One aspect of this management is concerned with network controls for networks owned and operated by the organization. The document provides implementation guidance for these in-house networks. An example of a control follows: Restoration procedures should be regularly checked and tested to ensure that they are effective and that they can be completed within the time allotted in the operational procedures for recovery. Similarly, the document provides guidance for security controls for network services provided by outside vendors. An example of guidance in this area follows: The ability of the network service provider to manage agreed-upon services in a secure way should be determined and regularly monitored, and the right to audit should be agreed upon.

As can be seen, some ISO 17700 specifications are detailed and specific, whereas others are quite general.

Common Criteria

The *Common Criteria for Information Technology Security Evaluation* (CC) is a joint international effort by numerous national standards organizations and government agencies[3,4,5]. U.S. participation is by the *National Institute of Standards and Technology* (NIST) and the *National Security Agency* (NSA). CC defines a set of IT requirements of known validity that can be used in establishing security requirements for prospective products and systems. The CC also defines the *Protection Profile* (PP) construct that allows prospective consumers or developers to create standardized sets of security requirements that will meet their needs.

The aim of the CC specification is to provide greater confidence in the security of IT products as a result of formal actions taken during the process of developing, evaluating, and operating these products. In the development stage, the CC defines sets of IT requirements of known validity that can be used to establish the security requirements of prospective products and systems. Then the CC details how a specific product can be evaluated against these known requirements, to provide confirmation that it does indeed meet them, with an appropriate level of confidence. Lastly, when in operation the evolving IT environment may reveal new vulnerabilities or concerns. The CC details a process for responding to such changes, and possibly reevaluating the product.

Following successful evaluation, a particular product may be listed as CC certified or validated by the appropriate national agency, such as NIST or NSA in the United States. That agency publishes lists of evaluated products, which are used by government and industry purchasers who need to use such products.

The CC defines a common set of potential *security requirements* for use in evaluation. The term *Target of Evaluation* (TOE) refers to that part of the product or system that is subject to evaluation. The requirements fall into two categories:

- *Functional requirements:* Define desired security behavior. CC documents establish a set of security functional components that provide a standard way of expressing the security functional requirements for a TOE.
- *Assurance requirements:* The basis for gaining confidence that the claimed security measures are effective and implemented correctly. CC documents establish a set of assurance components that provide a standard way of expressing the assurance requirements for a TOE.

Both functional requirements and assurance requirements are organized into classes: A *class* is a collection of requirements that share a common focus or intent. Each of these classes contains numerous families. The requirements within each *family* share security objectives but differ in emphasis or rigor. For example, the audit class contains six families dealing with various aspects of auditing (for example, audit data generation, audit analysis, and audit event storage). Each family, in turn, contains one or more components. A *component* describes a specific set of security requirements and is the smallest selectable set of security requirements for inclusion in the structures defined in the CC.

For example, the cryptographic support class of functional requirements includes two families: cryptographic key management and cryptographic operation. The cryptographic key management family has four components, which are used to specify key generation algorithm and key size; key distribution method; key access method; and key destruction method. For each component, a standard may be referenced to define the requirement. Under the cryptographic operation family, there is a single component, which specifies an algorithm and key size based on a an assigned standard.

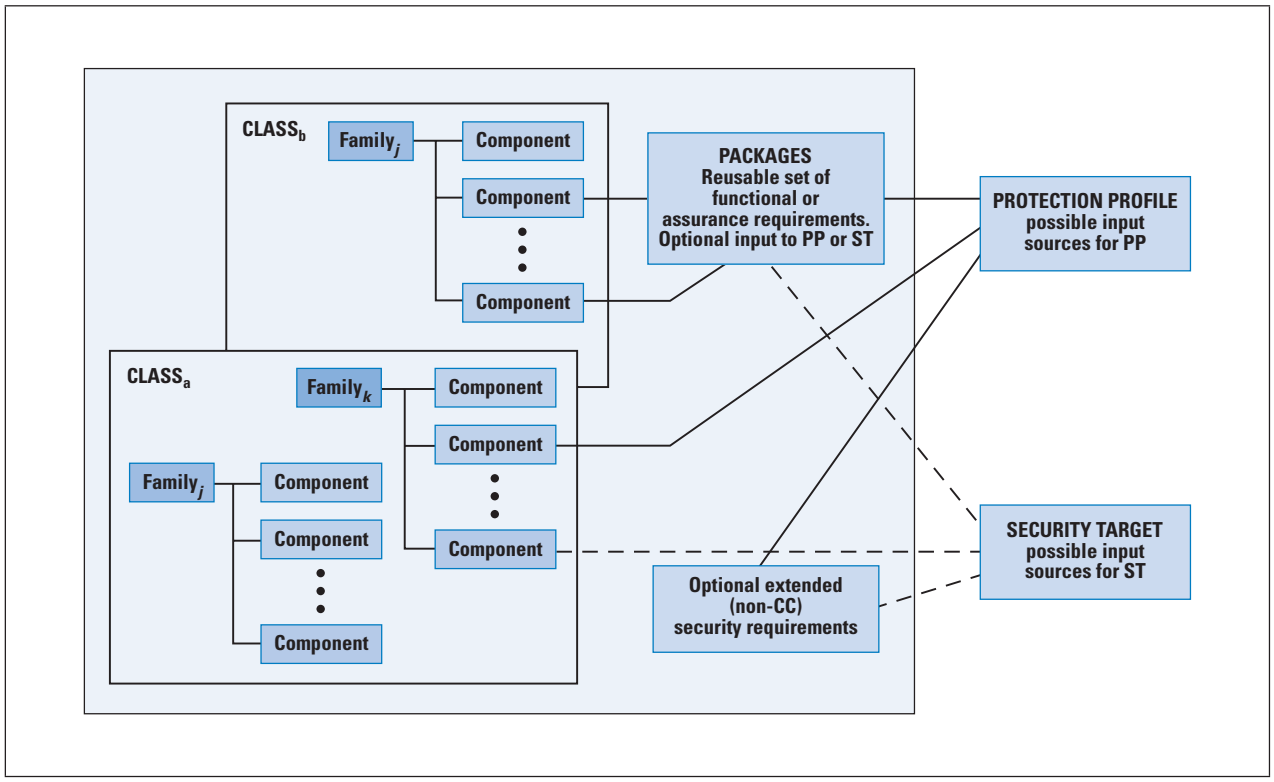
Sets of functional and assurance components may be grouped together into reusable packages, which are known to be useful in meeting identified objectives. An example of such a package would be functional components required for *Discretionary Access Controls*.

The CC also defines two kinds of documents that can be generated using the CC-defined requirements.

- *Protection profiles (PPs):* Define an implementation-independent set of security requirements and objectives for a category of products or systems that meet similar consumer needs for IT security. A PP is intended to be reusable and to define requirements that are known to be useful and effective in meeting the identified objectives. The PP concept has been developed to support the definition of functional standards and as an aid to formulating procurement specifications. The PP reflects user security requirements.
- *Security targets (STs):* Contain the IT security objectives and requirements of a specific identified TOE and define the functional and assurance measures offered by that TOE to meet stated requirements. The ST may claim conformance to one or more PPs and forms the basis for an evaluation. The ST is supplied by a vendor or developer.

Figure 2 illustrates the relationship between requirements on the one hand and profiles and targets on the other. For a PP, a user can select many components to define the requirements for the desired product. The user may also refer to predefined packages that assemble numerous requirements commonly grouped together within a product requirements document. Similarly, a vendor or designer can select numerous components and packages to define an ST.

Figure 2: Organization and Construction of Common Criteria Requirements



As an example for the use of the CC, consider the smart card. The protection profile for a smart card, developed by the *Smart Card Security User Group,* provides a simple example of a PP. This PP describes the IT security requirements for a smart card to be used in connection with sensitive applications, such as banking industry financial payment systems. The assurance level for this PP is *Evaluation Assurance Level* (EAL) 4, which is described subsequently. The PP lists *threats* that must be addressed by a product that claims to comply with this PP. The threats include the following:

- *Physical probing:* May entail reading data from the TOE through techniques commonly employed in *Integrated Circuit* (IC) failure analysis and IC reverse engineering efforts.
- *Invalid input:* Invalid input may take the form of operations that are not formatted correctly, requests for information beyond register limits, or attempts to find and execute undocumented commands. The result of such an attack may be a compromise in the security functions, generation of exploitable errors in operation, or release of protected data.
- *Linkage of multiple operations:* An attacker may observe multiple uses of resources or services and, by linking these observations, deduce information that may reveal security function data.

Following a list of threats, the PP turns to a description of *security objectives*, which reflect the stated intent to counter identified threats or comply with any organizational security policies identified. Nineteen objectives are listed, including the following:

- *Audit:* The system must provide the means of recording selected security-relevant events, so as to assist an administrator in the detection of potential attacks or misconfiguration of the system security features that would leave it susceptible to attack.
- *Fault insertion:* The system must be resistant to repeated probing through insertion of erroneous data.
- *Information leakage:* The system must provide the means of controlling and limiting the leakage of information in the system so that no useful information is revealed over the power, ground, clock, reset, or I/O lines.

Security requirements are provided to thwart specific threats and to support specific policies under specific assumptions. The PP lists specific requirements in three general areas: TOE security functional requirements, TOE security assurance requirements, and security requirements for the IT environment. In the area of *security functional requirements,* the PP defines 42 requirements from the available classes of security functional requirements.

For example, for security auditing, the PP stipulates what the system must audit; what information must be logged; what the rules are for monitoring, operating, and protecting the logs; and so on. Functional requirements are also listed from the other functional requirements classes, with specific details for the smart card operation.

The PP defines 24 *security assurance requirements* from the available classes of security assurance requirements. These requirements were chosen to demonstrate:

- The quality of the product design and configuration
- That adequate protection is provided during the design and implementation of the product
- That vendor testing of the product meets specific parameters
- That security functions are not compromised during product delivery
- That user guidance, including product manuals pertaining to installation, maintenance, and use, are of a specified quality and appropriateness

The PP also lists *Security Requirements of the IT Environment*. They cover the following topics:

- Cryptographic key distribution
- Cryptographic key destruction
- Security roles

The final section of the PP (excluding appendices) is a lengthy rationale for all the selections and definitions in the PP. The PP is an industrywide effort designed to be realistic in its ability to be met by a variety of products with a variety of internal mechanisms and implementation approaches.

The concept of *Evaluation Assurance* is a difficult one to define. Further, the degree of assurance required varies from one context and one function to another. To structure the need for assurance, the CC defines a scale for rating assurance consisting of seven EALs ranging from the least rigor and scope for assurance evidence (EAL 1) to the most (EAL 7). The levels are as follows:

- *EAL 1: Functionally tested:* For environments where security threats are not considered serious. It involves independent product testing with no input from the product developers. The intent is to provide a level of confidence in correct operation.
- *EAL 2: Structurally tested:* Includes a review of a high-level design provided by the product developer. Also, the developer must conduct a vulnerability analysis for well-known flaws. The intent is to provide a low to moderate level of independently assured security.

- *EAL 3: Methodically tested and checked:* Requires a focus on the security features, including requirements that the design separate security-related components from those that are not; that the design specifies how security is enforced; and that testing be based both on the interface and the high-level design, rather than a black box testing based only on the interface. It is applicable where the requirement is for a moderate level of independently assured security, with a thorough investigation of the TOE and its development without incurring substantial reengineering costs.
- *EAL 4: Methodically designed, tested, and reviewed:* Requires both a low-level and a high-level design specification; requires that the interface specification be complete; requires an abstract model that explicitly defines security for the product; and requires an independent vulnerability analysis. It is applicable in those circumstances where developers or users require a moderate to high level of independently assured security in conventional commodity TOEs, and there is willingness to incur some additional security-specific engineering costs.
- *EAL 5: Semiformally designed and tested:* Provides an analysis that includes all of the implementation. Assurance is supplemented by a formal model and a semiformal presentation of the functional specification and high-level design and a semiformal demonstration of correspondence. The search for vulnerabilities must ensure resistance to penetration attackers with a moderate attack potential. Covert channel analysis and modular design are also required.
- *EAL 6: Semiformally verified design and tested:* Permits a developer to gain high assurance from application of specialized security engineering techniques in a rigorous development environment, and to produce a premium TOE for protecting high-value assets against significant risks. The independent search for vulnerabilities must ensure resistance to penetration attackers with a high attack potential.
- *EAL 7: Formally verified design and tested:* The formal model is supplemented by a formal presentation of the functional specification and high-level design, showing correspondence. Evidence of developer "white box" testing of internals and complete independent confirmation of developer test results are required. Complexity of the design must be minimized.

The first four levels reflect various levels of commercial design practice. Only at the highest of these levels (EAL 4) is there a requirement for any source code analysis, and this analysis is required only for a portion of the code. The top three levels provide specific guidance for products developed using security specialists and security-specific design and engineering approaches.

National Institute of Standards and Technology

NIST has produced a large number of *Federal Information Processing Standards Publications* (FIPS PUBs) and special publications (SPs) that are enormously useful to security managers, designers, and implementers. Following are a few of the most significant and general. *FIPS PUB 200* "Minimum Security Requirements for Federal Information and Information Systems," is a standard that specifies minimum security requirements in 17 security-related areas with regard to protecting the confidentiality, integrity, and availability of federal information systems and the information processed, stored, and transmitted by those systems[6].

NIST *SP 800-100* "Information Security Handbook: A Guide for Managers," provides a broad overview of information security program elements to assist managers in understanding how to establish and implement an information security program[7]. Its topical coverage overlaps considerably with ISO 17799.

Several other NIST publications are of general interest. *SP 800-55* "Security Metrics Guide for Information Technology Systems," provides guidance on how an organization, through the use of metrics, identifies the adequacy of in-place security controls, policies, and procedures[8]. *SP 800-27* "Engineering Principles for Information Technology Security (A Baseline for Achieving Security)," presents a list of system-level security principles to be considered in the design, development, and operation of an information system[9]. *SP 800-53* "Recommended Security Controls for Federal Information Systems," lists management, operational, and technical safeguards or countermeasures prescribed for an information system to protect the confidentiality, integrity, and availability of the system and its information[10].

Other Standards and Guidelines

Another important set of standards is the *Control Objectives for Information and Related Technology* (COBIT)[11], a business-oriented set of standards for guiding management in the sound use of information technology. It has been developed as a general standard for information technology security and control practices and includes a general framework for management, users, IS audit, and security practitioners. COBIT also has a process focus and a governance flavor; that is, management's need to control and measure IT is a focus point. COBIT was developed under the auspices of a professional organization, the *Information Systems Audit and Control Association* (ISACA). The documents are quite detailed and provide a practical basis for not only defining security requirements but also implementing them and verifying compliance.

Another excellent source of information is "The Standard of Good Practice for Information Security" from the *Information Security Forum*. The standard is designed as an aid to organizations in understanding and applying best practices for information security. Because it addresses security from a business perspective, The Standard appropriately recognizes the intersection between organizational factors and security factors.

In addition to these standards, numerous informal guidelines are widely consulted by organizations in developing their own security policy. The *CERT Coordination Center* (**www.cert.org**) has an Evaluations and Practices section of its Website with a variety of documents and training aids related to information security for organizations. The *Chief Information Officers Council* (**cio.gov**) has published a collection of Best Practices and other documents related to organizational security.

Looking Toward the Future

by Vint Cerf, Google

The *Internet Corporation for Assigned Names and Numbers* (ICANN) was formed 9 years ago, following a period of considerable debate about the institutionalization of the basic functions performed by the *Internet Assigned Numbers Authority* (IANA)[1]. Nearly simultaneous with the inauguration of ICANN in September 1998 came the unexpected and untimely death of the man, Jonathan B. Postel[2], who had responsibility for these functions for more than a quarter century. The organization began with very limited sources of funds, a small and overworked staff, and contentious debate about its organizational structure, policy apparatus, and operational procedures. The organization underwent substantial change through its *Evolution and Reform Process* (ERP)[3]. Among the more difficult constituencies to accommodate in the organization's policy-making process was the general public. An *At-Large Advisory Committee* (ALAC)[4] emerged from the ERP and has recently formed *Regional At-Large Organizations* (RALOs) in all of ICANN's five regions.

Today, ICANN is larger, more capable, more international, and better positioned to fulfill its mandate. It stands for one global, interoperable Internet, and the model of stakeholder representation has worked. But the Internet and its vast user population have grown during the same time by a factor of more than 20 in all dimensions. The 50 million users of 1997 have become nearly 1.2 billion users today. The 22 million hosts on the network have increased to nearly 500 million today. The bandwidth of the core data circuits in the Internet have grown from 622 million bits per second to between 10 and 40 billion bits per second. This dramatic growth in physical size has been accompanied by an equally dramatic growth in the number and diversity of applications running on the Internet. All forms of media now appear on and are carried by Internet packets. Consumers of information are producing more and more of it themselves with e-mail, blogs, instant messaging, social and game-playing Websites, video uploads, and podcasts. The Internet continues to evolve and although ICANN has achieved more than most people realize, it must continue to evolve along with it.

Operational Priorities

ICANN's primary responsibility is to contribute to the security and stability of the Internet system of unique identifiers. In the most direct way, it carries out this mandate through its operation of the IANA. There is no doubt that the conduct of this function in an exemplary fashion is essential not only to ICANN's mission but also to inspiring confidence in ICANN as an organization.

But ICANN's role in the Internet goes beyond these specific IANA functions. ICANN is an experiment in the balancing of multiple stakeholder interests in policy about the implementation, operation, and use of the *Domain Name System* (DNS) and the address spaces of the Internet. Its policy choices can directly affect the business models of operating entities involved in the management of domain names and Internet addresses. The privacy and Internet-related rights of registrants and, more generally, Internet users may also be directly affected. Some policy choices raise public policy concerns in the view of governments and methods and will be needed to factor such concerns into the making of ICANN policy.

Effective, fair, and timely policy development should be a priority for ICANN. That this policy development needs to be achieved in a global setting is simply another challenge to be met. ICANN leadership and staff must seek to maintain and improve the ability of all of ICANN's many constituencies to achieve consensus or at least to prepare the ICANN Board to make choices when consensus may not be forthcoming. Because policies often have technical, economic, social, and governance implications, it is vital that ICANN's practices draw on expertise in all these domains.

Clarity in the roles and responsibilities of the many participants in the Internet arena, especially those with specific interest in ICANN policies and practices, will be helpful and should be documented. In some cases, the documentation might take the form of relatively formal relationships such as the contracts between ICANN and domain-name registries and registrars. In other cases, they may need only to characterize in plain terms the roles that each party plays.

In some areas, such as root-zone operation, excellence can be measured in such terms as responsiveness, scalability, resilience to disruption, and ability to adapt to changing needs such as *Domain Name System Security* (DNSSEC)[5], *Internationalized Domain Names* (IDNs)[6], and the addition of IPv6 records to the root zone. Many parties currently play a role in the maintenance of the root-zone file, and clear documentation of responsibility and lines of authority will be beneficial. As the technology of the Internet continues to evolve, the roles of various parties may need to change to meet the objectives of stability and security of the Internet system of unique identifiers. Managing the evolution of these roles represents another priority for policy development and implementation.

Because of the potential effect of decisions made through the ICANN policy process, it is important to implement checks and balances that make all aspects of ICANN's operation accountable and transparent. Work is still necessary in this area so that independent review of legitimate concerns arising out of policy making is possible when deemed necessary.

At the same time, it is vital that the mechanisms chosen do not have the effect of locking up the policy-making process and preventing any decisions from being made. We need to seek a balance between a potentially unfair tyranny of the majority and an equally unacceptable tyranny of the minority.

The general success of the *Uniform Dispute Resolution Process* (UDRP)[7] suggests that ICANN should seek mechanisms for resolving disputes arising in connection with implementing ICANN policies that scale, permit choice without abusive "forum shopping," and make efficient use of ICANN resources.

Outreach, transparency, and broadly participatory processes on an international basis are not inexpensive. It is vital for ICANN to continue to refine its models for sustainable operation, accounting for the economics of the various actors in the Internet arena that rely on ICANN's operation, and fairly apportioning costs of ICANN operation to appropriate sources of support. Not all of the beneficiaries of ICANN's work derive the same level of revenue from the Internet (and some, none at all). ICANN must account for this discrepancy when devising mechanisms for supporting its operation, and it should work to make transparent the need to provide services to parties who may not be able to contribute commensurate with cost. Adequate and stable funding for ICANN is necessary if ICANN is to fulfill its charter. Over the past several years, ICANN has significantly increased its ability to staff vital functions, contributing to the effectiveness of the organization. It should be a priority to assure adequate reserves to weather unanticipated expenses or periods of decreased income.

Organizational Perspectives

ICANN is a multistakeholder institution operating in the private sector but including the involvement of governments. Throughout its history, ICANN has sought to draw on international resources and to collaborate, coordinate, and cooperate with institutions whose expertise and responsibilities can assist ICANN in the achievement of its goals. ICANN should seek to establish productive relationships with these institutions, cementing its own place in the Internet universe while confining its role to its principal responsibilities.

As part of its normal operation, ICANN engages in self-examination and external review of the effectiveness of its organizational structure and processes. Improvements in all aspects of ICANN operation and structure will increase confidence in the organization and its ability to sustain long-term operation.

Finding and engaging competent participants and leaders in each of ICANN's constituent parts must be a priority. ICANN should seek to improve its ability to identify from around the world and attract highly qualified staff, executive leadership, board, and supporting organization participants. It is possible and even likely that improvements in the processes by which this process is done today will have significant payoff in the future.

Although ICANN does not bear a specific responsibility for achieving the *Millennium Development Goals* (MDGs) developed during the conduct of the *World Summit on the Information Society* (WSIS)[8], it has an opportunity to contribute to them both directly and indirectly. Its operation of its IANA functions and support for actors in the domain-name, Internet-address, and standards-development areas provides ICANN with a specific opportunity. Participation in forums dedicated to developing policies for Internet expansion and use offer indirect ways for ICANN to draw upon and provide expertise in these areas.

It has been demonstrated that the presence of ICANN staff in various regions and time zones around the world and familiarity with local languages and customs has been beneficial to parties reliant on ICANN for its services. ICANN should continue to seek ways to improve its effectiveness in this area. The introduction of the Fellowship program that supports the participation of qualified candidates in ICANN-related activities is a vital step in facilitating ICANN's outreach to the developing world. We should pursue expansion of this program through partnerships with other like-minded organizations in the interest of the globalization of ICANN.

It is possible that the present formulation of ICANN as a not-for-profit, charitable research and education entity under California law could be beneficially adapted to a more international framework. As part of its long-term strategic development, ICANN should evaluate a variety of alternatives on the possibility that a change could increase the effectiveness of its operation.

The successful creation of five Regional At-Large Organizations, one in each of ICANN's five regions, needs to be followed by a serious effort to engage these entities in the formulation of ICANN policies and in dialog with the general user community. The various constituency reviews that form part of ICANN's normal processes should address the role of these entities in the conduct of ICANN business. To the extent that civil society is not fully represented through the *Governmental Advisory Committee* (GAC)[9] and the ALAC/RALO system, an organizational home may be needed to accommodate the interests of that constituency.

The five *Regional Internet Registries* (RIRs)[10] represent a key element in the Internet and ICANN pantheon. The RIRs have responsibility for allocating IP address space to Internet service providers and sometimes individual end-user organizations. They are the means by which bottom-up global policy is developed and recommended, through the *Number Resource Organization* (NRO)[11], to ICANN. It will require substantial coordination and cooperation between the RIRs and ICANN to work through the coming years of depletion of available new IPv4 address space and the rising implementation of the new IPv6 address space.

There is little doubt that economic incentives will emerge that will distort fair and neutral IPv4 address-space allocations as the available space is depleted. Minimizing the effect of this transition will be the joint responsibility of ICANN and the RIRs.

Similarly, ICANN's cooperative relationship with the *Root Server Operators*[12] will also demand coordination and capacity building as IPv4 and IPv6 addresses are associated with old and new domain names and as the IPv6 infrastructure grows. A vital objective is to assure that the IPv6 Internet and the IPv4 Internet are, to the extent possible, completely and totally coterminous. Every termination needs to be reachable through both address spaces. In the absence of this uniformity, some IPv6 addresses may be unreachable from others, defeating the goal of a single, interoperable, and fully reachable network.

Meeting the Challenges

As ICANN approaches the close of its first decade, the operational Internet will be turning 25. In the course of its evolution, it has become a global digital canvas on which a seemingly endless array of applications has been painted. Despite the broad swath of its current applications, it is almost certain that many, many more will be invented. All of them will rely, for the foreseeable future, on the basic architecture of the system, including the global Internet address space and the DNS. But the structure will become more complex. Two parallel address spaces, IPv4 and IPv6, will be in use. ICANN needs to promote the adoption of IPv6 so as to limit the side effects of the exhaustion of the unique address space provided by IPv4.

A vast and new range of non-Latin, internationalized domain names may be registered, certainly at the second or lower levels in the domain-name hierarchy, and many will be proposed for the top level. Their diversity will create new challenges for the protection of users from confusing and potentially abusive registrations. New dispute resolution principles may be needed to deal with domain-name registrations and delegations of new top-level domains. The exposure of ASCII *punycode* strings in browsers or other applications may produce additional stresses in the intellectual property arena (for example **`xn--cocacola`**).

Digital signatures will play an increasingly important role in validating the assignment of domain names and Internet addresses, and new protocols are certain to be invented and their parameters recorded by the IANA. Infrastructure for the management of digital certificates or other authentication mechanisms will be needed to realize the value of the DNSSEC concept.

More generally, the multilayer architecture of the Internet shows vulnerabilities of various kinds that demand redress. Attacks against the DNS root servers, name resolvers, and general name servers at all levels must be mitigated.

Some of the components of the DNS are actually used to exacerbate the effects of *Denial-of-Service* (DoS) attacks. Although ICANN does not have responsibility for developing the Domain Name technology, it can use its visibility and area of responsibility to highlight the need for increased security measures for the protection of the technical infrastructure of the Internet and to facilitate its implementation where ICANN has a direct involvement in its operation.

An increasing number of mobile devices will become Internet-enabled, as will appliances of all kinds. Access speeds will increase, enabling many new applications and enhancing older ones. All of this activity will contribute to increasing reliance on the Internet for a wide range of functions by an increasingly larger user population. Electronic commerce will continue to expand, placing high priority on the stable, secure, and reliable operation of all aspects of the Internet, including those within ICANN's purview.

Although some of these aspects of the evolution of the Internet will be of direct concern to ICANN, the ICANN organization and processes will need to pay attention to additional matters as well. The business processes that sustain the management of the Internet address space and domain names will almost certainly need to adapt to account for new applications. Some of these applications will monetize various aspects of the Internet in unexpected and innovative ways that will challenge existing policy and procedures. It will be extremely important for ICANN to evolve and strengthen its implementation of multistakeholder policy development. The interests of a wide range of entities must be balanced in the process.

Although adherence to a set of technical standards has allowed millions of component networks and systems to interwork on the Internet, it is also the case that many varying business models have sustained their operation. The richness and diversity of these models is one of the reasons that the Internet has proved to be so resilient in many dimensions. ICANN's policy-development processes need to account for an informed understanding of the economics of these varying business models and the ways in which ICANN policy may affect them.

On the Domain Name side, the development of market-savvy rules of operation for operators will be essential. ICANN needs to assure compliance with policies developed through the ICANN consensus process to establish confidence in the policy processes and their execution. Clear rules for the creation of new *Top Level Domains* (TLDs) of all kinds must be adopted and enforced.

The roles of registrars, registries, wholesale registry operators, root-server operators, regional Internet address registries, governments, and standards and technical research and development bodies, among others, need to be characterized so as to set expectations and permit the establishment of practical working relationships. The documentation of best practices will be beneficial, especially where the introduction of the Internet is new.

In matters of public policy—including but not limited to public safety, security, privacy, law enforcement, conduct of electronic commerce, protection of digital property, and freedom of speech—broad and international agreements may be needed if the Internet is to serve as a useful, global infrastructure. Many of these matters lie outside the formal purview of ICANN, but some ICANN policies and resulting operational practices will contribute to the global framework for life online. ICANN must seek to contribute to public confidence in the Internet and the processes that govern its operation. It cannot accomplish this objective alone. The coordinated and cooperative efforts of many distinct entities will be essential to achieving this goal. At the same time, ICANN must protect its processes from capture or abuse by interests that are inimical to the openness and accessibility of the Internet for everyone.

A Collective Goal

As of this writing, only about 1.2 billion people around the world use the Internet. Over the course of the next decade, that number could conceivably quintuple to 6 billion, and users will be depending on ICANN, among many others, to do its part to make the Internet a productive infrastructure that invites and facilitates innovation and serves as a platform for egalitarian access to information. It should be a platform that amplifies voices that might otherwise never be heard and creates equal opportunities for increasing the wealth of nations and their citizens.

ICANN's foundation has been well and truly fashioned. It is the work of many heads and hands. It represents a long and sometimes difficult journey that has called for personal sacrifices from many colleagues and bravery from others. It has demanded long-term commitments, long hours, days, months, and years. It has called upon many to transform passion and zeal into constructive and lasting compromises. ICANN has earned its place in the Internet universe. To those who now guide its path into the future comes the challenge to fashion an enduring institution on this solid foundation. I am confident that this goal is not only attainable but now also necessary. The opportunity is there: make it so.

VINTON G. CERF is vice president and chief Internet evangelist for Google. In this role, he is responsible for identifying new enabling technologies to support the development of advanced Internet-based products and services from Google. He is also an active public face for Google in the Internet world. Cerf is the former senior vice president of Technology Strategy for MCI. In this role, he helped guide corporate strategy development from a technical perspective. Previously, he served as MCI's senior vice president of Architecture and Technology, leading a team of architects and engineers to design advanced networking frameworks, including Internet-based solutions for delivering a combination of data, information, voice, and video services for business and consumer use.

Widely known as one of the "Fathers of the Internet," Cerf is the co-designer of the TCP/IP protocols and the architecture of the Internet. In December 1997, President Clinton presented the U.S. National Medal of Technology to Cerf and his colleague, Robert E. Kahn, for founding and developing the Internet. Kahn and Cerf were named the recipients of the ACM Alan M. Turing Award, sometimes called the "Nobel Prize of Computer Science," in 2004 for their work on the Internet protocols. In November 2005, President George Bush awarded Cerf and Kahn the Presidential Medal of Freedom for their work. The medal is the highest civilian award given by the United States to its citizens.

Prior to rejoining MCI in 1994, Cerf was vice president of the Corporation for National Research Initiatives (CNRI). As vice president of MCI Digital Information Services from 1982 to 1986, he led the engineering of MCI Mail, the first commercial e-mail service to be connected to the Internet.

During his tenure from 1976 to 1982 with the U.S. Department of Defense Advanced Research Projects Agency (DARPA), Cerf played a key role leading the development of Internet and Internet-related packet-data and security technologies.

Vint was seated on the ICANN Board of Directors at the 1999 annual meeting, having been selected by the Protocol Supporting Organization. He was then selected by the nominating committee for a term on the board of directors that ran from June 2003 through the 2004 annual meeting. At the end of that term, he was selected by the 2004 nominating committee to an additional term, which ran from the end of the 2004 annual meeting through the conclusion of the ICANN annual meeting in 2007. He served as founding president of the Internet Society from 1992 to 1995, and in 1999 served a term as chairman of the board. In addition, Cerf is honorary chairman of the IPv6 Forum, dedicated to raising awareness and speeding introduction of the new Internet Protocol. Cerf served as a member of the U.S. Presidential Information Technology Advisory Committee (PITAC) from 1997 to 2001 and serves on several national, state, and industry committees focused on cyber security. Cerf sits on the board of directors for the Endowment for Excellence in Education, Avanex Corporation, and the ClearSight Systems Corporation. Cerf is a Fellow of the IEEE, ACM, and American Association for the Advancement of Science, the American Academy of Arts and Sciences, the International Engineering Consortium, the Computer History Museum, and the National Academy of Engineering.

Cerf is a recipient of numerous awards and commendations in connection with his work on the Internet, including the Marconi Fellowship, Charles Stark Draper Award of the National Academy of Engineering, the Prince of Asturias Award for science and technology, the National Medal of Science from Tunisia, the Alexander Graham Bell Award presented by the Alexander Graham Bell Association for the Deaf, the NEC Computer and Communications Prize, the Silver Medal of the International Telecommunications Union, the IEEE Alexander Graham Bell Medal, the IEEE Koji Kobayashi Award, the ACM Software and Systems Award, the ACM SIGCOMM Award, the Computer and Communications Industries Association Industry Legend Award, installation in the Inventors Hall of Fame, the Yuri Rubinsky Web Award, the Kilby Award, the Yankee Group/Interop/Network World Lifetime Achievement Award, the George R. Stibitz Award, the Werner Wolter Award, the Andrew Saks Engineering Award, the IEEE Third Millennium Medal, the Computerworld/Smithsonian Leadership Award, the J.D. Edwards Leadership Award for Collaboration, the World Institute on Disability Annual Award, and the Library of Congress Bicentennial Living Legend medal. In December 1994, People magazine identified Cerf as one of that year's "25 Most Intriguing People."

In addition to his work on behalf of MCI and the Internet, Cerf has served as a technical advisor to production for the "Gene Roddenberry's Earth: Final Conflict" television series and made a special guest appearance on the program in May 1998. Cerf has appeared on television programs NextWave with Leonard Nimoy and on World Business Review with Alexander Haig and Caspar Weinberger. He is also a distinguished visiting scientist at the Jet Propulsion Laboratory, where he is working on the design of an interplanetary Internet.

Cerf holds a Bachelor of Science degree in Mathematics from Stanford University and Master of Science and Ph.D. degrees in Computer Science from UCLA. He also holds honorary doctorate degrees from the Swiss Federal Institute of Technology (ETH), Zurich; Luleå University of Technology, Sweden; University of the Balearic Islands, Palma; Capitol College, Maryland; Gettysburg College, Pennsylvania; George Mason University, Virginia; Rovira i Virgili University, Tarragona, Spain; Rensselaer Polytechnic Institute, Troy, New York; the University of Twente, Enschede, The Netherlands; Brooklyn Polytechnic; and the Beijing University of Posts and Telecommunications.

Cerf's personal interests include fine wine, gourmet cooking, and science fiction. Cerf and his wife Sigrid were married in 1966 and have two sons, David and Bennett.

Remembering Itojun: The IPv6 Samurai

by Bob Hinden, Nokia

"Itojun" (Dr. Junichiro Hagino) passed away on October 29, 2007. He was 37 years old. Memorial events were held in Tokyo in November and in Vancouver at the IETF meeting in December.

Itojun was an active participant in the IETF and a member of the IAB from 2003 to 2005. He worked as a Senior Researcher at the *Internet Initiative Japan* (IIJ) and was a member of the board of the *Widely Integrated Distributed Environment* (WIDE) project. He was a strong supporter of open standards development and open software, working as a core researcher at the KAME project, a joint effort of six companies in Japan to provide a free stack of IPv6, IPsec, and Mobile IPv6 for BSD variants, from 1998 to 2006.

Itojun was totally dedicated to the development and deployment of IPv6. Most of his work was centered around building a much larger worldwide Internet based on IPv6. He was simply the "IPv6 Samurai."

Photographer: Diane Bruce

Quotes from Internet Colleagues

Steve Deering: "Those of us who got to know Itojun through his work in the Internet Engineering Task Force have lost a dear friend and much-admired colleague. From the day he arrived at his first IETF meeting, he won the respect of all in the way most honored by Internet engineers: by helping to build consensus based on running code. Moreover, he provided the best possible example of collaboration, generosity, and leadership, making not only extraordinary technological contributions but also many friends and a better world. His untimely passing is a huge loss to all who knew him, and to all those who will never have that chance."

Randy Bush: "An open heart, a big soul, and very kind and patient. A very special person. He wrote a lot of great code and got great joy from doing so."

Marc Blanchet: "Itojun adopted the Samurai's philosophy in his life: *Bushido,* which consists of values such as Honesty, Justice, Courtesy, Heroic Courage, Honor, Compassion, Sincerity, Duty, and Loyalty. Very difficult to achieve, he encompassed all these. Moreover, he was always available to help, anyone, without judging. His intelligence, his competency, and his dedication has inspired a generation of network engineers for the project he took as a mission: IPv6. Many computers in the world now run his code. My family always enjoyed meeting Itojun. He was always interested in sharing his knowledge with my children, even with the French-to-Japanese-through-English language barrier. Itojun, it was an honor to know you and to meet you. You will always be a source of inspiration to me, to my family, and to many network engineers in the world. We miss you."

Rod Van Meter: "I didn't know Itojun very well; I met him for the first time about five years ago at an IPv6 meeting in the Silicon Valley, once or twice in between, and then spent three days at the WIDE Camp this past September co-supervising (with Bill Manning, Brad Huffaker, and Kenji Saito) a group of students trying to establish long-term goals for WIDE in the area of naming. Itojun was gentle but insistent with students, a good mentor. That was the last time I saw him. Go in peace, Itojun."

Joel Jaeggli: "He cared more for the people who were going to use the code and the product of his and our labor than anyone would have had a right to expect. The Itojun that I know, our friend, has been taken from us, but we'll be the beneficiary of the fact that he cared, for decades."

Itojun IPv6 Fund

Itojun's family has expressed sincere appreciation to all who attended the memorial and funeral services. His family has set up a memorial fund in Itojun's name under the directorship of the IETF/Internet Society. The fund will be used to award an R&D grant to a person who has contributed to the deployment and further advancement of IPv6. ISOC has set up an e-mail address to accept commitments for the *Itojun IPv6 Fund*. The address is: **itojun-fund@isoc.org**

The procedure for making contributions is being developed; if you wish to contribute now, please send a note to the e-mail address describing the amount you want to contribute (and in what currency), and ISOC will collect the funds.

ROBERT HINDEN is a Nokia Fellow at Nokia and is located in Mountain View, California, USA. He has been involved in the Internet since it was a research project at ARPA. He developed one of the first TCP/IP implementations and his team at Bolt, Beranek, and Newman, Inc. built and operated the routers that formed the early Internet backbone. He was co-recipient of the 2008 IEEE Internet Award "For pioneering work in the development of the first Internet routers." He has been active in the IETF since 1985 and is the author of 35 RFCs. He was recently appointed to a position on the IETF Administrative Oversight Committee (IAOC) and co-chairs the IPv6 Maintenance (6man) working group. Prior to this he served on the Internet Architecture Board (IAB), was Area Director for Routing in the Internet Engineering Steering group from 1987 to 1994, and chaired the IPv6, Virtual Router Redundancy Protocol, Simple Internet Protocol Plus, IP over ATM, and Open Routing working groups. Hinden is also a member of the RFC Editorial Board. He holds a B.S.E.E. and a M.S. in Computer Science from Union College, Schenectady, New York. E-mail: **bob.hinden@nokia.com**

Book Review

Network Routing

Network Routing: Algorithms, Protocols, and Architectures, by Deepankar Medhi and Karthikeyan Ramasamy, Morgan Kaufmann Publishers, ISBN-13:978-0120885886, 2007,
`http://www.NetworkRouting.net`

Routing is a fundamental architectural component of any network, and in this book the authors examine in detail the routing technologies of the Internet and the *Public Switched Telephone Network* (PSTN).

Organization

The book is divided into five parts, with an additional advanced section provided on CDROM. The first part examines the fundamentals of routing technology, looking in detail at the basic approaches of distance-vector and link-state routing. The second part looks at the routing protocols used in the Internet today, as well as Traffic Engineering. The third part addresses routing in the PSTN, examining the SS7 signaling protocol and the overall architecture of the PSTN. The next part explores the internal architecture of routers, address-lookup algorithms, and packet-classification techniques. Finally, the authors consider topics encompassed in the so-called "Next-Generation Network," including *Quality-of-Service Routing, Multiprotocol Label Switching* (MPLS), and *Voice over IP* (VoIP). The advanced-topic section includes a more detailed examination of packet-switching approaches, scheduling, and conditioning. This book is positioned as a graduate-level text, and each chapter is accompanied by exercises that review the material.

The book covers a broad range of material: each topic has been the subject of entire books. The level of detail in the book varies considerably. In some instances, such as in the area of IP Traffic Engineering, it presents a highly detailed mathematical analysis of aspects of the topic, whereas in other instances, such as in the treatment of the *Border Gateway Protocol* (BGP), the material appears to be obviously condensed. I was expecting a little more use of algorithms to illustrate routing concepts, and found at times the mathematical analysis to be unhelpful in terms of understanding the underlying problem space being described.

Comparison

In this area of Internet routing, any publication is inevitably compared to Radia Perlmann's book *Interconnections: Bridges, Routers, Switches and Internetworking Protocols,* and this book is no exception. To my mind it falls a little short of this rather demanding standard. Radia spends some time discussing the underlying rationale as to why a particular technology was devised for a given problem space, and also discusses the strengths and limitations of the technology in various areas of application.

In *Network Routing* the authors limit their approach to a description of the technology by looking at packet payloads and protocol interactions and numerous deployment scenarios that illustrate the features of this particular routing technology. The consideration of choices made in the development of the protocol, and the consequent implications of such design choices, are missing in such a treatment, and the reader is often left wondering why a routing protocol has chosen to support certain functions but not others.

I found this to be a very ambitious book, because it appears to position itself both as a reference publication on routing technologies and architecture and also on the description of routing protocols, while at the same time wanting to encompass the role of a course text. This goal could have been attainable if the book had chosen a tighter focus, but the all-encompassing approach that led to the inclusion of considerations of the PSTN topics makes the outcome less than fully satisfying.

Recommended

However, the book manages to bring together the basic topics in routing in both the Internet and the PSTN, and it not only includes a good description of the routing technologies in use today, but also looks at some of the advanced topics in routing today. I found the major strength of the book in its role as a graduate-course text, where there is sufficient description of the topic to lead into further reading of current research papers and more-detailed technical material. Although the book has some shortcomings, I'd certainly recommend it as a suitable addition to the shelves of any professional in the area of Internet routing technologies and architecture.

—Geoff Huston
gih@apnic.net

The Author Responds:

I thank Geoff Huston for writing a well-thought-out review; in general, this review is fair. This book was certainly an ambitious project. I wanted to do it as I've investigated various routing protocols for almost two decades—and many people I talked to thought that it would be useful to have such a book. In fact, Dave Clark, when he read the original book proposal, wrote "It is ambitious—there may be issues of how much depth they can get on all these topics in one book," but felt that "...the approach is distinctive and very valuable. So I support the idea." As can be observed from the book, the depth on different topics remained a major trade-off we pondered without making the book go over 1000 pages (with 140 pages on CD-ROM it came pretty close).

There were a few "design" decisions I deliberately made in organizing and writing this book. One of them was based on years of teaching and interacting with industry folks: I decided to divide materials broadly on "how and why" away from "what;" this approach is somewhat surprising, but people's learning style seems to fall into these two categories (certainly there are overlaps). Therefore, details on "how and why" of different protocols went into Chapter 3 (and for algorithms into Chapter 2), while details on "what" went with chapters on specific protocols such as OSPF or BGP. Similarly, I also separated out the topic of "how" routing in the global Internet works and is organized (such as public exchange points) from the chapter on BGP. Secondly, we separated math parts from non-math parts—this way, those who are interested, for example, in detailed Traffic Engineering modeling can read the relevant chapters. Others may skip them and read just the first couple of overview sections; it should be noted that math-oriented chapters are generally organized from simple concepts to difficult concepts. Thirdly, we covered address lookup, packet filtering and classification, and router architectures separately because they can be read independently; Karthik brought his wealth of experience in writing these chapters.

I want to take this opportunity to respond to a few of Geoff's comments:

1. "...expecting a little more use of algorithms to illustrate routing concepts." I suspect that Geoff didn't think that Chapters 2 and 3 covered enough, although these chapters included details illustrative of distance-vector protocols, link-state protocols, path-vector protocols (and their pitfalls), and so on. As stated previously, by design of the book, illustrative examples of routing concepts were separated from specific protocols so that readers can read different portions of the material according to their interests. As an indicator to the reader, each chapter starts with a brief "reading guideline" (which is a unique feature of this book) that states how the material is organized and its relation to other chapters or sections in the rest of the book.
2. "The consideration of choices made in the development of the protocol, and the consequent implications of such design choices are missing in such a treatment." We did indeed cover these aspects in many instances. For example, the book covers why, for I-BGP scalability, the route reflector or the confederation approach are needed; why route flap damping was developed; why ROUTE-REFRESH was added; what MPLS was trying to solve that IP-only couldn't do at that time; the need for age with Sequence Number field in link-state protocols; what led to the development of dynamic call routing from hierarchical routing in the PSTN, and so on.

That said, I did not include certain discussions because some choices on protocols have been based on personality clashes and "camps;" I felt that this is not easily explainable in many instances—trying to do so would require quite a bit of discussion, and could potentially divert from the main focus of the book. For example, I explained why the route reflector or confederation approach was needed for I-BGP scalability, but I didn't discuss why both route reflector and confederation approaches were developed simultaneously when both convey the same idea conceptually.

3. "... the all-encompassing approach that led to the inclusion of considerations of the PSTN topics into this book make the outcome less than fully satisfying." I included routing in the PSTN because of its historic context, and particularly to make readers aware of the evolution from hierarchical routing to dynamic routing and recent changes in routing due to Local Number Portability—these lessons are important ones to learn for anyone interested in routing or designing future routing protocols. Secondly, many concepts in MPLS/GMPLS have parallels in the PSTN, thus certain aspects in MPLS/GMPLS are easily explainable if a reader is familiar with PSTN details. We therefore felt it was appropriate to include all this material in one place. Furthermore, control- and data-path separation in GMPLS is strikingly similar to separation of signaling in PSTN through SS7 from actual voice communication. Thus, lessons learned from failure propagation from SS7 to voice paths are relevant lessons to be aware of for anyone involved in deploying GMPLS-based networks. Lastly, to discuss VoIP routing, it is critical to tie into PSTN because in the real operational environment PSTN-Internet interworking for VoIP routing is expected to remain prevalent for years to come.

Finally, the "barrier to entry" in learning about routing is very high, especially for entry-level professionals—I've attempted to position the book as both a text and a reference for professionals. Thus, I very much appreciated Geoff's concluding comment "... as a suitable addition to the shelves of any professional in the area of Internet routing technologies and architecture."

Read Any Good Books Lately?

Then why not share your thoughts with the readers of IPJ? We accept reviews of new titles, as well as some of the "networking classics." In some cases, we may be able to get a publisher to send you a book for review if you don't have access to it. Contact us at **ipj@cisco.com** for more information.

Fragments

Nii Quaynor Receives 2007 Postel Service Award

The *Internet Society* (ISOC) has awarded pioneering Internet engineer Nii Quaynor the prestigious *Jonathan B. Postel Service Award* for 2007 for his leadership in advancing Internet technology in Africa and galvanizing technologists to improve Internet access and capabilities throughout the continent. ISOC presented the award, including a $20,000 [USD] honorarium, during the 70th meeting of the *Internet Engineering Task Force* (IETF) in Vancouver, BC, Canada.

"Dr. Quaynor has selflessly pioneered Internet development and expansion throughout Africa for nearly two decades, enabling profound advances in information access, education, healthcare and commerce for African countries and their citizens," said ISOC president Lynn St. Amour. "Today, Dr. Quaynor continues to champion not just technological advances but also African involvement in Internet standards, processes and deployments, discussion on Internet policies and regulations, and ensuring African interests are well-represented globally. He has shaped a community of Africans who share his vision and reflect the dedication shown by Jon Postel."

"I am humbled by the award and what Jon Postel represents to our community in Africa. Jon Postel's efforts and the global view he maintained on the operation of the *Domain Name System* and the numbering services assured that Africa would share in the Internet growth and early. I thank the Internet Society for the recognition and am very pleased to be associated with Jon's memorial," said Dr. Nii Quaynor. "We will work to develop more African engineers to meet the fast network growth needs of the region, being a late starter, and to join the technical policy processes. Our overall objective is to strengthen education and research in network technologies in Africa."

The annual ISOC award is named after Dr. Jonathan B. Postel to commemorate his extraordinary stewardship exercised throughout his thirty-year career in networking. Between 1971 and 1998, Postel managed, nurtured and transformed the RFC series of notes, which encompasses the technical specifications and recommendations for the Internet and was created by Steve Crocker in 1969 as a part of his work on the ARPANET, the forerunner of today's Internet. Postel was a founding member of the Internet Architecture Board and the first individual member of the Internet Society, where he also served as a trustee until his untimely death.

Dr. Quaynor is chairman of *Network Computer Systems* (NCS) Ghana.COM and a professor of computer science at University of Cape-Coast, Ghana. He is also the convener of the *African Network Operators Group* (AfNOG), a network technology transfer institution since 2000 and the founding chairman of AfriNIC, the African numbers registry.

Dr. Quaynor began his pioneering Internet work in Africa in 1993 when he returned to his home country of Ghana to establish the first Internet Service operated by NCS in West Africa. At NCS, he and his team worked on the early development of the Internet in Africa. Today, there are more than 43 million Internet users in Africa.

Prior to NCS, Dr. Quaynor worked with Digital Equipment Corporation in the United States from 1977 till 1992. In 1979, he established the Computer Science department at the University of Cape Coast, Ghana. Dr. Quaynor graduated from Dartmouth College in 1972 with B.A (Engineering Science) and received a Ph.D. (Computer Science) in distributed systems in 1977 from State University of New York at Stony Brook.

The Jonathan B. Postel Service Award was established by the Internet Society to honor those who, like Postel, have made outstanding contributions in service to the data communications community. The award is focused on sustained and substantial technical contributions, service to the community, and leadership. With respect to leadership, the nominating committee places particular emphasis on candidates who have supported and enabled others in addition to their own specific actions.

Previous recipients of the Postel Award include Jon himself (posthumously and accepted by his mother), Scott Bradner, Daniel Karrenberg, Stephen Wolff, Peter Kirstein, Phill Gross, Jun Murai, Bob Braden, and Joyce K. Reynolds. The award consists of an engraved crystal globe and $20,000 [USD]. This year's award is sponsored in part by Afilias Global Registry Services. For more information about ISOC, please visit: **`www.isoc.org`**

Steps Taken for Multilingual Internet

The *Internet Corporation for Assigned Names and Numbers* (ICANN), the *International Telecommunication Union* (ITU), and the *United Nations Educational, Scientific and Cultural Organization* (UNESCO) will collaborate on global efforts to forge universal standards towards building a multilingual cyberspace. The three agencies organized a workshop on this subject during the second *Internet Governance Forum* (IGF) which took place in Rio de Janeiro, Brazil from 12 to 15 November 2007.

The Internet is a key factor in developing a more inclusive and development-oriented information society, which stresses plurality and diversity instead of global uniformity. Multilingualism is a key concept to ensure cultural diversity and participation for all linguistic groups in cyberspace. There is growing concern that hundreds of local languages may be sidestepped, albeit unintentionally in the radical expansion of Internet communication and information. The *World Summit on the Information Society* (WSIS) recognized the importance attached to linguistic diversity and local content, with UNESCO given the responsibility to coordinate implementation of the *Summit Action Line*.

"The discussions at this multilingualism workshop—combined with our current evaluation of *Internationalized Domain Names* (IDNs)—are going to help ICANN keep moving toward full implementation of Internationalized Domain Names," said Dr Paul Twomey, ICANN's President and CEO. "ICANN is in the midst of the largest ever evaluation of IDNs at the top level."

Thanks to ICANN's evaluation of Internationalized Domain Names, Internet users around the globe can now access wiki pages (see **`http://idn.icann.org/`**) with the domain name **`example.test`** in the 11 test languages—Arabic, Persian, Chinese (simplified and traditional), Russian, Hindi, Greek, Korean, Yiddish, Japanese and Tamil. The wikis will allow Internet users to establish their own sub pages with their own names in their own language; one suggestion is: **`example.test/yourname`**

Domain Names, which are currently mainly limited to characters from the Latin or Roman scripts, are seen as an important element in enabling the multilingualization of the Internet, reflecting the diverse and growing language needs of all users. "ITU is fully committed to assist its membership in promoting the diversity of language scripts for domain names," said Dr Hamadoun Touré, Secretary-General of ITU. "This workshop represents an important opportunity to strengthen the need for cooperation with relevant organizations, such as UNESCO, the *World Intellectual Property Organization* (WIPO) and ICANN among others to ensure Internet use and advancement across language barriers."

The Plenipotentiary Conference of ITU, which took place in Antalya, Turkey in November 2006, recognized the need to make Internet content available in non-Latin based scripts. Internet users are more comfortable reading or browsing through texts in their own language and a multilingual Internet is essential to make it more widely accessible. The WSIS outcomes also focused on the commitment to work towards multilingualization of the Internet as part of a multilateral, transparent and democratic process involving governments and all stakeholders.

UNESCO, joined by both ITU and ICANN, seeks to convene all major stakeholders around the world towards an agreement on universal standards regarding language issues in cyberspace. Such issues are far broader than the single issue of IDNs as they extend to standards for fonts and character sets, text encoding, language implementations within major computer operating systems, content development tools, automatic translation software, and search engines across languages. Ultimately, equitable access to information can be only achieved if we resolve language barriers at the same time we build communications infrastructures and capacity building programs.

RIPE Community Resolution on IPv4 Depletion and Deployment of IPv6

During the RIPE 55 meeting in Amsterdam in October 2007, the RIPE community agreed to issue the following statement on IPv4 depletion and the deployment of IPv6:

"Growth and innovation on the Internet depends on the continued availability of IP address space. The remaining pool of unallocated IPv4 address space is likely to be fully allocated within two to four years. IPv6 provides the necessary address space for future growth. We therefore need to facilitate the wider deployment of IPv6 addresses.

While the existing IPv4 Internet will continue to function as it currently does, the deployment of IPv6 is necessary for the development of future IP networks.

The RIPE community has well-established, open and widely supported mechanisms for Internet resource management. The RIPE community is confident that its *Policy Development Process* meets and will continue to meet the needs of all Internet stakeholders through the period of IPv4 exhaustion and IPv6 deployment.

We recommend that service providers make their services available over IPv6. We urge those who will need significant new address resources to deploy IPv6. We encourage governments to play their part in the deployment of IPv6 and in particular to ensure that all citizens will be able to participate in the future information society. We urge that the widespread deployment of IPv6 be made a high priority by all stakeholders."

For more information, see: **http://ripe.net/ripe/**

Upcoming Events

The next *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT) will be held in Taipei, Taiwan from February 20th to 29th, 2008. As usual, this conference is co-located with an APNIC Open Policy Meeting. For more information about these events see: **http://www.apricot2008.net/** and **http://www.apnic.net/meetings/25/index.html**

The *Internet Engineering Task Force* (IETF) will meet in Philadelphia, Pennsylvania, March 9–14 and "somewhere in Europe" July 27–August 1. (The announcement of the exact location is expected soon). The final IETF meeting in 2008 will take place in Minneapolis, Minnesota, November 16–21. For more information see: **http://www.ietf.org/meetings/0mtg-sites.txt**

The *Internet Corporation for Assigned Names and Numbers* (ICANN) will meet in New Delhi, India, February 10–15, and in Paris, France, June 22–27. See: **http://icann.org/meetings/**

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

The Internet Protocol Journal is published quarterly by the Chief Technology Office, Cisco Systems, Inc.

In This Issue

From The Editor

The *Domain Name System* (DNS) was not designed to support anything beyond 7-bit ASCII characters. Thus my middle name, Jørgen, or my colleague's surname, Fältström, cannot be used in a domain name. In fact, even using such strings on the left side of the @-sign—or in the body of an e-mail message—is problematic. We often find ourselves ignoring this limitation, using either "Jorgen" and "Faltstrom" or in some cases the two-letter convention "Joergen" and "Faeltstroem." As Scandinavians, Mr. Fältström and I are relatively lucky in that our languages contain only three characters in addition to those that can be represented by 7-bit ASCII. This, of course, isn't true for such languages as Arabic, Chinese, Japanese, or Korean, to name just a few. The IETF, ICANN, and others have been working hard to design and deploy a system that will allow native characters to appear in the DNS. Our first article discusses these efforts, known collectively as *Internationalized Domain Names* (IDNs). Geoff Huston gives an overview of IDNs and describes the many technical and political challenges that must be overcome in order to deploy such a system.

Recent activities have focused much attention on IPv6 deployment. Experiments have been conducted at several major Internet events (NANOG, APRICOT, and IETF) to "turn off" IPv4 for a period of time to test connectivity and interoperability to the outside world. You can read more about these experiments in our "Fragments" section on page 41. Such experiments provide valuable information about what works and what doesn't, and several more IPv4 "outages" are planned for 2008 and beyond. At the same time, researchers have been looking at ways to scale the routing system of the Internet, regardless of IP protocol version. One such approach is the *Locator/Identifier Separation Protocol* (LISP), which Dave Meyer describes in our second article.

The next issue of *The Internet Protocol Journal*, to be published sometime in June 2008, will be our Tenth Anniversary issue. We would love to hear your reflections on the last ten years of this journal and about the Internet as a whole over the same time period. Send your Letters to the Editor to **ipj@cisco.com**

Internationalizing the Domain Name System

by Geoff Huston, APNIC

Considering the global reach of the Internet, internationalizing the network sounds like a tautology. Surely the Internet is already truly "international," isn't it? The Internet reaches around the globe to every country, doesn't it? And no matter where you may travel these days, an Internet café is just around the corner. How much more "international" can you get?

But maybe I'm just being too parochial here when I call it a tautology. I use a dialect of the English language, and all the characters I need are contained in the *Western Latin* character set. Therefore, I avoid using a non-English language on the Internet; the only language I use on the Internet is English, and all the characters I need are encompassed in the ASCII character set. If I tried to use the Internet with a language that has a non-Latin character set and a different script, my experience would probably be different—and acutely frustrating. If my native language used a different script and a different text flow than English, I would probably give the Internet an extremely low score for ease of use. It is not as simple as managing glyph sets to represent the characters of the language; although it is relatively easy to present pictures of characters in a variety of fonts and scripts, using them in an intuitive and natural way in the context of the Internet becomes more challenging.

Mostly what is needed is good *localization,* or adapting the local computing environment to suit local linguistic needs. This environment may include support for additional character sets and additional language scripts, and perhaps altering the direction of text flow, or even the entire layout of the information.

For example, Japanese is traditionally written in a format called *Tategaki.* In this format, the text flows in columns going from top to bottom, with columns ordered from right to left. Modern Japanese also uses another writing format, called *Yokogaki.* This writing format is identical to that of European languages such as English, where the text flows from left to right in successive rows from top to bottom.

Today, the left-to-right direction is dominant in Japanese *Kana,* Chinese characters, and Korean *Hangul* for horizontal writing. This change is due partly to the influence of English, and partly to the increased use of computerized typesetting and word-processing software, most of which does not directly support right-to-left layout of East Asian languages. It would appear that even *Yokogaki* is an outcome of the lack of capability of IT systems to correctly cope with localization.[1]

One topic, however, does not appear to have a compellingly obvious localization solution in this multilingual environment: the *Domain Name System* (DNS). The subtle difference here is that the DNS is the "glue" that binds all users' language symbols together, and performing localized adaptations to suit local language use needs is not enough. The DNS spans the entire network, so what works for me in the DNS must also work for you. What we need is a means to allow the use of all of these language symbols within the same system, or *internationalization*.

The DNS is the most prevalent means of initiating a network transaction, whether it is a *BitTorrent* session, the Web, e-mail, or any other form of network activity. But the DNS name string is not just an arbitrary string of characters. What you find in the DNS is most often a sequence of words or their abbreviations, and the words are generally English words, using characters drawn from a subset of the Latin character set. Perhaps unsurprisingly, some implementations of the DNS also assume that all DNS names must be constructed only from this ASCII character set, and these implementations are incapable of supporting a larger character repertoire. If you want to use a larger character set in order to represent various diacritics, such as acute and grave symbols, umlauts and similar marks, then the deployed DNS can be resistant to this use, and may provide incorrect responses to queries that include such characters. And if you want to use words drawn from languages that do not use the western script for their characters, such as Japanese or Thai, for example, then the DNS is highly resistant to this form of multilingual use.

Latin and Roman Alphabets

The default Latin alphabet is the Roman[2] alphabet, supplemented with G, J, U, W, Y, Z, and lowercase variants. Additional letters may be formed:

- As *ligatures,* as W was from VV, for example Æ (*ash*) from AE, *oethel* Œ from OE, *eszett* ß from ſz (long s + z), *engma* ŋ from NG, *ou* Ȣ from OU, Ñ from NN, or ä from ae
- By *diacritics,* such as Å, Č, and Ų
- As *digraphs,* such as fi and fl
- By modification, as J was from I, G from C, Ø from O, *eth* Ð from D, *yogh* Ȝ from G, or *schwa* Ə from E
- By borrowing from another alphabet entirely, as *thorn* Þ and *wynn* Ƿ were from Futhark (Runic)

Over the years we have done a reasonable job of at least displaying non-Latin-based scripts within many applications, and although at times it appears to represent a less-than-reasonable compromise, it is possible to enter non-Latin characters on computer keyboards. So it appears to be possible to customise a local computing environment to use a language other than English in a relatively natural way.

But what happens when we extend the scope to consider multilingual support in the wider world of the Internet?

Again the overall story is not all that bad. We can use non-Latin character scripts in e-mail, in all kinds of Web documents, and in a wide variety of network applications. We can tag content with a language context to allow display of the content in the correct language using the appropriate character sets and presentation glyphs. However, until recently, one area continued to stick steadfastly to its ASCII roots: the DNS. This article addresses DNS internationalization, or *Internationalized Domain Names* (IDNs).

What do we mean when we talk of "internationalizing the DNS"? It refers to an environment where English, and the Latin character set, is just one of many languages and scripts in use, and where a communication is initiated in one locale and then the language and presentation are preserved wherever the communication is received.

Terminology

The following terms are used in this article:

Language: A language uses characters drawn from a collection of scripts.

Script: A script is a collection of characters that are related in their use by a language.

Character: A character is a unit of a script.

Glyph: The presentation of a character within the style of a font is called a glyph.

Font: A font is a collection of glyphs encompassing a script character set that share a consistent presentation style.

Multiple languages can use a common script, and any locale or country may use many languages, reflecting the diversity of its population and the evolution of local dialects within communities.

It is also useful to remember the distinction between internationalization and localization. *Internationalization* is concerned with providing a common substrate that many—preferably all—languages and all users can use, whereas *localization* is concerned with the use of a particular language within a particular locale and within a defined user population. Unsurprisingly, the two concepts are often confused, particularly when true internationalization is often far more difficult to achieve than localization.

Internationalizing the DNS

The objective is the internationalization of the DNS, such that the DNS can support the union of all character sets while preserving the absence of ambiguity and uncertainty in terms of resolution of any individual DNS name. We need to describe all possible characters in all languages and allow their use in the DNS. So the starting point is the "universal character set," and that appears to be Unicode.

One of the basic building blocks for internationalization is a character set that is the effective union of all character sets. *Unicode*[3] is intended to be such a universal encoding of characters (and symbols) in the contexts of all scripts and all languages. The current version of the *Unicode Standard,* Version 5.0, contains 98,884 distinct coded graphic characters.

A sequence of Unicode code points can be represented in multiple ways by using different character encoding schemes in a *Unicode Transformation Format* (UTF). The most commonly used schemes are UTF-8 and UTF-16.

UTF-8 is a variable-length encoding using 8-bit words, meaning that different code points require different numbers of bytes. The larger the index number of a code point, the more bytes are required to represent it using UTF-8. For example, the first 127 Unicode code points, which correspond exactly to the values used by the ASCII character set (which maps only 127 characters), can be represented using only 8 bits in UTF-8, using the same 8-bit values as in ASCII. UTF-8 can require up to 32 bits to encode certain code points. A criticism of UTF-8 is that it "penalizes" certain scripts by requiring more bytes to represent their code points. The IETF has made UTF-8 its preferred default character encoding for internationalization of Internet application protocols.

UTF-16 is a variable-length character encoding using 16-bit words. Characters in the *Basic Multilingual Plane* are mapped into a single 16-bit word, with other characters mapped into a pair of 16-bit words.

UTF-32 is a fixed-length encoding that uses 32 bits for every code point. This encoding tends to make for a highly inefficient coding that is, generally, unnecessarily large, because most language uses of Unicode draw characters from the Basic Multilingual Plane, making the average code size 16 bits in UTF-16 as compared to the fixed-length 32 bits in UTF-32. For this reason UTF-32 is far less commonly used than UTF-8 and UTF-16.

But languages, which we humans change in various ways every day, are not always definitive in their use of characters, and Unicode has some weaknesses in terms of identifying a context of a script and a language for a given character sequence. The common approach to using Unicode encodings in application software is to use an associated "tag," allowing content to be tagged with a script and an encoding scheme. For example, a content tag might read: "This text has been encoded using the KOI-8 encoding of the CYRILLIC script."

Tagging allows for decoding of the encoded characters in the context of a given script and a given language. This decoding has been useful for e-mail or Web page content, but tagging breaks down in the context of the DNS. There is no natural space in DNS names to contain language and script tags, implying that attempting to support internationalization in the DNS has to head toward a "universal" character set and a "universal" language context. Another way of looking at this situation is that the DNS must use an implicit tag of "all characters and all languages."

The contexts of the use of DNS names have numerous additional artefacts. What about domain-name label separators? This "dot" between DNS "words," or a DNS label separator, is an ASCII period character. In some languages, such as Thai, for example, there is no natural use of such a label separator. In a similar vein, are URLs intended to be visible to end users? If so, then we may have to transform the punctuation components of the URL into the script of the language. Therefore, we may need to understand how to manage protocol strings, such as "http:" and separators such as the "/" character. To complete the integrity of the linguistic environment, these elements may also require local presentation transformations.

For example, the Thai alphabet uses 44 consonants and 15 basic vowel characters, which are horizontally placed, from left to right, with no intervening space, to form syllables, words, and sentences. Vowels associated with consonants are nonsequential: they can be located before, after, above, or below their associated consonant, or in a combination of these positions. The latter in particular causes problems for computer encoding and text rendering[4].

The DNS name string reads left to right, and not right to left or top to bottom as in other script and language cultures. How much of this string you can encode in the DNS and how much must be managed by the application is part of the problem here. Is the effort to internationalize the DNS with multiple languages restricted to the "words" of the DNS, leaving the implicit left-to-right ordering and the punctuation of the DNS unaltered? If so, how much of this ordering and punctuation is a poor compromise, in that these DNS conventions in such languages are not natural translations?

The Unicode UTF-8, UTF-16, and UTF-32 encodings all require an "8-bit clean" storage and transmission medium. Because "traditional" DNS domain names are representable with 7-bit ASCII characters, not all applications that process domain names preserve the status of the eighth bit; in other words, they are not 8-bit clean. This situation stimulated significant debate in the IETF's *IDN Working Group* and influenced the direction of the standards development into the area of application assistance: the group took a very conservative view of the capabilities of the DNS as a restricted ASCII code application.

Accordingly, we now see the DNS itself as a heavily restricted "language." The prudent use of the DNS specifies, in RFC 1035[5], a sequence of "words" (or "labels"), where each label conforms to the "*L*etter, *D*igit, *H*yphen" (LDH) restriction. Each DNS label must begin with a letter, restricted to the Latin character subset of "A" through "Z" and "a" through "z", followed by a sequence of letters, digits, or hyphens, with a trailing letter or digit, and no trailing hyphen. Furthermore, the case of the letter is not important to the DNS, so, within the DNS "a" is equivalent to "A", and so on, and all characters are encoded in monocase ASCII. The DNS uses a left-to-right ordering of these labels, with the ASCII period as the label delimiter. This restriction is often referred to as the *LDH Convention.*

The challenge posed with the effort of *internationalizing* the DNS is one of attempting to create a framework that allows Internet applications—and the DNS in particular—to be set in the user's own language in an entirely natural fashion, and yet allow the DNS to operate in a consistent and deterministic manner within its restricted "language." In other words, we all should be able to use browsers and e-mail systems using our own language and scripts, yet still be able to communicate naturally with others who may be using a different language interface.

The most direct way of stating the choice set of IDN design is that IDNs either change the "prudent use" of the deployed DNS into something quite different by permitting a richer character repertoire in all parts of the DNS, or IDNs change the applications that want to support a multilingual environment such that they have to perform some form of encoding transfer to map between a language string using Unicode characters and an "equivalent" string using the restricted DNS LDH character-set repertoire. It appears that options other than these two lead us into fragmented DNS roots, and having already explored that particular concept in the past, not many of us want to return to that subject. So if we want to maintain a cohesive and unified symbol space for the DNS, then either the deployed DNS has to become 8-bit clean, or applications have to do the work and present to the DNS an encoded form of the Unicode sequences that conform to the restricted DNS character repertoire.

The IDN Framework

If you are an English language user with the ASCII character set, the DNS name you enter into the browser—or the domain part of an e-mail address—is almost the same string as the string that is passed to the DNS resolver to resolve into an address (the difference is the conversion of the characters into monocase). If you want to send a mail message, you might send it to **`user@example.com`**, for example, and the domain name part of this address, **`example.com`**, is the string used to query the DNS for an *MX Resource Record* in order to establish how to actually deliver the message.

But what if you want to use a domain name that is expressed in another language? What if the e-mail address is **`user@`**記念**`.com`**? The problem here is that this domain name cannot be "naturally" expressed in the restricted syntax of the DNS, and although this domain name may have a perfectly reasonable Unicode code sequence, this encoded sequence is not a strict LDH sequence, nor is it case-insensitive (whatever "case" may mean in an arbitrary non-Latin script). It is here that IDNs depart from the traditional view of the DNS and use a hybrid approach to the task of mapping these language strings into network addresses.

The IDN Working Group of the IETF was formed in 2000 with the goal of developing standards to internationalize domain names. The working group's charter was to specify a set of requirements and develop IETF standards-track protocols to allow use of a broader range of characters in domain names. The outcome of this effort was the *IDN in Applications* (IDNA) framework, published as RFCs 3454, 3490, 3491, and 3492.[6,7,8,9]

Rather than attempting to expand the character repertoire of the DNS itself, the IDN working group used an *ASCII Compatible Encoding* (ACE) to encode the binary data of Unicode strings that would make up IDNs into an ASCII character encoding. The concept is similar to the Base64 encoding used by the *Multipurpose Internet Mail Extension* (MIME) e-mail standards, but whereas Base64 uses 64 characters from ASCII, including uppercase and lowercase, the ACE approach requires the smaller DNS-constrained LDH subset of ASCII.

The working group examined various ACE algorithms in its efforts to converge to a single standard (because different encoding algorithms have different compression goals and yields) and encode the data using slightly different subsets of ASCII. Most proposals specified a prefix to the ACE coding to tag the fact that this string was, in fact, an encoded Unicode string. The IETF adopted *punycode* as its standard IDN ACE[9]. Punycode was chosen for its efficient encoding compression properties that produce short ACE strings. For example, the domain name of 記念**`.com`** encodes with punycode to **`xn--h7tw15g.com`**.

IDN in Applications

Although an ASCII-compatible encoding of Unicode characters allows representation of an IDN in a form that will probably not be corrupted by the deployed DNS infrastructure on the Internet, an ACE alone is not a full solution. The IDN approach also needs to specify how and where the ACE should be applied.

The overall approach to IDNs is relatively straightforward. In IDN the application has a critical role to play. The application takes a domain name that is expressed in a particular language using a particular script—and potentially in a particular character and word order that is related to that language—and produces an ASCII-compatible LDH-encoded version of this DNS name. Equally, when presenting a DNS string to the user, the application should take the LDH-encoded DNS name and transform it to a presentation sequence of glyphs that correspond to the original string in the original script.

It is critical that all applications perform this encoding and decoding function correctly, deterministically, and uniformly. In fact, this capability is critical to the entire IDN framework.

The basic shift in the DNS semantics that IDNs bring to the DNS is that the actual name itself is no longer in the DNS. An encoded version of the canonical name form sits in the DNS, and applications need to perform the canonical name transformation, as well as the mapping between the Unicode character string and the encoded DNS character string. So we need to agree on what are the "canonical" forms of name strings in every language. We also need to agree on the encoding method, and our various applications must have precise equivalents of these canonical name and encoding algorithms, or the symbolic consistency of the DNS will fail. The problem here is that the DNS does not perform approximate matches or return a set of possible answers to a query. The DNS is a deterministic system that performs a precise match on the query in order to generate a response. The implication here is that if we want the same IDN character sequence to map to the same network response in all cases and all contexts, then all applications must perform precisely the same operations on the character sequence in order to generate the ACE-equivalent label sequence.

RFC 3454[6] defines a presentation layer in IDN-aware applications that is responsible for the punycode ACE encoding and decoding. This new layer in the application architecture is responsible for encoding any internationalized input in domain names into punycode format before the corresponding LDH encoded domain name is passed to the DNS for resolution. This presentation layer is also responsible for decoding the punycode format in IDNs and rendering the appropriate glyphs for the user.

It is a matter of personal perspective whether this solution is an elegant one or it simply shifts an unresolved problem from one area of the IETF to another. The IDNA approach assumes that it is easier to upgrade applications to all behave consistently in interpreting IDNs than it is to change the underlying DNS infrastructure to be 8-bit clean in a manner that would support direct use of Unicode code points in the DNS.

The Presentation Layer Transform for IDNs

The objective here is to define a reliable and deterministic algorithm that takes a Unicode string in a given language and produces a DNS string as expressed in the LDH character repertoire. This algorithm should not provide a unique 1:1 mapping, but should group "equivalent" Unicode strings, where "equivalence" is defined in the context of the language of use, into the same DNS LDH string. Any reverse mapping from the DNS LDH string into the Unicode string should deterministically select the single "canonical" string from the group of possible IDN strings.

Stringprep

The first part of the presentation layer transform is to take the original Unicode string and apply numerous transformations to it to produce a "regular" or "canonical" form of the IDN string. This form of the string is then transformed using the punycode ACE into an encoded DNS string form. The generic name of this process is, in IDN language, "stringprep,"[6] and the particular profile of transformations used in IDNAs is termed "nameprep."[8]

This transform of a Unicode string into a canonical format is based on the observation that many languages have a variety of ways to display the same text and a variety of ways to enter the same text. Although we humans are unconcerned about this concept of expressing an idea in multiple ways, the DNS is an exact equivalence match operation and it cannot tolerate imprecision. So how can the DNS tell that two text strings are intended to be identical, even though their Unicode strings are different? The IDN approach is to transform the string so that all equivalent strings are mapped to the same canonical form, or "stringprep" the string. The stringprep specification is not a complete algorithm, and it requires a "profile" that describes the applicability of the profile, the character repertoire (at the time of writing RFC 3454, it was Unicode 3.2, although the Unicode Consortium has subsequently released Unicode Version 4.0, 4.1, and 5.0), mapping tables normalization, and prohibited output characters.

Mapping

In converting from a string to a *normal,* or canonical, form, the first step is to map each character into its *normalized* equivalent, using a mapping table. This table is conventionally used to map characters to their lowercase equivalent value to ensure that the DNS string comparison is case-insensitive.

Other characters are removed from the string by using this mapping operation because their presence or absence in the string does not affect the outcome of a string-equivalence operation, such as characters that affect glyph choice and placement, but without semantic meaning.

The mapping function will create monocase (specifically lowercase) outcomes and also will eliminate non-significant code points (such as, for example, the Unicode code point 1806; MONGOLIAN TODO SOFT HYPHEN or the Unicode code point 200B; ZERO WIDTH SPACE, if you really wanted to know what a non-significant code point was).

Normalization

Numerous languages use different character sequences for the same meaning. Characters may appear the *same* in presentation format as a glyph sequence, yet have *different* underlying code points. This may be associated with variables ways of combining diacritics, or using canonical code points, or using compatibility characters, and, in some language contexts, performing character reordering. For example, the character Ä can be represented by a single Unicode code point 00C4; LATIN CAPITAL A WITH DIARESIS. Another valid representation of this character is the code point 0041; LATIN CAPITAL LETTER A followed by the separate code point 0398; COMBINING DIARESIS.

The intent of normalization is to ensure that every class of character sequences that are equivalent in the context of a language is translated into a single canonical, consistent format. This consistency of format allows the equivalence operator to perform at the character level using direct comparison without additional language-dependent equivalence operations.

Languages in daily use are not rigid structures, and human use patterns of languages change. Normalization is no more than a best-effort process to detect equivalences in a rigid, rule-managed manner, and it may not always produce predictable outcomes. This unpredictability can be a problem with regard to namespace collisions in the DNS, because it does not increase the confidence level of the DNS as a deterministic exact-match information-retrieval system. IDNs introduce some forms of name approximation into the DNS environment, and the DNS is extremely ill-suited to the related "fuzzy-search" techniques that accompany such approximations.

Filtering Prohibited Characters

The last phase in string preparation is removal of prohibited characters, including the various Unicode white-space code points, control code points and joiners, private-use code points, and other code points used as surrogates or tags.

Right-to-Left Characters

As an option for a particular stringprep profile, you can perform a check for right-to-left displayed characters, and if any are found, make sure that the whole string satisfies the requirements for bidirectional strings. The Unicode standard has an extensive discussion of how to reorder glyphs for display when dealing with bidirectional text such as Arabic or Hebrew. All Unicode text is stored in logical order as distinct from the display order.

Nameprep: A Stringprep Profile for the DNS

The nameprep profile[8] specifies stringprep for internationalized domain names, specifying a character repertoire (in this case the specification references Unicode 3.2) and a profile of mappings, normalization (form "KC"), prohibited characters, and bidirectional character handling. The outcome is that two-character sequences can be considered equivalent in the context of IDNs if, by following the sequences of operations defined by the nameprep profile, the resultant sequences of Unicode code points are identical. These code point sequences are the "canonical" forms of names that the DNS uses.

The Punycode ASCII-Compatible Encoding

The next step in the processing of IDN names by the application is to transform this canonical form of the Unicode name string into a LDH-equivalent string using an ACE. The algorithm used, *punycode,* uses a highly efficient encoding, attempting to limit the extent to which Unicode sequences become extended-length ACE strings.

The algorithm first divides the input code points into a set of "basic" code points that require no further encoding, and the set of "extended" code points. The algorithm takes the basic code points and reproduces this sequence in the encoded string: the "literal portion" of the string. A delimiter is then added to the string. This delimiter is a basic code point that does not occur in the remainder of the string. The extended code points are then added to the string as a series of integers expressed through an encoding into the basic (LDH) code set.

These additions of the extended code points are done primarily in the order of their Unicode values, and secondarily in the order in which they occur in the string. The encoding of the code point and its insertion position is done by using a difference, or offset, encoding, so that sequences of clustered code points, such as would be found in a single language, encode efficiently.

For example, the German language string *bücher* uses basic codes for all characters except the *ü* character. The punycode algorithm copies all the basic codes, followed by a "-". The value and position of the *ü* insertion now has to follow.

The encoded form for *ü* (code 252) is at the position between the first and second basic characters. Using the punycode[10] algorithm gives a delta code of 745, a value that can be expressed in base 35 as (21 x 35) + 10. This code point and the position information are expressed in base 35 notation as (10,22,1), or in reverse notation, with the encoding **kva**. So the punycode encoding of *bücher* is **bcher-kva**. The internationalized domain-name format prepends the string **xn--** to the punycode string, resulting in the encoded IDN domain-name form of **xn--bcher-kva**.

IDNS and Our Assumptions About the DNS

At this stage it should be evident that we have the code points for characters drawn from all languages, and the means to create canonical forms of various words and express them in an encoded form that the DNS can resolve.

However, there is more to IDNs than the encoding algorithm. Although a massive number of discrete code points exist in the realm of Unicode, all these distinct characters are not necessarily displayed in unique ways. Indeed, given a relatively finite range of glyphs, the same glyph can display numerous discrete code points.

The often-quoted example with IDNs and name confusion is the name **paypal**. What is the difference between **www.paypal.com** and **www.paypal.com**? There is a subtle difference in the first "a" character, where the second domain name has replaced the Latin *a* with the Cyrillic *a*. Did you spot the difference? Of course not. These *homoglyphs* are cases where the underlying domain names are distinct, yet their appearance is indistinguishable. In the first case the domain name **www.paypal.com** is resolved in the DNS with the query string **www.paypal.com**, yet in the second case the query string **www.paypal.com** is translated by the application to the DNS query string **www.xn--pypal-4ve.com**. How can you tell one case from the other?

This example is by no means a unique case in the IDN realm. The reports "Unicode Security Considerations" (Unicode Technical Report 36) and "Unicode Security Mechanisms" (Unicode Technical Report 39) provide many more examples of postnormalization homographs.

There is no clear and unique relationship between characters and glyphs. Cyrillic, Latin, and Greek share numerous common glyphs. Glyphs may change their shape depending on the character sequence, multiple characters may produce a single glyph, such as the character pair *f l* being displayed as the single glyph *fl*, and a single character may generate multiple glyphs.

Homoglyphs extend beyond a conventional set of characters and include syntax elements as well. For example, the Unicode point 0244 FRACTION SLASH is often displayed using the slash glyph, allowing URLs of the form **http://a.com/e.com**. Despite its appearance, this is not a reference to **a.com** with a locator suffix of **e.com**, but is a reference to the domain **a.com/e.com**.

The basic response is that if you maintain IDN integrity at the application level, then the user just cannot tell. The punycode transform of **www.paypal.com** into **www.xn--pypal-4ve.com** is intended to be a secret between the application and the DNS, because this ASCII-encoded form is simply meaningless to the user. But if this encoded form remains invisible to the user, how can the user detect that the two identically presented name strings are indeed different? Sadly, the only true "security" we have in the DNS is the "look" of the DNS name that is presented to the user, and the user typically works on the principle that if the presented DNS string looks like the real thing, then it must be the real thing.

When this homoglyph problem was first exposed, the response from many browser implementations was to turn off all IDN support in their browser. The next response was to deliberately expose the punycode version of the URL in the browser address bar, so that directing the browser to **http://www.paypal.com** would display in the address bar the URL value of **http://www.xn--pypal-4ve.com**.

The distinction between the two equivalently displayed names was then visible to the user, but the downside was that we were back to displaying ASCII names again, and in this case ASCII versions of punycode-encoded names. If trying to "read" Base64 was difficult, then the displaying—and understanding—of displayed punycode names is surely equally as difficult, if not more so. The encoded names can be completely devoid of any form of useful association or meaning. Although the distinction between ASCII and Cyrillic may be evident by overt differences in their ASCII-encoded names, what happens when the homoglyph occurs across two non-Latin languages? The punycode strings are different, but which string is the "intended" one? Did you mean **http://xn--21bm4l.com** or **http://xn--q2buub.com** when you enter a Hindi script URL?

Using ASCII as the fall-back to resolve name confusion in response to the problem of ambiguities in non-ASCII script names appears to be a nonsensical solution. We appear to be back to guessing games in the DNS again, unfortunately, and particularly impossible guessing games at that.

These days most popular browsers display the glyphs, rather than the ASCII punycode, but once more we are back to the homoglyph problem.

If the intention in the IDN effort was to preserve the deterministic property of DNS resolution, such that a DNS query can be phrased deterministically and not have the query degenerate into a search term or require the application of fuzzy logic to complete the query, then we are not quite there yet.

The underlying observation is that languages are indeed human-use systems. They can be tricky, and they invariably use what appear to be rules in strange and inconsistent ways. They are also resistant to automated processing and the application of rigid rule sets. The canonical name forms that are produced by nameprep-like procedures are not comprehensive, nor does it appear that such a rigidly defined rule-driven system can produce the desired outcomes in all possible linguistic situations. And if the intention of the IDN effort was to create a completely "natural" environment using a language environment other than English and a display environment that is not reliant on ASCII and ASCII glyphs, while preserving all the other properties of the DNS, then the outcome does not appear to match our original IDN expectations.

The underlying weakness here is the implicit assumption that in the DNS "what you see is what you get," and that two DNS names that look identical are indeed references to the same name, and when resolved in the DNS produce precisely the same resolution outcome. When you broaden the repertoire of appearances of the DNS, such that the entire set of glyphs can be used in the DNS, then the mapping from glyph to underlying code point is not unique. Any effort to undertake such a mapping needs additional context in the form of a language and script context. But the DNS does not carry such a context, making the task of maintaining uniqueness and determinism of DNS name translation essentially impossible if we also want to maintain the property that it is the appearance, or presentation format, of DNS names to the user that is the foundation stone of the integrity of our trust in the DNS.

Some concerns still remain in this space, including the inclusion of various forms of character codes that are in effect invisible. In addition, homoglyphs could be better managed by using a refined definition of IDN labels that lists which Unicode code points can be used in the context of IDNs, excluding all others. It would be helpful if confusing and non-reversible character mappings were removed from the IDN space, including the consistent treatment of ligatures and diacritics, refining the treatment of right-to-left and left-to-right scripts, and removing the dependency on a particular version of the Unicode standard. This effort is under way in the IETF in the context of revisions to the IDNA specification documents.

IDNS, TLDs, and the Politics of the DNS

So why is there a very active debate, particularly within ICANN-related forums, about putting IDN codes into the root of the DNS as alternative *top-level domains* (TLDs)?

I have seen two major lines of argument here; namely the argument that favors the existence of IDNs in all parts of the DNS, including the TLDs, and the argument that favors a more restricted view of IDNs in the root of the DNS that links their use to that of an existing (ASCII-based) DNS label in the TLD zone.

Apparently, those who favor the approach of using IDNs in the top-level zone as just another DNS label see this as a natural extension of adding punycode-encoded name entries into lower levels of the DNS. Why should the root of the DNS be any different, in terms of allowing IDNs? Why should a non-Latin script user of the Internet have to enter the TLD code in its ASCII text form, while entering the remainder of the string in a local language? And in right-to-left scripts, where does this awkward ASCII appendage sit when a user attempts to enter it into an application?

Surely, goes the argument, the more natural approach is to allow any DNS name to be wholly expressible in the user's language, implying that all parts of the DNS should be able to carry native language-encoded DNS names. After all, コンピュータは予約する**.jp** looks wrong as a monolingual domain name. What is that **.jp** appendage doing there in that DNS name? Surely a Japanese user should not have to resort to an ASCII English abbreviation to enter in the country code for Japan, when 日本 is obviously more "natural" in the context of a Japanese user using Japanese script. If we had punycode TLDs then, goes the line of argument, users could enter the entire domain name in their language and have the punycode encoding happen across the entire name string, and then successfully perform a DNS lookup on the punycode equivalent. This way the user would enter the Japanese character sequence: コンピュータは予約する**.**日本 and have the application translate this entry to the DNS string **xn--88j0bve5g9-bxg1ewerdw490b930f.xn--wgv71a**. For this process to work in its entirety uniformly and consistently, the name **xn--wgv71a** needs to be a TLD name.

We can always take this thought process one step further and question the ASCII string **http** and the punctuation symbols **://** for precisely the same reason, but I have not heard (yet) calls for multilingual equivalents of protocol identifier codes. The multilingual presentation of these elements remains firmly in the provenance of the application, rather than attempting to alter the protocol identifiers in the relevant standards.

The line of argument also encompasses the implicit threat that if the root of the DNS does not embrace TLDs as expressed in the language of the Internet's users, then language communities will break away from a single DNS root and meet their linguistic community's requirements in their own DNS hierarchy. Admitting such encoded tags into the DNS root is the least problematic, including the consequence of inactivity, which is cited as being tantamount to condoning the complete fragmentation of the Internet's symbol set.

Of course having an entirely new TLD name in an IDN name format does not solve all of the potential problems with IDNs. How can a user tell what domain names are in the ASCII top level, and what are in the "equivalent" IDN-encoded TLDs? Are any two name spaces that refer to the same underlying name concept equivalent? Is **xn--88j0bve5g9bxg1ewerdw490b930f** appropriately a subdomain of **.jp**, or a subdomain of **xn--wgv71a**? Should the two domains be tightly synchronized with respect to their zone content and represent the same underlying token set, or should they be independent offerings to the marketplace, and allow registrants and the end-user base make implicit choices here? In other words, should the pair of domain names, namely **xn--88j0bve5g9bxg1ewerdw490b930f.xn--wgv71a** and **xn--88j0bve5g9bxg1ewerdw490b930f.jp**, reference precisely the same DNS zone, or should they be allowed to compete, and each find their own "natural" level of market support based on decoupled TLD names of **.jp** and **.xn--wgv71a**?

What does the term *equivalence* really imply here? Is equivalence something as loose as the relationship between **.com** and **.biz**, namely being different abbreviations of words that reflect similar concepts with different name-space populations that reflect market diversity and a competitive supply industry? Or is equivalence a much tighter binding in that equivalent names share precisely the same subdomain name set, and a registration in one of these equivalence names is in effect a name registration across the entire equivalence set?

Even this subject is not readily resolvable given our various interpretations of *equivalence*. In theory, the DNS root zone is populated by ISO two-letter country codes and numerous "generic" TLDs. Under what basis, and under what authority, is **xn--wgv71a** considered an "equivalent" of the ISO 3166 two-letter country code JP? Are we falling into the trap once again of making up the rules as we go along? Is the distinction between **.com** and **.biz** apparent only in English? And why should this distinction apply only to non-Latin character sets? Surely it makes more sense for a native German language speaker to refer to commercial entities as *kommerze,* and the abbreviated TLD name as **.kom**? When we say "multilingual" are we in fact ignoring "multilingual" and looking exclusively at "multiscript"?

Let's put aside the somewhat difficult concept of name equivalence for a second, and assume that this equivalence problem is solved. Also suppose that we want tight coupling across equivalence sets of names.

In other words, what we want is that a name registered in any of the elements of the equivalent domain-name set in all scripts is, in effect, registered in all the equivalent DNS zones. The question is: how should it be implemented in the DNS? One approach that could support tight synchronization of equivalence is to use the DNAME record[11] to create these TLD name aliases for their ASCII equivalents, thereby allowing a single name registration to be resolvable using a root name expressed in any of the linguistic equivalents of the original TLD name. The DNAME entry for all but the "canonical" element of the equivalence set effectively translates all queries to a query on the canonical name. The positive aspects of such an approach is uniformity across linguistic equivalents of the TLD name form—a single name delegation in a TLD domain becomes a name within all the linguistic equivalents of the TLD name without any further delegation or registration required.

Using DNAME as a tool to support sets of equivalent names in the DNS is still in the early stages. The limited experience so far with DNAME indicates that CNAME synthesis places load back on the name servers that would otherwise not be there, and the combination of this synthetic record and DNSSEC starts to get very unwieldy. Also, the IETF is reviewing the DNAME specification with the intention to remove the requirement to perform CNAME synthesis. All of these factors may explain why there is no immediate desire to place DNAMEs in the DNS root zone.

Different interpretations of equivalence in IDN names are possible. The use of DNAMEs as aliases for existing TLDs in effect "locks up" IDNs into the hands of the incumbent TLD name-registry operators. Part of the IDN debate, is, as usual, a debate over the generic TLD registry operators and the associated perception of incumbent monopolies. An alternative approach is to associate a single registrar with each IDN variant of the same generic TLD, allowing a form of "competition" between the various registrars. From the perspective of a coherent symbol space where the same symbol, expressed in any language script, resolves in the same fashion, such independent registries are not overly consistent with such a model of registry diversity in a multilingual environment. In this case such an artifice of IDN "competition" may well do more harm than good for Internet users.

It appears that another line of argument is that the DNS top-level name space is very conservatively managed, and new entries into this space are not made lightly. There are concerns of stability of operation, of attempting to conserve a coherent namespace, and the ever-present consideration that if we manage to "break" the DNS root zone it would be an irrevocable act.

This line of argument recognizes the very hazy nature of name equivalence in a multilingual environment and is based on the proposition that the DNS is incapable of representing such imprecision with any utility. The DNS is not a search engine, and the DNS does not handle imprecision at all well. Again, goes the argument, if this is the case then can we push this problem back to the application rather than trying to bend the DNS? If an application is capable of translating, say, 日本 into **xn--wgv71a**, and considering that the TLD name space is relatively small, it appears that having the application performing a further translation of this intermediate form punycode string into the ASCII string **jp** is not a particularly challenging form of table lookup. In such a model no new TLD aliases or equivalences are required in the root zone of the DNS. If we are prepared to pass the execution of the presentation layer of the DNS to the application layer to perform, then why not also ask this same presentation layer to perform the step of further mapping the punycode ACE equivalents of the TLDs to the actual ASCII TLDs, using some richer language context that the application may be aware of that is not viable strictly within the confines of the DNS?

So, with respect to the question of whether IDN TLDS should be loaded into the DNS at all, and, if so, whether they should represent an opportunity for further diversity in name supply or be constrained to be aligned to existing names, and precisely how name equivalence is to be interpreted in this context, then it appears that ICANN has managed to place itself in a challenging situation. In not making a decision, those with an interest in having diverse IDN TLDs appear to derive some pleasure in pointing out that the political origins of ICANN and its strong linguistic bias to English are influencing it to ignore non-English language use and non-English language users of the Internet. Where dramatic statements are called for, such statements often use terms such as "cultural imperialism" to illustrate the nature of the linguistic insult. The case has been made repeatedly, in support of IDN TLDs, that an overwhelming majority of Internet users and commercial activity of the Internet is in languages other than native English, and the imposition of ASCII labels on the DNS is an unnatural imposition on the overwhelming majority of Internet users.

On the other hand, most decisions to permit some form of entry in the DNS are generally seen as irrevocable, and building a DNS that is littered with the legacy of various non-enduring name technologies and poor ad hoc decisions to address a particular concern or problem without any context of a longer-term framework seems also to represent a step along a direction leading to a heavily littered and fragmented Internet where, ultimately, users cannot communicate with each other.

What about global interoperability and the Internet? Should we just take the easy answer and simply give up on the entire concept? Well of course not! But, taking a narrower perspective, are IDNs simply not viable in the DNS? I would suggest that not only is this question one that was overtaken by events years ago, but even if we want to reconsider it now, then the answer remains that any users using their local language and local script should have an equally "natural" experience. IDNs are a necessary and valuable component of the symbol space of any global communications system, and the Internet is no exception. However, we also should recognize that we do need combinations of both localization and globalization, and that we are voicing some pretty tough objectives. Is the IDNA approach enough? Is our assumption that an unaltered DNS with application-encoded name strings represents a rich enough platform to preserve the essential properties of the DNS while allowing true multilingual use of the DNS? On the other hand, taking a pragmatic view of the topic, is what we have with IDNA enough for us to work on, and is the alternative of reengineering the entire fabric of the DNS into an 8-bit clean system just not a viable option?

I suspect that the framework of IDNA is now the technology for IDNs for the Internet, and we simply have to move on from here and deliberately take the stance of understanding the space from users' perspectives when we look at the policy concerns of IDNs. The salient questions from such perspectives include: "What is the "natural" thing to do?" and "What causes a user the least amount of surprise?" Because in this world, what works for the user is what works for the Internet as a whole.

Further IDN News

IDNs are by no means completed work. Development continues in the Unicode forum on elaboration of character sets, and there are further proposals in the IETF to continue a complementary standards activity of refining the IDN documents.

In February 2008 the *Applications Area* of the IETF announced a proposal for further work on IDNs. The proposal has noted that the existing RFC documents are tied to version 3.2 of Unicode, while the Unicode Consortium has released version 5.0.0.

The proposed work is to consider revision of the IDN documents to untie the Internet specifications that define validity based on Unicode properties from specific versions of Unicode using algorithms. It is also proposed that these updates study revision of bi-directional algorithms, and to permit the use of some scripts that were inadvertently excluded by the original Internet specification.

This is not intended to be a major rewrite of the IDN approach, and, in particular, IDNs will continue to use the **xn--** prefix, the same Punycode ASCII-compatible encoding, and the bidirectional algorithm is intended to follow the same design as presently specified.

Further Reading

It is possible to reference an overwhelming amount of commentary on this topic, so I have deliberately kept this list of further reading on the topic of IDNs relatively brief:

The Locator Identifier Separation Protocol (LISP)

by David Meyer, Cisco Systems

The *Internet Architecture Board's* (IAB)'s October 2006 *Routing and Addressing Workshop*[8] renewed interest in the design of a scalable routing and addressing architecture for the Internet. Many concerns prompted this renewed interest, including the scalability of the routing system and the impending exhaustion of the IPv4 address space. Since the IAB workshop, several proposals have emerged that attempt to address the concerns expressed both at the workshop and in other forums[7,9,12,13,14]. All of these proposals are based on a common concept: the separation of locator and identifier in the numbering of Internet devices, often termed the "Loc/ID split." This article focuses on one proposal for implementing this concept: the *Locator/Identifier Separation Protocol* (LISP)[3].

The basic idea behind the Loc/ID split is that the current Internet routing and addressing architecture combines two functions: *Routing Locators* (RLOCs), which describe how a device is attached to the network, and *Endpoint Identifiers* (EIDs), which define "who" the device is, in a single numbering space, the IP address. Proponents of the Loc/ID split argue that this "overloading" of functions makes it virtually impossible to build an efficient routing system without forcing unacceptable constraints on end-system use of addresses. Splitting these functions apart by using different numbering spaces for EIDs and RLOCs yields several advantages, including improved scalability of the routing system through greater aggregation of RLOCs. To achieve this aggregation, we must allocate RLOCs in a way that is congruent with the topology of the network ("Rekhter's Law"). Today's "provider-allocated" IP address space is an example of such an allocation scheme. EIDs, on the other hand, are typically allocated along organizational boundaries. Because the network topology and organizational hierarchies are rarely congruent, it is difficult (if not impossible) to make a single numbering space efficiently serve both purposes without imposing unacceptable constraints (such as requiring renumbering upon provider changes) on the use of that space.

LISP, as a specific instance of the Loc/ID split, aims to decouple location and identity. This decoupling will facilitate improved aggregation of the RLOC space, implement persistent identity in the EID space, and, in some cases, increase the security and efficiency of network mobility.

Implementing the Locator/ID Separation

There are two basic approaches to implementing the Loc/ID split: *map-and-encap* and *address rewriting*. Each is briefly discussed in the following sections.

Map-and-encap

In the map-and-encap scheme (genenerally considered to have evolved from Bob Hinden's ENCAPS protocol[24]), when a source sends a packet to the EID of a destination outside of the source domain, the packet traverses the domain infrastructure to a border router (or other border element). The border router maps the destination EID to a RLOC that corresponds to an entry point in the destination domain (hence an EID-to-RLOC mapping system is needed; proposals are discussed later in the article). This phase is the "map" phase of map-and-encap. The border router then encapsulates the packet and sets the destination address to the RLOC returned by the mapping infrastructure (if any; it may be statically configured as well). This phase is the "encap" phase of the map-and-encap model.

Thus map-and-encap works by appending a new header to the existing packet; the "inner-header" source and destination addresses are EIDs, and the "outer-header" source and destination addresses are in most cases RLOCs. When an encapsulated packet arrives at the destination border router, the router decapsulates the packet and sends it on to its destination. Note that this process suggests that EIDs may need to be routable in some scope (likely scoped to the domain).

Map-and-encap schemes have the desirable property that they do not in general require host changes or changes to the core routing infrastructure. In addition, map-and-encap schemes work with both IPv4 and IPv6, and retain the original source address (a feature that is useful in various filtering scenarios). Controversy remains, however, as to whether or not the encapsulation overhead of map-and-encap schemes is problematic; opinions exist on both sides of this topic (see, for example, [18]).

Address Rewriting

The basic idea behind the address-rewriting schemes, originally proposed by Dave Clark and later by Mike O'Dell in his 8+8/GSE specification[11], is to take advantage of the 128-bit IPv6 address and use the top 64 bits as the routing locator ("Routing Goop," or RG), and the lower 64 bits as the endpoint identifier (hence rewriting works only for IPv6). In this scheme, when a host emits a packet destined for another domain, the source address contains its identifier (frequently a IEEE MAC address) in the lower 64 bits, and a special value (meaning unspecified) in the RG. The destination address contains the fully specified destination address (RG and EID).

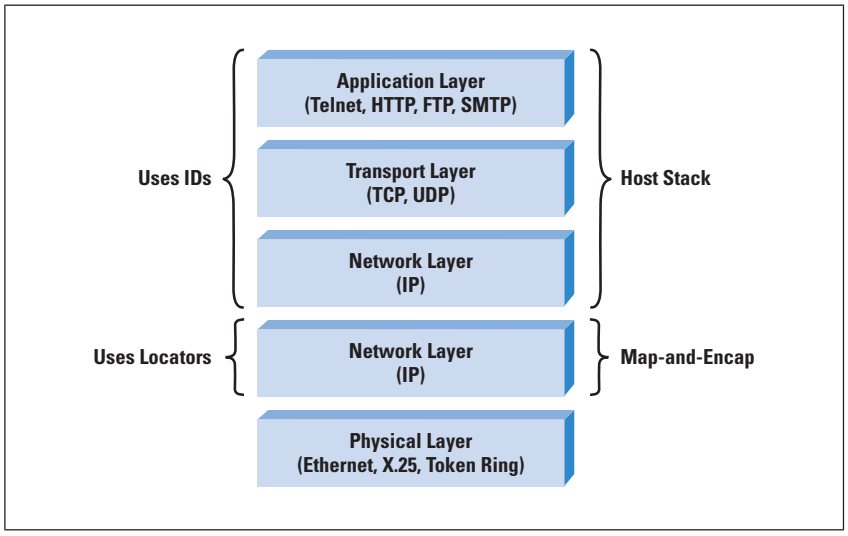
When a packet destined for a remote domain arrives at the local domain egress router, the source RG is filled in (forming a full 128-bit address), and the packet is routed to the remote domain. On ingress to the remote domain, the destination RG is rewritten with the unspecified value, ensuring that the host does not know what its RG is.

This process, in theory, would enable the ease of renumbering that would be required to maintain congruence between prefix assignment and physical network topology that is required for the kind of "aggressive" renumbering envisioned in the 8+8/GSE specification.

The Locator/Identifier Separation Protocol (LISP)

LISP is designed to be a simple, incremental, network-based map-and-encap protocol that implements separation of Internet addresses into EIDs and RLOCs. Because LISP is a map-and-encap protocol, it requires no changes to host stacks and no major changes to existing database infrastructures. It is designed to be implemented in a relatively small number of routers. LISP is also an instance of what is architecturally called a "jack-up," because the existing network layer is "jacked up" and a new network layer is inserted below it (the term "jacked up" is attributed to Noel Chiappa). The LISP jack-up is depicted in Figure 1.

Figure 1: LISP is a Jack-Up



The LISP design aims to improve site multihoming (for example, by controlling site ingress without complex protocols), improve *Internet Service Provider* (ISP) multihoming, decouple site addressing from provider addressing, and reduce the size and dynamic properties of the core routing tables.

The LISP data plane (the map-and-encap operation) and the LISP control plane (the EID-to-RLOC mapping system) are very modular. In particular, although the base LISP specification defines the format of messages to query the mapping system and to receive responses from that system, it makes no assumptions on the architecture of potential mapping systems. As a result, several mapping systems have been proposed[0,1,4,5,6,10].

LISP Network Elements

The LISP specification defines two network elements: The Egress Tunnel Router (ETR) and the Ingress Tunnel Router (ITR).

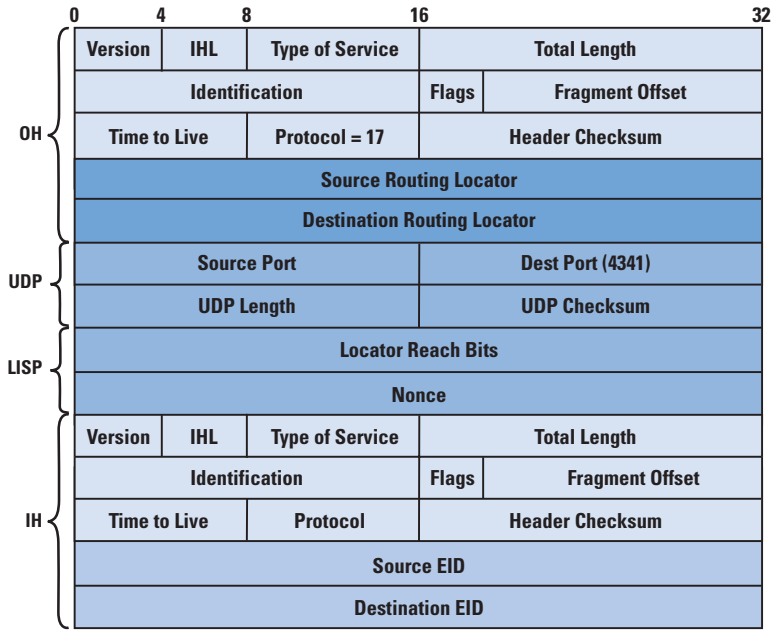
A LISP *Egress Tunnel Router* (ETR) receives LISP-encapsulated IP packets from the Internet on one side and sends decapsulated IP packets to site end systems on the other side. In particular, an ETR accepts an IP packet where the destination address in the "outer" IP header is one of its own RLOCs. The router strips the "outer" header and forwards the packet based on the next IP header found.

A LISP *Ingress Tunnel Router* (ITR) accepts IP packets from site end systems on one side and sends LISP-encapsulated IP packets toward the Internet on the other side. In particular, an ITR accepts an IP packet with a single IP header (more precisely, an IP packet that does not contain a LISP header). The router treats this "inner" IP destination address as an EID and performs an EID-to-RLOC mapping lookup if necessary (that is, it does not already have an EID-to-RLOC mapping for the EID). The router then prepends an "outer" IP header with one of its globally routable RLOCs in the Source Address field and the result of the mapping lookup in the Destination Address field. Note that this destination RLOC may be an intermediate, proxy device that has better knowledge of the EID-to-RLOC mapping closest to the destination EID.

LISP Data-Plane Operation

When a host in a LISP-capable domain emits a packet, it puts its EID in the packet source address, and EID of the correspondent host in its destination address (note that hosts will typically look up EIDs in the *Domain Name System* [DNS]). If the destination of the packet is in another domain, the packet traverses the source domain infrastructure to one of its ITRs. The ITR maps destination EID to a RLOC that corresponds to an ETR that is either in the destination domain or a proxy for the destination domain (how this mapping is accomplished in LISP is discussed later in the article). The ITR then encapsulates the packet, setting the destination address to the RLOC of the ETR returned by the mapping infrastructure or by static configuration. Note that LISP is address family-agnostic and as such can be used with both IPv4 and IPv6 (or any other address family). Figure 2 depicts the LISP IPv4 in IPv4 encapsulation.

Figure 2: LISP Header Format



When the packet arrives at the destination ETR, it decapsulates the packet and sends it on to its destination. Again, note that this scenario implies that EIDs need to be routable in some scope (likely scoped to the domain).

As mentioned previously, the LISP specification defines three packet types designed to support an EID-to-RLOC mapping system. The first type of packet, the *Data Probe*, is a data packet that an ITR may send into the mapping system to probe for the mapping; the authoritative ETR responds to the ITR with a Map-Reply message when it receives such a data packet. Note that in this case the ETR detects that the packet is a Data Probe by noticing that the inner *Destination Address* (DA) was copied to the outer DA by the ITR, that is, the inner DA equals the outer DA and is an EID. The second type of LISP packet used to support the mapping system is the *Map Request*. An ITR may query the mapping system by sending a Map-Request message into the mapping system to request a particular EID-to-RLOC mapping. As in the Data Probe case, the authoritative ETR responds with a Map-Reply message.

The third type of LISP packet used to support the mapping system is the *Map Reply*. An ETR emits a Map Reply under two conditions. First, if the ETR receives a LISP-encapsulated packet in which the outer-header destination address is the same as that of the inner header, it knows that the packet is a Data Probe and can respond with a Map Reply to the source ITR. The ETR may also receive a Map Request, in which case it replies to the requesting ITR with the mapping.

LISP Control Plane

Both map-and-encap and address-rewriting models rely on an additional of level of indirection in the addressing architecture to make the routing system scale reasonably. Because packets are sourced with an EID in the Destination Address field and EIDs are not in general routable on the global Internet, the destination EID must be mapped to an RLOC in order to deliver the packet to another domain (that is, across the Internet). In the case of the map-and-encap schemes, it is a direct translation: an EID is mapped to a RLOC. The situation is subtly different for the rewriting schemes; in general such schemes must look up the entire destination address (usually proposed to reside in the DNS)[11,13], but must somehow determine the source RG when rewriting the source address at the domain border.

In either Loc/ID split model, an EID-to-RLOC mapping service is needed to make the system scale reasonably and to make it operationally viable. There are three important scale parameters to consider when architecting a mapping service: the rate of updates to the mapping database, the state of the mapping service required, and the latency incurred during database lookup. The scaling properties of the database are frequently characterized as a (*Rate* × *State*) problem (ignoring for the moment the subject of lookup latency); because most estimates put the size of the mapping database at $O(10^{10})$, the database update rate must be small (note that this situation is a primary reason that current mapping proposals do not incorporate reachability information into the mapping database). In addition, the choice of push vs. pull also affects latency: if you push the entire database close to the edge, you improve lookup latency at the cost of increased state; if you architect a service that requires a mapping request and you find an authoritative server for that mapping (that is, pull), you reduce state at the cost of increased lookup latency.

LISP-Alternative-Topology: A LISP Control Plane

The basic idea behind *LISP-Alternative-Topology* (LISP-ALT)[4] is to build an alternative logical topology for managing EID-to-RLOC mappings for LISP. This logical topology uses existing technology and tools, specifically the *Border Gateway Protocol* (BGP)[17] and its multiprotocol extension[15], along with the *Generic Routing Encapsulation* (GRE)[16] protocol to construct an overlay network of devices that advertise EID prefixes only.

As was the case for the LISP data plane, an important design goal of LISP-ALT is to minimize the number of changes to existing hardware and software that are required to deploy the mapping system. Therefore, LISP-ALT requires modifications to neither BGP nor GRE.

Note that LISP-ALT is a hybrid push/pull architecture. Aggregated EID prefixes are "pushed" among the LISP-ALT routers and, optionally, to ITRs (which may elect to receive the aggregated information, as opposed to simply using a default mapping). Specific EID-to-RLOC mappings are "pulled" by ITRs either by Map Requests or Data Probes, both of which are routed over the alternate topology and result in Map Replies being generated by ETRs.

The basic idea behind in LISP-ALT, then, is to use BGP running over a GRE overlay to build the reachability required to route Data Probes, Map Requests, and Map Replies over the alternate topology. The ALT *Routing Information Base* (RIB) comprises EID prefixes and associated next hops. The LISP-ALT routers talk *External BGP* (eBGP) to each other in order to propagate EID prefix update information, which is learned either over eBGP connections from the authoritative ETR or by configuration. ITRs may also eBGP peer with one or more LISP-ALT routers in order to route Data Probe packets or Map Requests.

In summary, the LISP-ALT uses BGP to propagate EID-prefix reachability information used by ITRs and ETRs to forward Map Requests, Map Replies, and Data Probes. This reachability is carried as IPv4 or IPv6 *Network Layer Reachability Information* (NLRI) without modification (because the EID space has the same syntax as IPv4 or IPv6). LISP-ALT routers eBGP peer with one another, forming the overlay network. A LISP-ALT router near the edge learns EID prefixes that originate with authoritative ETRs. In general then, LISP-ALT routers aggregate EID prefixes, and forward Data Probes, Map-Requests, and Map-Replies.

Threat Models and Mitigation

As in any Loc/ID split approach, a critical operation is the creation of locator-to-ID binding state that devices will use over time. In the case of LISP, the critical operation is the creation of EID-to-RLOC mappings in the ITR and the ETR. We can obtain these mappings in three ways:

- By using the information obtained from a LISP data packet
- By using the information contained in the Map-Reply message
- By using an EID-to-RLOC mapping database

LISP mitigates attacks on the first two techniques by including a *nonce* in the LISP header; the nonce is a 32-bit randomly generated number (generated by the source ITR) that is used to test route returnability.

More specifically, an ETR echoes the nonce back to the ITR in a Map-Reply message. That is, the nonce, combined with the ITR accepting only solicited Map Replies, provides a base level of authentication for Map Replies. Note however, that these techniques do not protect against man-in-the-middle attacks.

The LISP design assumes that many (if not most) security mechanisms are part of the mapping database service when using control-plane procedures for obtaining EID-to-RLOC mappings. *Denial-of-Service* (DoS) attack prevention, on the other hand, depends on the ability of an implementation to rate-limit Map Requests and Map Replies (in the control plane), as well as its ability to rate limit the number of data-triggered Map Replies (for example, in response to Data Probe packets).

Refer to [19] for a more detailed preliminary threat analysis for LISP.

LISP and Fast Endpoint Mobility

Fast endpoint mobility occurs when an endpoint moves relatively rapidly, changing its IP layer network attachment point, and maintenance of session continuity is a goal. Mobile IPv4[20] and Mobile IPv6[21,22,27] mechanisms can be used in this case; note however, that the interaction of Mobile IP with LISP needs further exploration. Refer to the LISP specification[3] for additional details.

In summary, the major problem introduced by a Loc/ID split scheme is that as an endpoint moves, changes to the mapping between its EID and a set of RLOCs for its new network location may be required. When this change is added to the overhead of mobile IP binding updates, some packets might be delayed or dropped. In general, the problem is controlling the update rate (that is, the [*Rate* × *State*] product described previously), and is an area of ongoing research.

Multicast

A multicast group address, as defined in the original Internet architecture, is an identifier of a grouping of topologically independent receiver host locations. The address encoding itself does not determine the location of the receiver(s). The multicast routing protocol and the network-based state the protocol creates determine the location of the receivers.

In the LISP context, a multicast group address is both an EID and a RLOC. As such, no specific action is necessary for destination addresses; a group address that appears in an inner IP header (built by a source host) is used as the destination EID by an ITR as a destination address when it LISP-encapsulates the packet (that is, the ITR uses the same group address as the destination RLOC).

The source RLOC, as is usually the case, is the ITR IP address (that is, one of its RLOCs).

At the receiving side, *Protocol Independent Multicast* (PIM)[23] has to translate the source-address Join/Prune messages from RLOCs to EIDs when multicast packets are forwarded by the ETR. However, in contrast to the unicast case (where a Map Request is sent by the ITR at forwarding time), a Map Request can be sent when the multicast tree is being built.

Putting It All Together: A Day in the Life of a LISP Packet

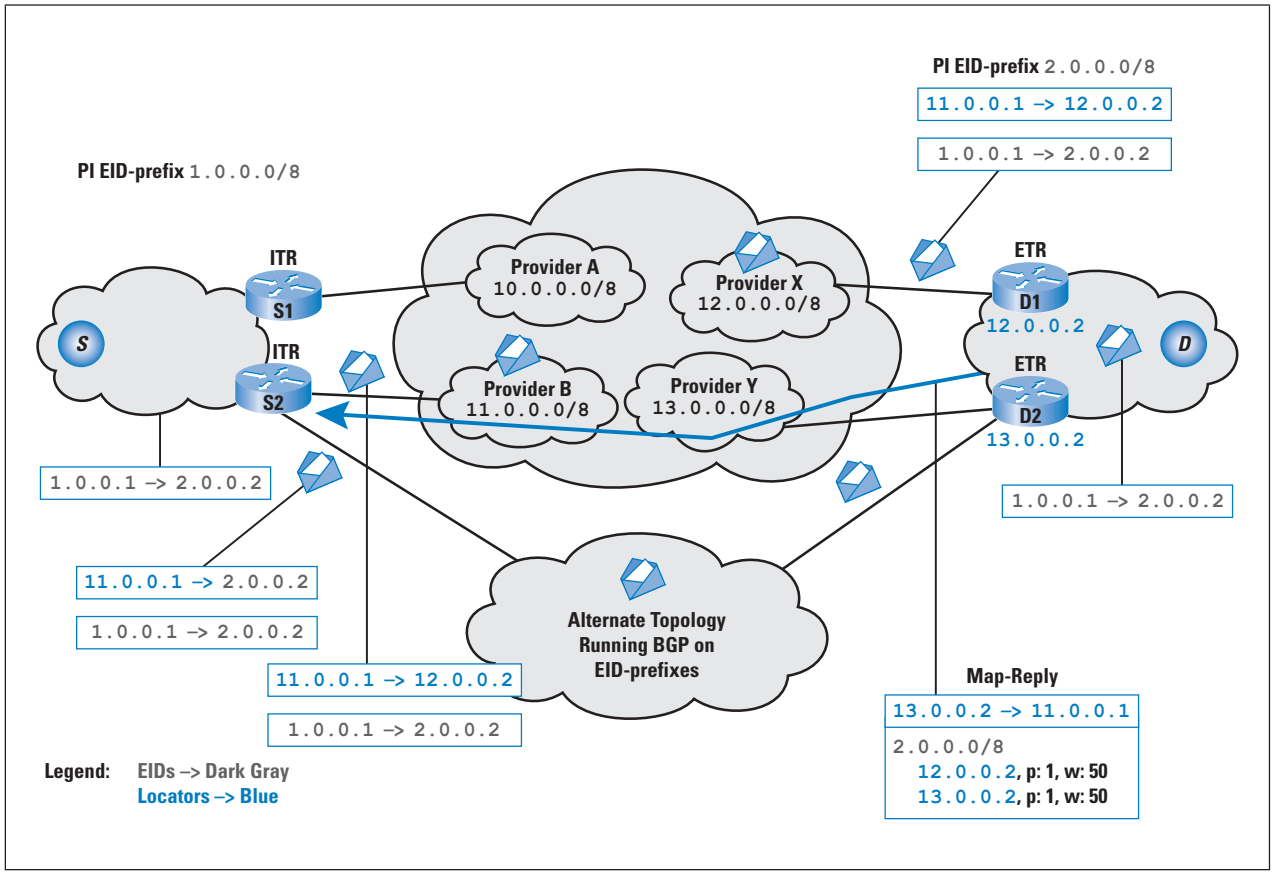
When a host in a LISP-capable domain wants to send a packet, it first looks up the correspondent host's EID in the DNS. It then puts its EID in the packet source address, and EID of the correspondent host in its destination address; if the destination of the packet is in another domain, the packet traverses the source domain infrastructure to one of the domain ITRs.

If the ITR has cached the EID-to-RLOC mapping for the destination EID, it sets the destination RLOC in the outer (encapsulated) header to the cached RLOC, and the source RLOC to its RLOC (note that the inner header has the source host's EID as the source and the destination's EID in the Destination field). The packet is then sent over the Internet to the ETR indicated in the destination RLOC, which decapsulates the packet and sends it on to the destination EID.

If, on the other hand, the ITR does not have a EID-to-RLOC mapping for the destination EID, it encapsulates the packet in a LISP header in which the destination address is the same as the inner header destination address, namely, the EID of the destination host. This packet is a Data Probe packet, and is routed over the LISP-ALT topology to the LISP-ALT router (typically an ETR, but this type of router is not required) that is authoritative for the EID-to-RLOC mapping. When the ETR receives the Data Probe packet, it decapsulates the packet and sends it on to the destination EID and sends a Map Reply to the source ITR so subsequent packets are sent natively over the Internet (as opposed to over the LISP-ALT overlay network). This query/response transaction is required only for the first packet sent between sites; all subsequent packets are sent LISP-encapsulated directly between the ITR and the ETR (and in particular, not over the LISP-ALT topology). Finally, note that the ITR could also preload its cache with mappings for popular destinations using the Map-Request message, avoiding the Data Probe packet (and associated latency, if any) altogether.

For example, consider the scenario depicted in Figure 3. In this case, a source *S* with EID `1.0.0.1` wants to send a packet to destination *D* whose EID is `2.0.0.2`. The packet arrives at ITR S2, which does not have an EID-to-RLOC mapping for `2.0.0.2`. S2 LISP-encapsulates the packet with the outer header having its RLOC (`11.0.0.1`) as the source address, copies the destination EID (`2.0.0.2`) from the inner header to the outer-header destination, and sends the data packet (a Data Probe) into the LISP-ALT topology. The packet follows the paths computed by BGP in the LISP-ALT topology to ETR D2. When D2 receives the packet, it decapsulates it and forwards the packet to the destination `2.0.0.2`; D2 also responds with a Map-Reply message that tells S2 (`11.0.0.1`) that the EID-to-RLOC mapping for `2.0.0.0/8` has two elements, ETR D1 (whose RLOC is `12.0.0.2`) and ETR D2 (whose RLOC is `13.0.0.2`). After receiving the Map Reply, ITR S2 can send LISP-encapsulated packets natively over the Internet (that is, not over the ALT topology).

Figure 3: A Day in the Life of a LISP Packet



Note that the mapping has priority (p) and weight (w) attributes. Priorities tell the ITR which ETRs to use in which order, and weights tell the ITR how to split load across ETRs of a given priority (w is a percentage of traffic that should go to each ETR). In this case, both ETRs have the same priority (1), and have weight 50 (that is, each ETR should receive 50 percent of the traffic).

New Functions Enabled by the Mapping System

Weights and priorities provide new capabilities for multihomed sites, which can use these features to control how traffic ingressing to the site is spread across its links without the complexity and overhead of running BGP. In particular, a multihomed site can configure its mapping database so that its links are used in an "active-active" configuration (that is, both links are in use). This situation is depicted in Figure 3, where the mapping databases entry `2.0.0.0/8` has two ETRs at the same priority that are equally weighted, meaning that the ITR will spread flows equally among the two ETRs.

This function is particularly attractive for *Small Office or Home Office* (SOHO) sites that desire both redundancy in their Internet connections and the ability to easily load share across those links in an active-active configuration, without the complexity and operational expense of running BGP.

Another interesting functionality enabled by the LISP control plane is the ability to mitagate some types of DoS attacks. In particular, if an ETR notices that it the subject of a DoS attack from behind an ITR (that is, DoS packets are destined to an EID-prefix for which it is authorative), it can use the LISP locator reachability bits (see Figure 2) to tell the the source ITR that the RLOC for that EID-prefix is not available. The ETR accomplishes this by sending a locator-reachability bit of zero for the RLOC to the offending ITR. Note that this functionality is similar to Ioannidis and Bellovin's "ICMP Pushback" proposal[25].

Performance Considerations

LISP and its associated mapping protocol(s) have two primary performance concerns:

- Encapsulation overhead
- EID-to-RLOC lookup latency and packet loss

In the case of encapsulation overhead, the concern is that the addition of the LISP header will cause the encapsulate packet to exceed the path *Maximum Transmission Unit* (MTU). As mentioned previously, this area of research is still active (see, for example, [18]).

In the case of lookup latency and packet loss, because LISP-ALT uses BGP to find a particular EID-to-RLOC mapping, there could be latency associated with the first few packets in the first flow between sites (note that it is only the first flow; subsequent flows can use the mapping installed in the ITR). However, this latency is mitigated, and the initial packets are not lost because LISP can send the first few data packets over the control plane; these packets are the Data Probe packets. There is additional latency associated with the time required for the destination ETR to return the Map Reply. However, after this initial transaction is completed, no additional latency is injected by the mapping system.

As mentioned previously, there is a trade-off in the mapping system among the state required to be held by network elements, the rate of updates to the mapping system, and the latency incurred when looking up an EID-to-RLOC mapping. LISP-ALT is a hybrid (push/pull) architecture that attempts to minimize the state requirements on ITRs, while at the same time minimizing lookup latency.

Conclusions

LISP is a new protocol that implements the Loc/ID split using a map-and-encap protocol. It obtains the advantages of the level of indirection afforded by the Loc/ID split while minimizing changes to hosts and to the core routing system. In addition, LISP enables new functions such as BGP-free multihoming in an active-active configuration.

Book Review

Patterns in Network Architecture

Patterns in Network Architecture: A Return to Fundamentals, by John Day, ISBN-10: 0132252422, ISBN-13: 9780132252423, Prentice Hall, 2007. **http://www.informit.com/store/product.aspx?isbn=0132252422**

It isn't every day (pun intended) that one of the true Old Guard writes and publishes a book, and it behooves us to take notice. In this case, the author's expertise and his subject matter are of particular timeliness, because of the worldwide resurgence of activities with regard to next-generation network architectures, that is, a replacement, or upgrade to the Internet (dare one say "Internet 2.0"?).

John Day is a well-known scholar of historical cartography, and this book, in a way, is a roadmap of network architecture. The roadmap starts back in 1970, tracing from the roots of connectionless packet-switched dynamically routed systems such as Cyclades, and the ARPANET, through to recent discussions on multihoming, multicast, and mobility, with a view along the way of naming, addressing, protocol stack design, protocol design, and concepts of layering.

That description makes the book sound fairly standard in terms of structure and content, but it isn't. The book includes many discursive elements whose intent is to provide a collection of *patterns*. Design patterns originated in the building trade as a way for crafts people to pass on successful methods of construction (in the sense of affordable and noncollapsing) to less-inventive people (or people who want to spend their inventive efforts in different areas). Software engineers picked up on this idea, applying the techniques in both the microscopic world: patterns allow you to decide what algorithm is applicable in solving a problem in the small; and the macroscopic world: architectural patterns allow you to decide on an approach to breaking down a large system into the right kind of components.

Essentially, this book does the same thing, at the protocol stack level, and at the system level, with a collection of historical and contemporary examples to support the arguments.

The book makes interesting reading, especially as it represents a fair balance in reporting the early ideas that came not just from the United States, and restates the importance of the *Opens Systems Interconnection* (OSI) model (not the ISO protocols) in understanding layering and beads-on-a-string, as well as reasserting the use of the model in clarifying the perennially confusing concepts of names, addresses, and routes.

The book begins with a discussion of seven principles that emerged through the early history of networking (I won't spoil the book for readers by listing them here), and ends in the tenth and final chapter, entitled "Backing Out of a Blind Alley," with an appeal to fundamentals. Essentially, the author points out that researchers (especially academics) are strongly motivated to keep moving on with claims of ever-newer tricks, but rarely to consolidate these tricks into a set of principles that stand for a long time (because then they would have to completely change the topic of their research). Thus uncovering a foundational theory of networking would put a whole generation of networkers out of work (or funding at least).

The book is peppered (saltily) with fine quotes and fascinating asides from philosophy (for this reader, especially, the Chinese diversions were most novel and illuminating). Illustrative of the range is that one finds Wittgenstein and Dave Clark, Confucius, and Dr. Seuss—Frege's useful reminder that "The sign '=' should be read as 'is easily confused with'" would make an excellent IETF T-shirt.

I found the book extremely readable and enjoyable, and although I might argue with some of the opinions in the book, I think that this is just more evidence that I should recommend the book to anyone interested in knowing why we are where we are in networking, and being better informed about where we should go next.

—Jon Crowcroft, University of Cambridge

ICANN Recovers Large Block of Internet Address Space

The *Internet Corporation for Assigned Names and Numbers* (ICANN) has found a little breathing room in the IPv4 address space with its recovery of a block of 16 million IPv4 addresses.

The IP addresses recovered were once used to connect older protocol packet-data networks with the fledgling Internet. The block of addresses, technically referred to as `14.0.0.0/8`, is also known as "Net-14."

"Net-14 was the easiest network to reclaim, the so-called low hanging fruit," said Barbara Roseman, General Manager with the *Internet Assigned Numbers Authority* (IANA), which is operated by ICANN. "None of the other legacy assignments in the IPv4 space are likely to be completely reclaimed as they are all in active use."

A small percentage of the addresses in Net-14 had been assigned, most more than 15 years ago. The assignments were so old that finding people who knew about them was a lengthy process. Nearly 50 organizations worked cooperatively with ICANN staff throughout 2007 to confirm that the 984 registrations were no longer in use. IANA undertook the reclamation effort to ensure that the greatest number of IPv4 addresses can be made available to Internet users as the overall free pool of IPv4 addresses is depleted. IANA allocates IPv4 and IPv6 addresses to *Regional Internet Registries* (RIRs). The five RIRs allocate addresses to network operators in their local regions. IANA allocated more than one /8 (16m IPv4 addresses) per month in 2007 and the rate of allocation is not expected to slow in 2008. The reclamation of Net-14 means there are now 43 unallocated /8s left.

"The recovery of these addresses offers some breathing room as the four billion addresses in IPv4 space are depleted, but it is only a temporary solution," added Roseman. "The real and lasting solution is the technical move to IPv6—the protocol that will make 340 trillion trillion trillion unique IP addresses available."

IPv6 Address Added for Root Servers in the Root Zone

ICANN recently took another step along the path of deployment for the next-generation IPv6 Internet addressing system. IPv6 addresses were added for six of the world's 13 *root server* networks (A, F, H, J, K, M) to the appropriate files and databases. This move allows for the possibility of fuller IPv6 usage of the *Domain Name System* (DNS). Prior to today, those using IPv6 had needed to retain the older IPv4 addressing system in order to be able to use domain names.

"The ISP community welcomes this development as part of the continuing evolution of the public Internet," said Tony Holmes, chair of ICANN's Internet Service and Connectivity Provider Constituency. "IPv6 will be an essential part our future and support in the root servers is essential to the growth, stability, and reliability of the public Internet."

Name server software relies on the root servers as a key part in translating domains like icann.org into the routing identifiers used by computers to connect to one another. In 2007 the ICANN *Security and Stability Advisory Committee* concluded that ICANN should move forward with the enhancement of the DNS root service by adding IPv6 addresses for the root servers."The addition of IPv6 addresses for the root servers enhances the end-to-end connectivity for IPv6 networks, and furthers the growth of the global interoperable Internet," added David Conrad, ICANN's Vice President of Research and IANA Strategy. "This is a major step forward for IPv6-only connectivity and the global migration to IPv6."

Further technical information on the move is available at:

`http://www.iana.org/reports/root-aaaa-announcement.html`

RIPE NCC Publishes Case Study of YouTube Hijack

As you may be aware from recent news reports, traffic to the **`youtube.com`** Website was "hijacked" on a global scale on Sunday February 24, 2008. The incident was a result of the unauthorized announcement of the prefix **`208.65.153.0/24`** and caused the popular video sharing Website to become unreachable from most, if not all, of the Internet. The RIPE NCC conducted an analysis into how this incident was seen and tracked by the RIPE NCC's *Routing Information Service* (RIS) and has published a case study at:

`http://www.ripe.net/news/study-youtube-hijacking.html`

The RIPE NCC RIS is a service that collects *Border Gateway Protocol* (BGP) routing information from roughly 600 peers at 16 *Internet Exchange Points* (IXPs) across the world. Data is stored in near real-time and can be instantly queried by anyone to provide multiple views of routing activity for any point in time. The RIS forms part of the RIPE NCC's suite of Information Services, which together provide a deeper insight into the workings of the Internet. The RIPE NCC is a neutral and impartial organization, and commercial interests therefore do not influence the data collected. The RIPE NCC Information Services suite also includes the *Test Traffic Measurement* (TTM) service, the *DNS Monitoring* (DNSMON) service and Hostcount. All of these services are available to anyone, and most of them are offered free of charge.

More information about RIPE NCC Information Services can be found at: **`http://is-portal.ripe.net`**

IETF Examines Future of the Internet by Going IPv6 Native

The *Internet Engineering Task Force* (IETF) put a spotlight on the next generation of Internet addressing when it switched off attendees' access to IPv4 during its March 2008 meeting. For an hour, Internet engineers at the meeting could only access the Internet using an IPv6 network.

During this event, IETF participants were encouraged to explore the Internet as it appears today in the IPv6 environment. The purpose of this exploration was to determine the next steps necessary toward deployment of IPv6 as the next generation of Internet addressing. The IETF undertook this activity at a time when IPv6-implementation is becoming a matter of global importance for the Internet. The event provided all IETF meeting attendees a first-hand opportunity to work with the Internet over an exclusive IPv6 network. "We get a lot of reports from members of our community who use IPv6, but this was an opportunity for everyone to observe and discuss the technical issues as a group," said Russ Housley, Chair of the IETF. "This first-hand data helps to inform our engineering decisions."

Some members of the Internet technical community assert that the ongoing deployment of IPv6 has been held back by a lack of IPv6-accessible Websites, creating the classic first-step dilemma for network operators. "It has been incredible to observe as members of the community organized themselves and updated their home networks to be ready for this event," said Leslie Daigle, Chief Internet Technology Officer at the Internet Society. "As we continue to solve the engineering and implementation obstacles to IPv6 deployment, creative engineers around the world will develop new uses for the Internet, through IPv6, in ways we can't yet imagine."

The IETF has provided dual stack IPv4/IPv6 network connectivity at its meetings for years, which has been useful for its regular IPv6-using attendees. The difference during this meeting was that a strictly IPv6 network was made available as well, and all attendees were encouraged to explore and experiment with the Internet as seen from IPv6. This focus was heightened when IPv4 access was deliberately shut off for an hour, leaving only IPv6 for connectivity. Following this—and other similar experiments—the engineering community expects to have a better understanding of the next steps necessary in the development of protocols and standards to support the continued deployment of IPv6 in support of the global Internet. The Comcast Corporation provided the facilities to conduct the live test of IPv6 and was the host sponsor of IETF-71 in Philadelphia.

Postel Network Operator's Scholarship 2008

The *North American Network Operators' Group* (NANOG) and the *American Registry for Internet Numbers* (ARIN) have been unique and successful cooperative fora for Internet builders in North America and other parts of the world. Senior practitioners from around the world contribute their time to NANOG and ARIN as presenters, teachers and trainers, to produce consistent non-commercial conferences of high-quality.

Since 2007, the generosity of an anonymous donor and the administration of the Internet Society, have allowed NANOG and ARIN to provide financial support to a person from a developing country to participate in the October joint NANOG/ARIN meeting through the *Postel Network Operator's Scholarship*.

The Scholarship Committee cordially invites suitable applicants to apply for fellowship funding to participate in the October 2008 joint NANOG/ARIN meeting. The Scholarship targets personnel from developing countries who are actively involved in Internet development, in any of the following roles: Engineers (Network Builders), Operational and Infrastructure Support Personnel, and Educators, Teachers, and Trainers

Successful applicants will be provided with transportation to and from the meetings and a reasonable allowance for food and accommodation. In addition all fees for participation in the conferences, tutorials, and social events will be waived. Applicants from any part of the world will be considered. The deadline for application is June 1, 2008, and the awardee will be informed by July 1, 2008.

To apply for the fellowship please read **`http://www.nanog.org/postel-scholarship.html`** and submit your application by e-mail to **`PostelNOS@nanog.org`**

For more information about NANOG and ARIN meetings, see: **`http://www.nanog.org/`** and **`http://www.arin.net/`**

JPNIC Releases IPv4 Exhaustion Report

The *Japan Network Information Center* (JPNIC) has released a report entitled "Study Report on the IPv4 Address Space Exhaustion Issue (Phase I)." The report can be downloaded from the following link:

`http://www.nic.ad.jp/en/ip/ipv4pool/ipv4exh-report-071207-en.pdf`

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is...?"), as well as implementation/operation articles ("How to..."). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, fire-walls, troubleshooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

The Internet Protocol Journal is published quarterly by the Chief Technology Office, Cisco Systems, Inc.

The Internet Protocol Journal

June 2008 Volume 11, Number 2

A Quarterly Technical Publication for Internet and Intranet Professionals

In This Issue

You can download IPJ back issues and find subscription information at: **www.cisco.com/ipj**

From The Editor

Ten years ago we published the first issue of *The Internet Protocol Journal* (IPJ). Since then, 41 issues and a total of 1,612 pages have been produced. Today, IPJ has about 37,000 subscribers all around the world. Although most of our readers prefer the paper edition, a growing number of subscribers are reading IPJ online or downloading the PDF version. This shift in reading habits may be related to the changes in technology over the last 10 years. Lower costs and higher-resolution displays and printers, as well as improvements in Internet access technologies, have made the online "experience" a lot better than in 1998.

Publishing is by no means the only area that has seen dramatic changes in the last decade. We asked Vint Cerf and Geoff Huston to reflect on Internet developments in this period, and the resulting articles, "A Decade of Internet Evolution" and "A Decade in the Life of the Internet," are included in this issue.

Let me take this opportunity to thank all those people who have made IPJ possible. Our authors deserve a round of applause for carefully explaining both established and emerging technologies. They are assisted by an equally insightful set of reviewers and advisors who provide feedback and suggestions on every aspect of our publications process. The process itself relies heavily on two individuals: Bonnie Hupton, our copy editor, and Diane Andrada, our designer. Thanks go also to our printers and mailing and shipping providers. Last, but not least, our readers provide encouragement, suggestions, and feedback. This journal would not be what it is without them.

Because we are considering some Internet history in this issue, I would like to announce a project that takes us even further back. Before joining Cisco in 1998 I worked at the Interop Company, where I was responsible for the monthly publication of *ConneXions—The Interoperability Report,* published from 1987 through 1996. Unlike IPJ, *ConneXions* was produced in the "old-fashioned way" using various pieces of text and artwork assembled onto paste-up boards, and then photographed for subsequent plate making and offset printing. Thus no PDF files were produced at the time, but I am pleased to announce that *The Charles Babbage Institute* at the University of Minnesota has scanned the complete collection (117 issues) and it is now available at: **http://www.cbi.umn.edu/hostedpublications/Connexions/index.html**

Our final article is a look at Mobile WiMAX. WiMAX is an emerging technology that was originally designed as a fixed wireless broadband technology, a "DSL replacement," but has evolved to support mobility.

— Ole J. Jacobsen, Editor and Publisher

A Decade of Internet Evolution

by Vinton G. Cerf, Google

In 1998 the Internet had about 50 million users, supported by approximately 25 million servers (Web and e-mail hosting sites, for example, but not desktops or laptops). In that same year, the *Internet Corporation for Assigned Names and Numbers* (ICANN)[1] was created. Internet companies such as Netscape Communications, Yahoo!, eBay, and Amazon were already 3 to 4 years old and the Internet was in the middle of its so-called "dot-boom" period. Google emerged that year as a highly speculative effort to "organize the world's information and make it accessible and useful." Investment in anything related to the Internet was called "irrational exuberance" by the then head of the U.S. Federal Reserve Bank, Alan Greenspan.

By April 2000, the Internet boom ended—at least in the United States—and a notable decline in investment in Internet application providers and infrastructure ensued. Domino effects resulted for router vendors, Internet service providers, and application providers. An underlying demand for Internet services remained, however, and it continued to grow, in part because of the growth in the number of Internet users worldwide.

During this same period, access to the Internet began to shift from dial-up speeds (on the order of kilobits to tens of kilobits per second) to broadband speeds (often measured in megabits per second). New access technologies such as digital subscriber loops and dedicated fiber raised consumer expectations of Internet capacity, in turn triggering much interest in streaming applications such as voice and video. In some locales, consumers could obtain gigabit access to the Internet (for example, in Japan and Stockholm). In addition, mobile access increased rapidly as mobile technology spread throughout the world, especially in regions where wireline telephony had been slow to develop.

Today the Internet has an estimated 542 million servers and about 1.3 billion users. Of the estimated 3 billion mobile phones in use, about 15 percent are Internet-enabled, adding 450 million devices to the Internet. In addition, at least 1 billion personal computers are in use, a significant fraction of which also have access to the Internet. The diversity of devices and access speeds on the Internet combine to produce challenges and opportunities for Internet application providers around the world. Highly variable speeds, display areas, and physical modes of interaction create a rich but complex canvas on which to develop new Internet applications and adapt older ones.

Another well-documented but unexpected development during this same decade is the dramatic increase in user-produced content on the Internet. There is no question that users contributed strongly to the utility of the Internet as the World Wide Web made its debut in the early 1990s with a rapidly growing menu of Web pages.

But higher speeds have encouraged user-produced audio and video archives (*Napster* and *YouTube*), as well as sharing of all forms of digital content through peer-to-peer protocols. Voice over IP, once a novelty, is very common, together with video conferencing (*iChat* from Apple, for example).

Geographically indexed information has also emerged as a major resource for Internet users. In the scientific realm, *Google Earth* and *Google Maps* are frequently used to display scientific data, sensor measurements, and so on. Local consumer information is another common theme. When I found myself in the small town of Page, Arizona, looking for saffron to make paella while in a houseboat on Lake Powell, a Google search on my Blackberry quickly identified markets in the area. I called one of them and verified that it had saffron in stock. I followed the map on the Website and bought 0.06 ounces of Spanish saffron for about $12.99. This experience reinforced my belief that having locally useful information at your fingertips no matter where you are is a powerful ally in daily living.

New business models based on the economics of digital information are also emerging. I can recall spending $1,000 for about 10 MB of disk storage in 1979. Recently I purchased 2 TB of disk storage for about $600. If I had tried to buy 2 TB of disk storage in 1979, it would have cost $200 million, and probably would have outstripped the production capacity of the supplier. The cost of processing, storing, and transporting digital information has changed the cost basis for businesses that once required the physical delivery of objects containing information (books, newspapers, magazines, CDs, and DVDs). The Internet can deliver this kind of information in digital form economically—and often more quickly than physical delivery. Older businesses whose business models are based on the costs of physical delivery of information must adapt to these new economics or they may find themselves losing business to online competitors. (It is interesting to note, however, that the Netflix business, which delivers DVDs by postal mail, has a respectable data rate of about 145 kbps per DVD, assuming a 3-day delivery time and about 4.7 GB per DVD. The CEO of Netflix, Reed Hastings, told me nearly 2 years ago that he was then shipping about 1.9 million DVDs per day, for an aggregate data rate of about 275 Gbps!)

Even the media that have traditionally been delivered electronically such as telephony, television, and radio are being changed by digital technology and the Internet. These media can now be delivered from countless sources to equally countless destinations over the Internet. It is common to think of these media as being delivered in streaming modes (that is, packets delivered in real time), but this need not be the case for material that has been prerecorded. Users of iPods have already discovered that they can download music faster than they can listen to it.

With gigabit access to the Internet, one could download an hour's worth of conventional video in about 16 seconds. This fact certainly changes my understanding of "video on demand" from a streaming delivery to a file transfer. The latter is much easier on the Internet because one is not concerned about packet inter-arrival times (jitter), loss, or even orderly delivery because the packets can be reordered and retransmitted during the file transfer. I am told that about 10 hours of video are being uploaded to YouTube per second.

The battles over *Quality of Service* (QoS) are probably not over yet either. Services such as *Skype* and applications such as iChat from Apple demonstrate the feasibility of credible, real-time audio and video conferencing on the "best-efforts" public Internet. I have been surprised by the quality that is possible when both parties have reasonably high-capacity access to the Internet.

Technorati is said to be tracking on the order of 112 million blogs, and the *China Internet Network Information Center* (CNNIC) estimates 72 million Chinese blogs that are probably in addition to those tracked by Technorati. Adding to these are billions of Web pages and, perhaps even more significant, an unknown amount of information online in the form of large databases. The latter are not indexed in the same way that Web pages can be, but probably contain more information. Think about high-energy physics information, images from the Hubble and other telescopes, radio telescope data including the *Search for Extra-Terrestrial Intelligence* (SETI)[2], and you quickly conclude that our modern society is awash in digital information.

It seems fair to ask how long accessibility of this information is likely to continue. By this question I do not mean that it may be lost from the Internet but, rather, that we may lose the ability to interpret it. I have already encountered such problems with image files whose formats are old and whose interpretation by newer software may not be possible. Similarly, I have ASCII text files from more than 20 years ago that I can still read, but I no longer have operating software that can interpret the formatting instructions to produce a nicely formatted page. I sometimes think of this problem as the "year 3000" problem: It is the year 3000 and I have just finished a Google search and found a PowerPoint 1997 file. Assuming I am running Windows 3000, it is a fair question whether the format of this file will still be interpretable. This problem would arise even if I were using open-source software. It seems unlikely that application software will last 1000 years in the normal course of events unless we deliberately take steps to preserve our ability to interpret digital content. Absent such actions, we will find ourselves awash in a sea of rotting bits whose meaning has long since been lost.

This problem is not trivial because questions will arise about intellectual property protection of the application, and even the operating system software involved. If a company goes out of business or asserts that it will no longer support a particular version of an application or operating system, do we need new regulations that require this software to be available on the public Internet in some way?

Even if we have skirted this problem in the past by rendering information into printed form, or microfilm, the complexity of digital objects is increasing. Consider spreadsheets or other complex objects that really cannot be fully "rendered" without the assistance of application software. So it will not be adequate simply to print or render information in other long-lived media formats. We really will need to preserve our ability to read and interpret bits.

The year 2008 also marks the tenth anniversary of a project that started at the U.S. Jet Propulsion Laboratory: *The Interplanetary Internet*. This effort began as a protocol design exercise to see what would have to change to make Internet-like capability available to manned and robotic spacecraft. The idea was to develop networking technology that would provide to the space exploration field the kind of rich and interoperable networking between spacecraft of any (Earth) origin that we enjoy between devices on the Internet.

The design team quickly recognized that the standard TCP/IP protocols would not overcome some of the long delays and disruptions to be expected in deep space communication. A new set of protocols evolved that could operate above the conventional Internet or on underlying transport protocols more suited to long delays and disruption. Called "delay and disruption tolerant networking"[3, 4] or DTN, this suite of protocols is layered in the same abstract way as the Internet. The Interplanetary system could be thought of as a network of Internets, although it is not constrained to use conventional Internet protocols. The analog of IP is called the *Bundle Protocol*[5], and this protocol can run above TCP or the *User Datagram Protocol* (UDP) or the new *Licklider Transport Protocol* (for deep space application). Ironically, the DTN protocol suite has also proven to be useful for terrestrial applications in which delay and disruption are common: tactical military communication and civilian mobile communication.

After 10 years of work, the DTN system will be tested onboard the Deep Impact mission platform late in 2008 as part of a program to qualify the new technology for use in future space missions. It is hoped that this protocol suite can be standardized for use by any of the world's space agencies so that spacecraft from any country will be interoperable with spacecraft of other countries and available to support new missions if they are still operational and have completed their primary missions. Such a situation already exists on Mars, where the Rovers are using previously launched orbital satellites to relay information to Earth's Deep Space Network using store-and-forward techniques like those common to the Internet.

The Internet has gone from dial-up to deep space in just the past 10 years. One can only begin to speculate about its application and condition 10 years hence. We will all have to keep our subscriptions to *The Internet Protocol Journal* to find out!

A Decade in the Life of the Internet

by Geoff Huston, APNIC

The evolutionary path of any technology can often take strange and unanticipated turns and twists. At some points simplicity and minimalism can be replaced by complexity and ornamentation, while at other times a dramatic cut-through exposes the core concepts of the technology and removes layers of superfluous additions. The technical evolution of the Internet appears to be no exception, and contains these same forms of unanticipated turns and twists.

This article presents a personal perspective of the evolution of the Internet over the last decade, highlighting my impressions of what has worked, what has not, and what has changed over this period. It has been an extraordinary decade for the Internet, encompassing a boom and a bust that would rate among history's best, a comprehensive restructuring of the communications industry, and a set of changes that have altered the way in which each of us now works and plays. And the Internet has even added a few new words to the language on the way.

Rather than offer a set of random observations, I will use the Internet Protocol model as a template, starting with the underlying transmission media, then looking at the internetwork layer, the transport layer, then applications and services, and, finally looking at the business of the Internet.

The Transmission Media Layer

It seems like it was in an entirely different lifetime, but the *Internet Service Provider* (ISP) business of 1998 was still centrally involved in the technology of dial-up modems. The state-of-the-art of modem speed had been continually refined from 9,600 bps to 14.4 kbps, to 28 kbps, to finally, 56 kbps, squeezing every last bit out the phase amplitude space contained in an analogue 3-KHz voice circuit. Modems were the bane of an ISP's life. They were capricious, constantly being superseded by the next technical refinement, unreliable, difficult for customers to use, and they were just slow. Almost everything else on the Internet was tailored to download reasonably quickly over a modem connection. Webpages were carefully tailored with compressed images, and plaintext was the dominant medium as a consequence.

Not all forms of Internet access were dial-up. ISDN was used in some places, but it was never cheap enough to take over as the ubiquitous access method. There were also access services based on *Frame Relay,* X.25, and various forms of digital data services. At the high end of the speed spectrum were T1 access circuits with 1.5-Mbps clocking, and T3 circuits clocked at 45 Mbps.

ISPs leased circuits from a telephony company (telco). In 1998 the ISP industry was undergoing a transition of its trunk IP infrastructure from T1 circuits to T3 circuits. It was not going to stop here, but squeezing even more capacity from the network was proving to be a challenge. Deployment of 622-Mbps IP circuits occurred, although many of these were constructed using 155-Mbps *Asynchronous Transfer Mode* (ATM) circuits using router load balancing to share the IP load over four of these circuits in parallel. Gigabit circuits were just beginning, and the initial tests of IP over 2.5-Gbps *Synchronous Digital Hierarchy* (SDH) circuits began in 1998.

In some ways 1998 was a pivotal year for IP transmission. Until this time IP was still just another application that was positioned as just another customer of the telco's switched-circuit infrastructure that was constructed primarily to support telephony. From the analogue voice circuits to the 64K digital circuit through to the trunk bearers, IP had been running on top of the voice network. By 1998 things were changing. The Internet had started to make ever larger demands on transmission capacity, and the factor accelerating further growth in the network was now not voice, but data. It made little sense to provision an ever larger voice-based switching infrastructure just to repackage it as IP, and by 1998 the industry was starting to consider just what an all-IP high-speed network would look like, from the photon all the way through to the application.

At the same time the fiber-optic systems were changing with the introduction of *Wavelength-Division Multiplexing* (WDM). Older fiber equipment with electro-optical repeaters and *Plesiochronous Digital Hierarchy* (PDH) multiplexers allowed a single fiber pair to carry around 560 Mbps of data. WDM allowed a fiber pair to carry multiple channels of data using different wavelengths, with each channel supporting a data rate of up to 10 Gbps. Channel capacity in a fiber strand is between 40 to 160 channels using *Dense WDM* (DWDM). Combined with the use of all-optical amplifiers, the most remarkable part of this entire evolution in fiber systems is that a Tbps cable system can be constructed today for much the same cost as a 560-Mbps cable system of the mid-1990s. The factor that accelerated deployment of these high-capacity fiber systems was never based on expansion of telephony, because the explosive growth of the industry was all about IP. So it came as no surprise that at the same time as the demand for IP transmission was increasing there was a shift in the transmission model, where instead of plugging routers into telco switching gear and using virtual point-to-point circuits for IP, we started to plug routers into wavelengths of the DWDM equipment and operate all-IP networks in the core of the Internet.

The evolution of access networks has seen a shift away from modems to numerous digital access methods, including DSL, cable modems, and high-speed wireless services. The copper pair of the telco network has proved surprisingly resilient, and DSL has achieved speeds of tens of megabits per second through this network, with the prospect of hundred-megabit systems appearing soon.

So, in terms of transmission, the last 10 years has seen the network migrate from an overlay system of kilobit-per-second access with multimegabit trunks operating as a customer of the telco switched network to a comprehensive IP network with access of megabits per second with multigigabit trunks, or a thousandfold increase in basic network capacity in that period.

The demand of the Internet for capacity continues, and we are now seeing work on standardizing 40- and 100-Gbps transmission systems in the IEEE; the prospect of terabit transmissions is now taking shape for the Internet.

The Internet Layer

If transmission has seen dramatic changes in the past decade, then what has happened at the IP layer over the same period?

The glib answer is "absolutely nothing!" But that answer would be ignoring a large amount of activity in this area. We have tried to change many parts of IP in the past decade, but, interestingly, none of the proposed changes has managed to gain any significant traction in the network, and IP today is largely no different from IP of a decade ago. *Mobility*[1], *Multicast*[2], and *IP Security* (IPSec)[3] remain poised in the wings, still awaiting adoption by the Internet mainstream.

Quality of Service (QoS) was a "hot" topic in 1998, and it involved the search for a reasonable way for some packets to take the fast path while others took a more leisurely way through the network. We experimented with various forms of signaling, packet classifiers, queue-management algorithms, and interpretations of the *Type of Service* bits in the IPv4 packet header, and we explored the QoS architectures of *Integrated and Differentiated Services* in great detail. However, QoS never managed to achieve wide acceptance in mainstream Internet service environments. In this case the Internet took a simpler direction: In response to not enough network capacity, the alternate approach to installing additional mechanisms in the network—in the host protocol stack and even in the application in order to ration the capacity you have—is to simply expand the network to meet the total level of demand. So far the simple approach has prevailed in the network, and QoS remains largely unused[4].

We have experimented with putting circuits back into the IP architecture in various ways, most notably with the *Multiprotocol Label Switching* (MPLS) technology[5]. This technology used the label-swapping approach used in X.25, Frame Relay, and ATM virtual circuit switching systems; it created a collection of virtual paths from each network ingress to each network egress. The idea was that in the interior of the network you no longer needed to load up a complete routing table into each switching element, and instead of performing destination-address lookup you could perform a much smaller, and hopefully faster, label lookup.

This process did not eventuate, and switching packets using the 32-bit destination address continued to present much the same level of cost-efficiency at the hardware level as virtual circuit label switching. When you add the additional overhead of an additional level of indirection in terms of operational management of MPLS networks, MPLS became another technology that so far has not managed to achieve traction in mainstream Internet networks. However, MPLS is by no means a dormant technology, and one place where MPLS has enjoyed considerable deployment is in the corporate service sector where many *Virtual Private Networks*[6] are constructed using MPLS as the core technology, steadily replacing a raft of traditional private data systems that used X.25, Frame Relay, ATM, *Switched Multimegabit Data Service* (SMDS), and switched Ethernet.

Of course one change at the IP level of the protocol stack that was intended in the past decade but has not occurred is *IP Version 6*[7]. In 1998 we were forecasting that we would have consumed all the remaining unallocated IPv4 addresses by around 2008. We were saying at the time that, because we had completed the technical specification of IPv6, the next step was that of deployment and transition. There was no particular sense of urgency, and the comfortable expectation was that with a decade to go we did not need to raise any alarms. And this plan has worked, to some extent, in that today's popular desktop operating systems of Windows, MacOS, and UNIX all have IPv6 support. But other parts of this transition have been painfully slow. It was only a few months ago that the root of the *Domain Name System* (DNS) was able to answer queries using the IPv6 protocol as transport, and provide the IPv6 addresses of the root nameservers. Very few mainstream services are configured in a dual-stack fashion, and the prevailing view is still that the case for IPv6 deployment has not yet reached the necessary threshold. Usage measurements for IPv6 point to a level of deployment of around one-thousandth of the IPv4 network, and, perhaps more worrisome, this metric has not changed to any appreciable level in the past 4 years. So what about that projection of IPv4 unallocated pool exhaustion by 2008? How urgent is IPv6 now? The good news is that the *Internet Assigned Numbers Authority* (IANA) still has some 16 percent of the address space in its unallocated pool, so IPv4 address exhaustion is unlikely to occur this year. The bad news is that the global consumption rate of IP addresses is now at a level such that the remaining address pool can fuel the Internet for less than a further 3 years, and the exhaustion prediction is now sometime around 2010 to 2011.

So why have we not deployed IPv6 more seriously yet? And if we are not going to deploy IPv6, then what is the alternative? Of all the technical refinements to IP that have occurred, one that received little fanfare when it was first published has enjoyed massive deployment over the past decade, and that is the technology of *Network Address Translation* (NAT)[8]. Today NAT devices are ubiquitous. It seems that every home access unit, every corporate firewall, every data center, and every service includes a NAT device.

One measure of the ubiquity of NATs is the transformation that has occurred in the application space. By 2008 applications have either adopted a strict client-server approach, where the client always initiates the network transaction, or were forced down a more complex path. Where there is some form of peer interaction, applications are now equipped with additional capabilities, including NAT behavior discovery, NAT binding management, application-level name spaces, and multiparty rendezvous mechanisms, all required to allow the application to function across NATs. So far we have managed to offload the problem of looming address scarcity in the Internet onto NATs, and the really significant change that has occurred in the past decade at the IP level is the default assumption about the semantics of an IP address. An IP address is no longer synonymous with the persistent identity of the remote party that anyone can use to initiate a communication, but a temporary token to allow a single transaction to complete. As a consequence, most Internet services have retreated into data centers and the business of hosting services has thrived. And the change that would have preserved the coherent end-to-end architecture of the Internet IP layer, namely IPv6, is still waiting for wide-scale deployment.

The next few years promise to be "interesting" in every form of meaning of the word. The exhaustion of the remaining IPv4 address pool is imminent, and if we are going to substitute IPv6 in place of IPv4, then we simply do not have enough time to achieve this substitution before the remaining IPv4 address pool is depleted. And although so far NATs have conveniently pushed the problem of increasing address scarcity off the network and over to the edge devices and onto applications, it is not clear that this approach can sustain an ever-growing Internet indefinitely. We have yet to understand just what a "carrier-grade NAT" might be, or whether it can even work in any useful manner. NATs were an accidental addition to the Internet, and their role in the coming years is unclear.

The early 1990s saw a flurry of activity in the routing space, and protocols were quickly developed and deployed. By 1998 the "standard" Internet environment involved the use of either *Intermediate System-to-Intermediate System* (IS-IS) or *Open Shortest Path First* (OSPF) as large-scale interior routing protocols and *Border Gateway Protocol 4* (BGP4) as the interdomain routing protocol[9]. This picture has remained constant over the past decade. In some ways it is reassuring to see a technology that is capable of sustaining a quite dramatic growth rate, but perhaps that is not quite the complete picture.

We never quite completed the specification for the next interdomain routing protocol, and BGP4 is now showing signs of stress[10]. The pool of *Autonomous System* (AS) numbers is forecast to run out early in 2011, and by then we need to have fielded a new variant of BGP that can operate with a much larger pool of AS numbers[11].

Fortunately the technology development has been completed and an approach that allows incremental deployment has been devised, so this transition is not quite the traumatic transition that is associated with IPv6. But deployment is slow, and of the current level of adoption of the larger AS number set is, oddly enough, comparable to IPv6, at a level of around one-thousandth of the total AS number pool. The routing system has also been growing inexorably, and the capability of switching systems to cope with ever larger routing tables while at the same time offering continual improvements in cost-efficiencies is now looking less certain. So, once again we appear to be examining routing protocol theory and practice, and looking at alternate approaches to routing that can offer superior scaling properties to BGP for the future.

No listing of the major highlights in IP over the past decade would be complete without some mention of the perennial issue of *location* and *identity*.[25] One of the original simplifications in the IP architecture was to place the semantics of identity, location, and forwarding into an IP address. Although that process has proved phenomenally effective in terms of simplicity of applications and simplicity of IP networks, it has posed some serious challenges with regard to mobility, routing, and network management. Each of these aspects of the Internet would benefit considerably if the Internet architecture allowed identity to be distinct from location. Numerous efforts have been directed at this problem over the past decade, particularly in IPv6, but so far we really have not arrived at an approach that feels truly comfortable in the context of IP.

So although it is possible to observe that not much has happened at the IP level in the past decade that is deployed in the Internet—and IP is still IP—there is still a considerable agenda to tackle at the Internet layer.

The Transport Layer

A decade ago, in 1998, the transport layer of the IP architecture consisted of the *User Datagram Protocol* (UDP) and TCP, and the network usage pattern was around 95-percent TCP and 5-percent UDP. Here, as well, not much has changed in the intervening 10 years.

We have developed two new transport protocols, the *Datagram Congestion Control Protocol* (DCCP) and the *Stream Control Transmission Protocol* (SCTP)[12], which can be regarded as refinements of TCP to cover flow control for datagram streams in the case of DCCP and flow control over multiple reliable streams in the case of SCTP. However, in a world of transport-aware middleware that is the Internet today, the level of capability to actually deploy these new protocols in the public Internet is marginal at best.

TCP has proved to be remarkably resilient over the years, but as the capacity of the network increases the ability of TCP to continue to deliver ever faster data rates over distances that span the globe is becoming a significant concern. Recent times have seen much work to devise revised TCP flow-control algorithms that still share the network fairly with other concurrent TCP sessions, yet can ramp up to multigigabit-per-second data-transfer rates and sustain those rates over extended periods[13]. At this stage much of this work is still in the area of research and experimentation, and TCP today as deployed on the Internet is much the same as TCP of a decade ago, with perhaps a couple of notable exceptions. The latest TCP stack from Microsoft in Vista uses dynamic tuning of the Receive window, and a larger inflation factor of the Send window in congestion avoidance where there is a large bandwidth delay product, and improved loss-recovery algorithms that are particularly useful in wireless environments. Linux now includes an implementation of *Binary Increase Congestion control* (BIC), which undertakes a binomial search to reestablish a sustainable send rate. Both of these approaches can improve the performance of TCP, particularly when sending the TCP session over long distances and trying to maintain high transfer speeds.

The Application and Service Layer

This area, unlike the transport layer, has seen quite profound changes over the past decade. A decade ago the Internet was on the cusp of portal mania, where *LookSmart* was the darling of the Internet boom and everyone were all trying to promote their own favorite "one stop shop" for all their Internet needs. We were still using various forms of hand-compiled directories, and navigation of the Internet was still the subject of various courses and books.

By 1998 *AltaVista* has made its debut, and change was already evident. This change, from directories and lists to active search, completely changed the Internet. These days we simply assume that we can type any query we have into a search engine and the search machinery will deliver a set of pointers to relevant documents. Each time this process occurs our expectations about the quality and utility of search engines are reinforced, and we have moved beyond swapping URLs as pointers and simply exchange search terms as an implicit reference to the material. Content is also changing as a result, because users no longer remain on a "site" and navigate around the site. Instead users are directing the search engines, and pulling the relevant page form the target site without reference to any other material.

Another area of profound change has been the rise of active collaboration over content, best typified in wikis. *Wikipedia* is perhaps the most cited example of user-created content, but almost every other aspect of content generation is also being introduced into the active user model, including *YouTube, Flickr, Joost,* and similar content.

Underlying these changes is another significant development, namely the changes in the content economy. In 1998 content providers and ISPs were competing for user revenue. Content providers were unable to make pay per view and other forms of direct financial relationship with users work in their favor, and were arguing that ISPs should fund content, because, after all, the only reason that users paid for Internet access was because of their perceived value of the content. ISPs, on the other hand, promoted the idea that content providers were enjoying a free ride across the ISP-funded infrastructure, and content providers should contribute to network costs. The model that has gained ascendency as a result of this unresolved tension was that of advertised-funded content services, and this model has sustained a vastly richer, larger, and more compelling content environment.

At the same time the peer-to-peer network has emerged, and from its beginnings as a music-sharing subsystem, the distributed data model of content sharing now dominates the Internet with audio, video, and large data sets now using this form of content distribution and its associated highly effective transport architecture. Various measurements of Internet traffic have placed peer-to-peer content movement at between 40 and 80 percent of the overall traffic profile of the network.

In many ways applications and services have been the high frontier of innovation in the Internet in the past decade. An entire revolution in open interconnection of content elements is embraced under the generic term *Web 2.0*, and "content" is now a very malleable concept. It is no longer the case of "my computer, my applications, and my workspace" but an emerging model where not only the workspace for each user is held in the network, but where the applications themselves are part of the network, and all are accessed through a generic browser interface.

Any summary of the evolution of the application space over the last decade would not be complete without noting that whereas in 1998 the Internet was still an application that sat on top of the network infrastructure used to support the telephone network, by 2008 voice telephony was just another application layered on the infrastructure of the Internet, and the Internet had even managed to swallow the entire telephone number space into its DNS, using an approach called *ENUM*[14].

The Business Layer

As much as the application environment of the Internet has been wildly erratic over the past decade, the business environment has been unpredictable as well, and the list of business winners and losers includes some of the historical giants of the telephone world as well as the Internet-bred new wave of entrants.

In 1998, despite the growing momentum of public awareness, the Internet was still largely a curiosity. It was an environment inhabited by geeks, game players, and academics, whose rites of initiation were quite arcane. As a part of the data networking sector, the Internet was just one further activity among many, and the level of attention from the mainstream telco sector was still relatively small. Most Internet users were customers of independent ISPs, and the business relationship between the ISP sector and the telco was tense and acrimonious. The ISPs were seen as opportunistic leeches on the telco industry; they ordered large banks of phone lines, but never made any calls; their customers did not hang up after 3 minutes, but kept their calls open for hours or even days at a time, and they kept ordering ever larger inventories of transmission capacity, yet had business plans that made the back of an envelope look professional by comparison. The telco was unwilling to make large long-term capital investments in additional infrastructure to pander to the extravagant demands of a wildcat set of Internet speculators and their fellow travelers. The telco, on the other hand was slow, expensive, inconsistent, ill-informed, and hostile to the ISP business. The telco wanted financial settlements and bit-level accounting, whereas the ISP industry appeared to manage quite well with a far simpler system of peering and tiering that avoided putting a value on individual packets or flows[15]. This relationship was never going to last, and it resolved itself in ways that in retrospect were quite predictable. From the telco perspective it quickly became apparent that the only reason the telco was being pushed to install additional network capacity at ever increasing rates was the requirements of the ISP sector. From the ISP perspective the only way to grow at a rate that matched customer demand was to become one's own carrier and to take over infrastructure investment. And, in various ways, both outcomes occurred. Telcos bought ISPs, and ISPs became infrastructure carriers.

All this activity generated considerable investor interest, and the rapid value escalation of the ISP industry and then the entire Internet sector generated the levels of wild-eyed optimism that are associated only with an exceptional boom. By 2000 almost anything associated with the Internet, whether it was a simple portal, a new browser development, a search engine, or an ISP, attracted investor attention, and the valuations of Internet start-ups achieved dizzying heights. Of course one of the basic lessons of economic history is that every boom has an ensuing bust, and in 2001 the Internet bust happened. The bust was as inevitable and as brutal as the preceding boom was euphoric. But, like the railway boom and bust of the 1840s, when the wreckage was cleared away, what remained was a viable—and indeed a valuable—industry.

By 2003 the era of the independent retail ISP was effectively over. ISPs still exist, but those that are not competitive carriers tend to operate as IT business consultants that provide services to niche markets. Their earlier foray in to the mass market paved the way for the economies of scale that only the carrier industry could implement on the market.

But the grander aspirations of these larger players have not been met, and effective monopoly positions in many Internet access markets have not translated to effective control over the user's experience of the Internet, or anything even close to such control. The industry was already "unbundled," with intense competition occurring at every level of the market, including content, search, applications, and hosting. The efforts of the telco sector to translate their investment into mass-market Internet access into a more comprehensive control over content and its delivery in the Internet has been continually frustrated. The content world of the Internet has been reinvigorated by the successful introduction of advertiser-funded models of content generation and delivery, and this process has been coupled with the more recent innovations of turning back to the users themselves as the source of content, so that the content world is once again the focus of a second wave of optimism, bordering on euphoria.

And Now?

It has been a revolutionary decade for us all, and in the last 10 years the Internet has directly touched the lives of almost every person on this planet. Current estimates put the number of regular Internet users at 19 percent of the world's population.

Over this decade some of our expectations were achieved and then surpassed with apparent ease, whereas others remained elusive. And some things occurred that were entirely unanticipated. At the same time very little of the Internet we have today was confidently predicted in 1998, whereas many of the problems we saw in 1998 remain problems today.

What we have today is not the technical Internet we thought we were building a decade ago. It is not a coherent end-to-end network with clear signaling across commodity packet switching fabric, but a network that is replete with all forms of active middleware[16], from NATs to firewalls[17] and filters, including packet shapers, torrent detectors, *Voice over IP* (VoIP) blockers, and load balancers. It is neither a secure nor a safe network, but one that includes a continual barrage on end hosts in the form of more than a million different forms of viruses[18], worms, and assorted malware[19], as well as a barrage on users in the form of torrents of spam[20]. The network is a host to a litany of hostile attacks, including gigabit traffic swamping attacks, redirection, inspection, passing off, and denial-of service attacks[21]. The attacks are directed at links, routers[22], the routing protocols[23, 24], hosts, and applications. Our ability to effectively defend the network and its connected hosts continues to be, on the whole, ineffectual. Our level of interest in paying a premium to support highly secure systems still remains slight. But somehow we are not deterred by this situation. Somehow each of us has found a way to make our Internet work for us.

I am not sure that the next decade will bring the same level of intensity of structural change to the global communications sector, and perhaps that is a good thing given the collection of other challenges that are confronting us all in the coming decades. At the same time I think it would be good to believe that the past decade of development of the Internet has completely rewritten what it means to communicate, rewritten the way in which we can share our experience and knowledge, and, hopefully, rewritten the ways in which we can work together on these challenges.

He has been closely involved with the development of the Internet for many years, particularly within Australia, where he was responsible for the initial build of the Internet within the Australian academic and research sector. The author of numerous Internet-related books, he is currently the Chief Scientist at APNIC, the Regional Internet Registry serving the Asia Pacific region. He was a member of the Internet Architecture Board from 1999 until 2005, and served on the Board of the Internet Society from 1992 until 2001. E-mail: **gih@apnic.net**

Mobile WiMAX

by Jarno Pinola and Kostas Pentikousis, VTT Technical Research Centre of Finland

One of the technologies that can lay the foundation for the next generation (fourth generation [4G]) of mobile broadband networks is popularly known as "WiMAX." WiMAX, *Worldwide Interoperability for Microwave Access,* is designed to deliver wireless broadband bitrates, with *Quality of Service* (QoS) guarantees for different traffic classes, robust security, and mobility. This article provides an overview of mobile WiMAX, which is based on the wireless local and *Metropolitan-Area Network* (MAN) standards IEEE 802.16-2004[1] and 802.16e-2005[2]. We introduce WiMAX and focus on its mobile system profile and briefly review the role of the WiMAX Forum. We summarize the critical points of the WiMAX network reference model and present the salient characteristics of the PHY and MAC layers as specified in [1] and [2]. Then we address how mobile nodes enter a WiMAX network and explain the fundamentals of mobility support in WiMAX. Finally, we briefly compare WiMAX with *High-Speed Packet Access* (HSPA), another contender for 4G.

The Role of the WiMAX Forum

The WiMAX Forum is a nonprofit organization formed in 2001 to enhance the compatibility and interoperability of equipment based on the IEEE 802.16 family of standards. The IEEE 802.16 standards provide a large set of fundamentally different options for designing a wireless broadband system, including, for example, multiple options for *Physical* (PHY) layer implementation, *Media Access Control* (MAC) architecture, frequency bands, and duplexing. So many options lead to several possible system variants, which are all compatible with the IEEE standards. Although such multiplicity allows for deployment in very diverse environments, it may spell either solely vertical, single-vendor deployments or no deployment at all, because operators do not want to be locked in with any particular implementation. Thus, a major motivation for establishing the WiMAX Forum was to develop predefined system profiles for equipment manufacturers, which include a subset of the features included in the IEEE 802.16 standards. WiMAX Forum-certified products are guaranteed to be interoperable and to support wireless broadband services from fixed to fully mobile scenarios. The aim is to enable rapid market introduction of new standard-compliant WiMAX equipment and to promote the use of the technology in different sectors.

From IEEE 802.16 to Mobile WiMAX

The IEEE 802.16 standard was originally meant to specify a fixed wireless broadband access technique for point-to-point and point-to-multipoint links. During its development, however, it was decided that mobility support should also be considered.

The WiMAX Forum defines two system profiles based on [1] and [2], called *fixed* and *mobile* system profiles, respectively. Both include mandatory and optional PHY and MAC layer features that are required from all corresponding WiMAX-certified products. Because [1] and [2] specify only the PHY and MAC layers, an end-to-end architecture specification was deemed necessary in order to enable fast growth in manufactured quantities, market share, and interoperability. In response, the WiMAX Forum established the *Network Working Group* (NWG) with the aim of developing an end-to-end network reference model architecture based on IP supporting both fixed and mobile WiMAX (refer to [3] and [4]).

In short, according to the NWG reference model, a WiMAX network is partitioned into three independent architectural components: the user equipment (also referred to as *Customer Premises Equipment* [CPE]), the *Radio Access Network* (RAN, based on IEEE 802.16), and the network providing IP connectivity with the rest of the Internet. Clearly, this model allows a single operator to freely mix and match offerings from different manufacturers for these three parts, at least after interoperable equipment becomes readily available. Furthermore, in principle, each of these components of an operational network can be deployed and managed by different service providers. This scenario makes the network architecture flexible, eases network operation and maintenance, can increase competition under certain conditions, and is conducive to new business models. For example, municipalities can venture jointly with local or national network operators to deploy WiMAX in suburban and rural areas.

In contrast with earlier wireless data networks[5], IP is fundamental in a WiMAX network. Indeed, IP currently plays a dominant role in the present state of the telecommunications industry. The premise is that by embracing IP, service providers and equipment manufacturers will face fewer problems when introducing WiMAX into their networks and product portfolios. Moreover, protocols standardized by the *Internet Engineering Task Force* (IETF) are preferred over proprietary solutions and are adopted as extensively as possible in the reference model.

Mobile WiMAX Network Reference Model

The WiMAX Forum NWG network reference model defines three basic architectural entities: the *Mobile Station* (MS), the A*ccess Service Network* (ASN), and the *Connectivity Service Network* (CSN). The role of the MS is to provide user access to the WiMAX network. The ASN is the Radio Access Network and is formed by numerous *Base Stations* (BSs) and *ASN Gateways* (ASN-GWs), managed by a *Network Access Provider* (NAP). CSN is the network entity providing IP connectivity to the WiMAX radio equipment, including all the IP core network functions required for internetworking with the rest of the world. CSNs are maintained by *Network Service Providers* (NSPs).

The ASN and CSN are further broken up into smaller functional entities, which communicate with each other using standardized interfaces called *reference points*. These reference points guarantee that a certain set of protocols and procedures are always supported and can function irrespective of the underlying hardware. The currently defined reference points are used for different control and management purposes, as well as for data bearing between the network entities. Figure 1 illustrates the network reference model and the main reference points.

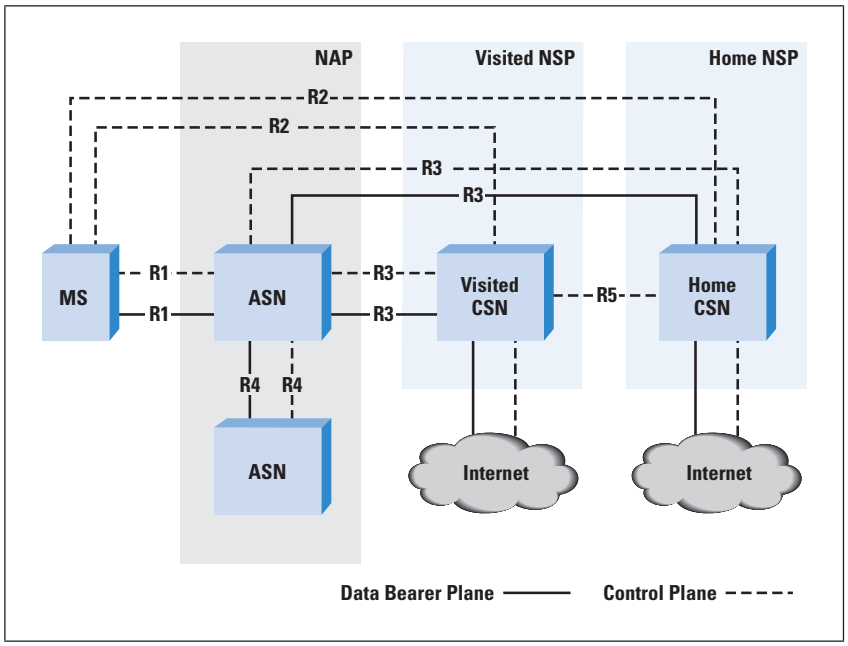

Figure 1: WiMAX Forum NWG Network Reference Model

The reference points are defined as follows in [3]: Reference point R1 consists of protocols and procedures compliant to [1], [2], and [6]. R1 implements the specifications of the air interface between the MS and the BS. R2, an interface between the MS and a CSN, is used solely for management purposes, including mobility management. R3 serves the same purpose between an ASN and a CSN, and R4 is used for micromobility management between two ASNs. R5 enables interworking between two CSNs for macromobility management.

In addition to reference points R1–R5, another three intra-ASN reference points are defined (not illustrated in Figure 1). R6, which consists of a set of control- and bearer-plane protocols for BS and ASN-GW communication, controls the data path and MS mobility events between these two ASN entities. R7 is an optional set of protocols used for coordinating R6 functions. Finally, R8 consists of bearer-plane protocols that enable data transfer between the base stations involved in a handover (also called *handoff*).

With respect to mobility, the reference model considers two different scenarios called *ASN-anchored mobility* and *CSN-anchored mobility.* ASN-anchored mobility (or intra-ASN mobility, or micromobility) management is employed when MS handovers occur from one BS to another, and both are controlled by the same ASN-GW. On the other hand, CSN-anchored mobility (or inter-ASN mobility, or macromobility) management is employed when MS movement dictates a handover from the currently serving BS to another one that is in a different subnetwork, controlled by a different ASN-GW. In the ASN-anchored case, handovers are managed solely by the MS and the ASN. In the CSN-anchored case, both ASN and CSN entities are engaged in mobility management.

Typically, ASN-anchored mobility procedures take precedence and CSN-anchored mobility management is employed only if necessary. Because ASN-anchored mobility takes place inside a single ASN, it does not change the MS network layer (IP) configuration. Three different functions are specified for ASN-anchored mobility management, all considered peer-to-peer interactions between different architectural entities:

- The *handoff* (HO) function controls the handover decision operation and handover signaling. The HO function supports mobile- and network-initiated handovers and, additionally, it may support *Fast Base Station Switching* (FBSS) or *Macro Diversity Handover* (MDHO)[2].
- The *Data Path* (DP) function manages the data path setup and data packet transmission between two functional entities.
- The context function addresses the exchanges required in order to retrieve or set up any state in the network elements.

On the other hand, when MS movement necessitates CSN-anchored mobility management, the MS IP layer configuration changes as a result of the handover. In this case, mobility management is based on *Mobile IPv4* (MIPv4)[7] or *Mobile IPv6* (MIPv6)[8], if the MS supports it. Alternatively, the reference model adopts *Proxy MIP* (PMIP)[9] to handle the handover. In PMIP, the MIP function is moved from the MS to a network instance called a *PMIPv4 client,* which takes care of all MIP signaling on behalf of the MS. Support for PMIP is specified only for MIPv4 in [3] and [4]. Note that in a handover from one ASN to another, MIP is used to complement ASN-anchored mobility management. The latter is still necessary to control the link-layer handover procedures. That is, after the micromobility handover is successfully completed, MIP independently takes care of the macromobility handover, that is, establishes communication paths between the new ASN-GW and the CSN. CSN-anchored mobility handovers are always network-initiated.

By embracing IETF protocols and providing an end-to-end architecture with independent functional entities, the WiMAX Forum NWG network reference model provides a clear framework for the application developers to work in. The model provides only operational requirements and does not prescribe particular technical solutions to realize them, allowing for proprietary yet standards-compliant implementations and enabling technical competition between different manufacturers.

Before examining mobility support in WiMAX, we review the basics of the IEEE 802.16 PHY and MAC layers.

OFDM and OFDMA

IEEE 802.16 and thus WiMAX adopted *Orthogonal Frequency Division Multiplexing* (OFDM), a multicarrier modulation scheme, as its PHY layer. In OFDM, the available bandwidth is divided into several parallel orthogonal subcarriers with lower bandwidth. A wideband channel is defined as a group of adjacent narrowband channels: a high-bitrate data stream is divided into these subcarriers and multiple narrowband data streams are transmitted over the air. Because the data symbol duration is inversely proportional to bitrate, the transmitted symbol duration is increased and the level of *Inter-Symbol Interference* (ISI) can be reduced. ISI is caused by multipath propagation in the wireless communication medium, where the transmitted data symbols can arrive at the receiver through different propagation routes because of reflections from buildings in urban areas and from hills and trees in rural areas. OFDM also uses guard intervals between successive data symbols and cyclic prefixes in order to decrease the effect of ISI even more.

One reason for the wide adoption of OFDM in modern broadband communication systems is its hardware implementation simplicity. OFDM signals can be formed and processed using *Inverse Fast Fourier Transform* (IFFT) and *Fast Fourier Transform* (FFT), at the transmitter and receiver, respectively, and both transforms can be implemented directly in hardware for higher performance. OFDM bodes well for mobile broadband systems through frequency diversity and adaptivity in both modulation and channel coding. By using *Adaptive Modulation and Coding* (AMC), the end-to-end quality deterioration due to the excess delays and deep fading conditions caused by mobility can be prevented, or at least diminished.

OFDM can also be used as a multiaccess scheme by having subcarriers grouped into subchannels, which can be assigned to different users contending for the data link. Each subchannel can contain a different number of subcarriers, and by altering the subcarrier group sizes and observing the channel conditions, it is possible to use differentiation in the channel allocation for different users.

This technique of using OFDM as a multiaccess scheme is called *Orthogonal Frequency Division Multiple Access* (OFDMA). Mobile WiMAX uses OFDMA as its PHY layer instead of plain OFDM, and subchannelization to both uplink and downlink transmissions is possible.

In OFDMA, the subcarriers assigned to subchannels can be either concurrent or taken from different regions of the total bandwidth. Both of these allocation schemes have advantages. When subcarriers assigned to one subchannel are distributed over the available bandwidth, frequency diversity can be attained. In mobile systems this diversity is advantageous because it can be used to make the transmission link more resistant against fast fading. A subchannelization scheme based on dispersed subcarrier allocation to subchannels, called *Partial Usage of Subcarriers* (PUSC), is mandatory in all mobile WiMAX implementations.

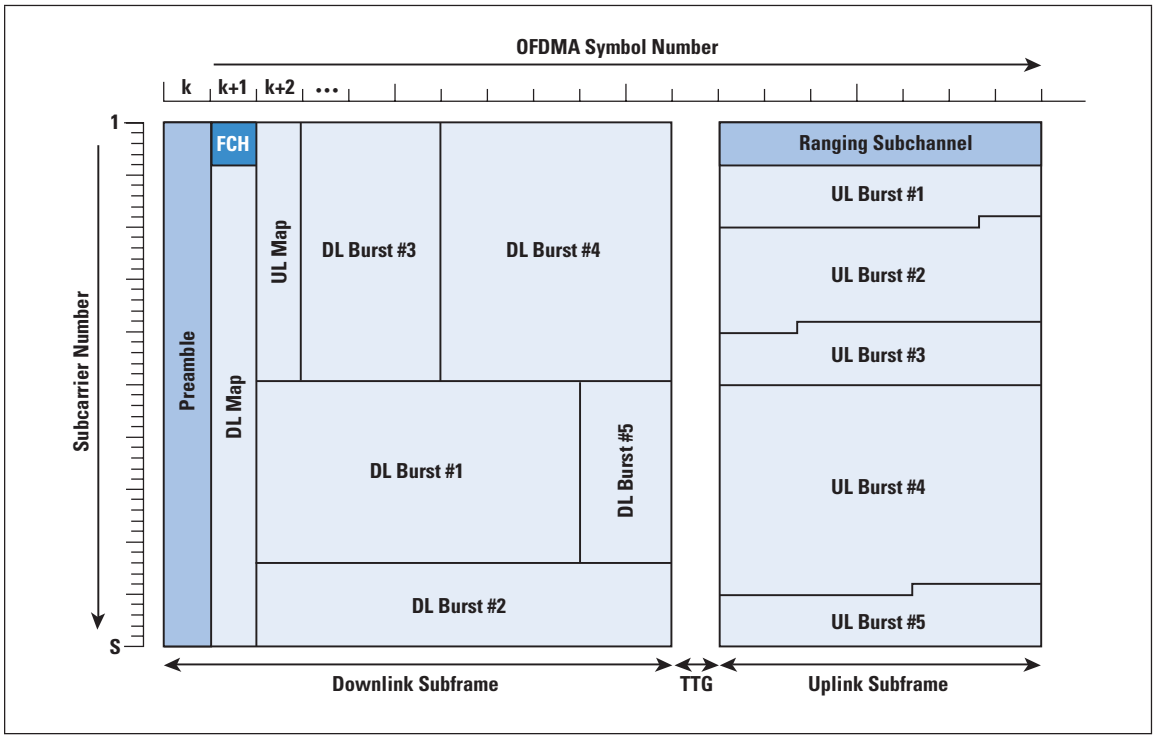
WiMAX systems can use *Time-Division Duplexing* (TDD) or *Frequency-Division Duplexing* (FDD) when allocating air interface resources to users. In TDD, the uplink and downlink transmissions are done over the same carrier frequencies and the separation between the transmission directions is done by assigning time slots, in which the transmission to one direction at a time is scheduled. In FDD, uplink and downlink transmissions are done simultaneously over different carrier frequencies.

Commonly used in mobile WiMAX equipment, TDD allows more flexible sharing of the available bandwidth between the uplink and downlink transmissions. On balance, TDD requires synchronization between multiple adjacent base stations so that transmissions in neighboring cells do not interfere with each other. A TDD frame (Figure 2) is divided into two subframes: first comes a downlink frame and after a short guard interval, called the *Transmit/Receive Transition Gap* (TTG), an uplink frame follows in the same frequency band. Each downlink subframe starts with a preamble, which is used for synchronization and channel estimation. To enhance tolerance against mobility-inflicted channel impairments, WiMAX allows optional support for a more frequent preamble repetition during transmission. In the uplink, short preambles, also called *midambles,* can be used after 8, 16, or 32 OFDM symbols, and in the downlink, short preambles in front of every data burst can be used. After the preamble comes a *Frame Control Header* (FCH), which consists of uplink and downlink *Media Access Protocol* (MAP) messages, which inform users about their transmission parameters.

Flexible data multiplexing from different users into one OFDM or OFDMA frame is also supported, as illustrated in Figure 2. Both uplink and downlink subframes can include data bursts of different types from multiple users, and they can be of variable length.

A small portion of the uplink subframe is reserved for transmission parameter adjustment and bandwidth request purposes. Moreover, small amounts of user data can be sent in this portion of the uplink subframe. The total OFDM frame size can range between 2.5 and 20 ms, but the initially supported frame size in present WiMAX equipment is 5 ms.

Figure 2: An example of a WiMAX OFDMA Frame

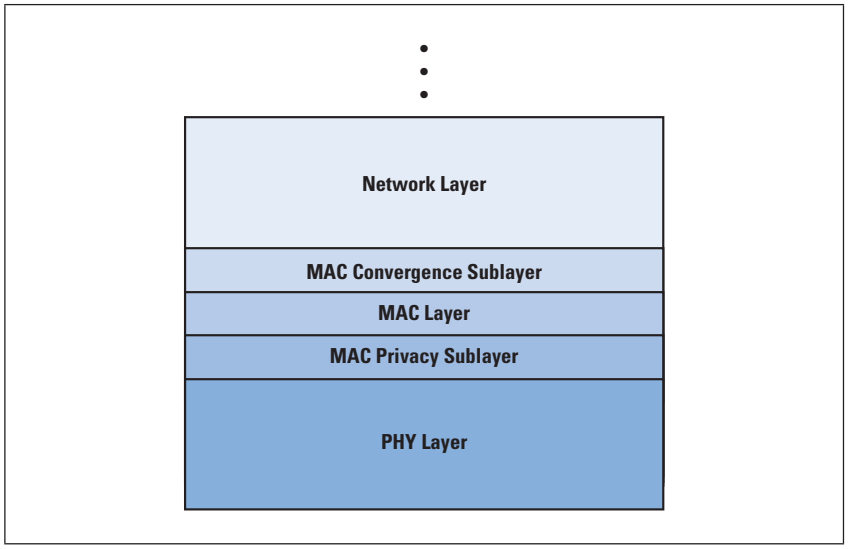


Media Access Control

The MAC layer is primarily an adaptation layer between the PHY layer and the upper layers. Its most important task, when transmitting data, is to receive *MAC Service Data Units* (MSDUs) from the layer above, aggregate and encapsulate them into *MAC Protocol Data Units* (MPDUs), and pass them down to the OFDM or OFDMA PHY layer for transmission. When data is received, the MAC layer takes MPDUs from the PHY layer, decapsulates and reorganizes them into MSDUs, and passes them on to the upper-layer protocols.

An additional layer between the MAC and upper protocol layers called the *Convergence Sublayer* (CS) is also defined in [1] and [2] and illustrated in Figure 3. For the upper layers, CS functions as an interface to the MAC layer. Even though in principle a CS is presented for a variety of different protocols, currently [3] and [4] support CS only for IP and Ethernet. Other protocols can, of course, use these CSs through encapsulation. The CS may also support upper-protocol header compression.

Figure 3: WiMAX Protocol Stack



Similarly with the PHY layer, shown in Figure 3, the MAC layer allows flexible allocation of transmission capacity to different users. Variably sized MPDUs from different flows can be included into one data burst before being handed over to the PHY layer for transmission. Multiple small MSDUs can be aggregated into one MPDU and, conversely, one big MSDU can be fragmented into multiple small ones in order to further enhance system performance. For example, by bundling up several MPDUs or MSDUs, the PHY and MAC layer header overheads, respectively, can be reduced.

It is important to remember that the BS MAC layer manages bandwidth allocation for both uplink and downlink transmissions. The BS assigns bandwidth for the downlink transmission according to incoming network traffic. For the uplink transmission, bandwidth is allocated based on the requests received from the MS. Because basically all connections are controlled by the BS, QoS can be efficiently implemented into WiMAX equipment. Currently, the MAC layer of a mobile WiMAX BS should include support for five different QoS classes, briefly summarized in Table 1.

Table 1: Mobile WiMAX QoS Classes

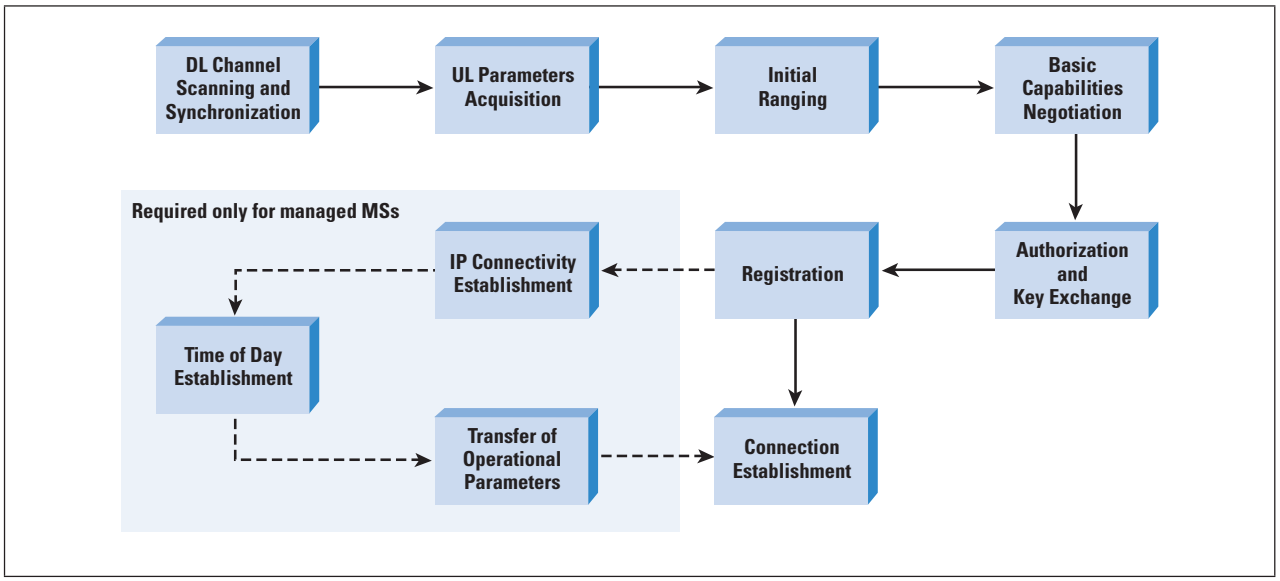
QoS Class	Supported Service	Example Application
Unsolicited Grant Services (UGS)	Latency- and jitter-sensitive applications with fixed-size data packets at Constant Bitrate (CBR)	Voice over IP (VoIP) without silence suppression
Real-Time Variable Rate (RT-VR)	Real-time applications with variable-size data packet bursts	Video and audio streaming
Non-Real-Time Polling Services (nrtPS)	Delay-tolerant applications with variable-size data packets and guaranteed bitrate demands	File transfers
Extended Real-Time Variable Rate (ERT-VR)	Real-time applications with Variable Bitrate (VBR) data streams and guaranteed bitrate and delay demands	VoIP with silence suppression
Best Effort (BE)	Data streams with no minimum service-level demands	Web browsing, instant messaging, and data transfer

Prior to any data transmission over a WiMAX link, the MS and the BS must form a unidirectional connection between their respective MAC layers. A unique identifier, called *Connection Identifier* (CID), is assigned to each uplink and downlink connection pair. The CID serves as a temporary address for the transmitted data packets over the WiMAX link. Another identifier, called *Service Flow Identifier* (SFID), is assigned by the BS to unidirectional packet flows with the same QoS parameters, that is, service flows. The BS also handles the mapping of SFIDs to CIDs in the QoS control process. Note that the MAC layer incorporates sophisticated power-management techniques and robust, state-of-the-art security features, but these features are out of scope for this article.

Network Entry and Reentry

Figure 4 illustrates the basic steps that every MS must go through when entering or reentering a WiMAX network. First, a MS scans the downlink channel and synchronizes with the BS, after which the MS acquires the transmit parameters for the uplink transmission from the BS *Uplink Channel Descriptor* (UCD) message and performs initial ranging, hence acquiring the correct timing offset and power adjustments. A MS extracts an initial ranging-interval time slot from an uplink MAP message. If a MS cannot complete the initial ranging successfully, it must start scanning for a new downlink channel.

Figure 4: Network Entry/Reentry Procedure



The basic capabilities negotiation process starts when the MS sends a message containing its capabilities to the BS; the BS responds with a message containing the capabilities it has in common with the MS. If *Privacy Key Management* (PKM) is enabled at both the MS and the BS, the next step is to perform the authorization and key-exchange procedure, so that the MS can register with the network. The BS sends back a registration response message that contains the secondary management CID, if the MS is managed.

After a managed MS obtains this secondary management CID, it becomes "manageable." The successful reception of the registration response message is a prerequisite for any MS in order to be able to transmit to and receive from the network.

When a managed MS enters the network, the next step is to establish IP connectivity by using the assigned secondary management connection and by either invoking the *Dynamic Host Configuration Protocol* (DHCP)[10] or DHCPv6[11], or using the IPv6 stateless address autoconfiguration[12], depending on the information provided by the BS registration response message. If the MS uses MIPv4 or MIPv6, it can secure its address by using the secondary management connection with MIP. The establishment of IP connectivity and time of day, as well as the transfer of the operational parameters, are needed only for managed MSs. These parameters can be managed with IP management messages through a secondary management connection, for example, by using the DHCP, *Trivial File Transfer Protocol* (TFTP)[13], or *Simple Network Management Protocol* (SNMP)[14]. These additional steps during network entry are necessary for the operation of the IP management protocols.

If DHCP is used to establish IP connectivity, a managed MS must also establish the time of day so that the management system can time-stamp certain events. Both the MS and the BS must be set at the same time of day, with an accuracy of the nearest second. The time of day is retrieved using the secondary management connection with the *Time Protocol*[15]. The current time is formed by combining the time retrieved from the server with the time offset extracted from the DHCP reply message. Although the time of day is not needed for the registration to complete successfully, it is required in order to keep the connection operational. Finally, the managed MS must acquire its operational parameters with TFTP.

After a managed MS has obtained its operational parameters, or after an unmanaged MS has registered with the network, the MS preprovisioned service-flow connections are established.

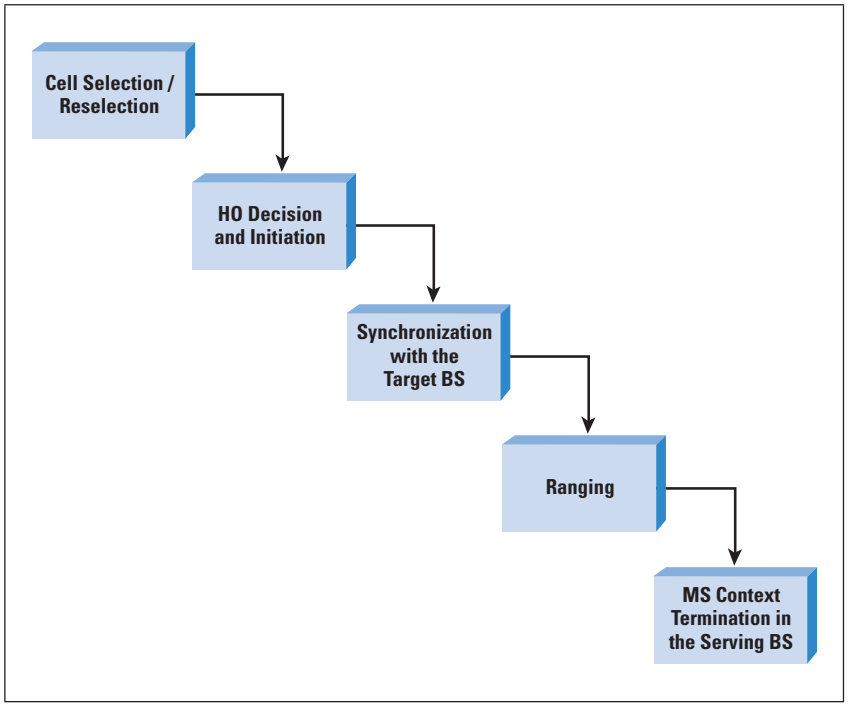
Mobility Support

As discussed previously, IEEE 802.16e introduced mobility support, defining an OFDMA PHY layer and signaling mechanisms to enable location and mobility management, paving the way for mobile WiMAX. The WiMAX Forum details four mobility scenarios in addition to the fixed WiMAX scenario. In the nomadic and portable mobility scenarios, the point of attachment of a fixed *Subscriber Station* (SS) can change. The simple mobility scenario allows MSs to roam within the coverage area with speeds up to 60 km/h, but handovers may cause connection interruptions of up to 1 second. In the so-called *full-mobility scenario,* the MS speed can be as much as 120 km/h, and transparent handovers are supported. This last scenario is what many might consider as the real mobile WiMAX scenario, but all five scenarios are "standards-compliant."

Although three different types of handovers are defined in [2], *Hard Handover* (HHO), *Macro Diversity Handover* (MDHO), and *Fast Base Station Switching* (FBSS), only HHO is mandatory for all mobile WiMAX equipment. This type of handover is often referred to as a *break-before-make handover:* first, the MS disconnects from the serving BS and then connects to the target BS. Because of the short disconnection period, packets may be lost; HHO is less sophisticated than either MDHO or FBSS and may be inappropriate for some applications. The MS must also register with the target BS and reauthenticate with the network, typically meaning further delays before actual data exchange can (re)start. If multiple handover types are supported and enabled, the BS decides which type should take precedence over the other. MDHO and FBSS are enabled or disabled during the registration of the MS with the BS.

Figure 5 illustrates the five stages of a successful HHO in mobile WiMAX. The first stage is to select the target BS cell based on information about the network topology surrounding the serving BS through periodically broadcasted neighbor advertisements. The advertisements include the same information on the serving BS neighbors that the *Downlink Channel Descriptor* (DCD) and *Uplink Channel Descriptor* (UCD) messages of the neighboring BSs would include. For example, a neighbor advertisement message includes channel information of the neighboring BSs so that the MS can synchronize with them and perform scanning operations to evaluate their suitability as potential targets for a HO.

Figure 5: The Five Phases of a Successful HHO



The second phase is to make the actual decision to initiate the handover procedure, when a certain network (say, congestion in the serving cell requires load balancing) or channel condition threshold (for example, low received *Signal-to-Interference + Noise Ratio* [SINR] in the current cell) is crossed. The actual decision to start the message exchange for the MS to migrate from the radio interface of the serving BS to the radio interface of another BS can be made by the MS, BS, or the network. In the third phase, the MS synchronizes with the downlink transmission of the target BS and obtains the transmission parameters for the downlink and the uplink. The time consumed to perform the synchronization procedure depends on the amount of information the MS received about the target BS in the neighbor advertisement messages prior to the handover. The average synchronization latency without previously acquired information about the target BS ranges from two to three frame cycles, or approximately 4 to 40 ms depending on the OFDMA frame duration used in the system. The more extensive the channel parameter list received in the neighbor advertisement messages prior to the handover, the shorter the time to achieve the synchronization.

After synchronizing, the MS and the target BS initiate the ranging procedure. During this fourth step in HHO, MS and BS exchange the required information so that the MS can reenter the network. The target BS can request information about the MS from the (previously) serving BS and other network entities. Again, the more information made available to the target BS, the shorter the time to reenter the network, because the target BS may skip some steps from the network (re)entry procedure described earlier. In short, sharing context information before the actual handover optimizes the handover procedure and decreases its latency. In the last step of a HHO, the MS context at the serving BS is terminated and resources are released.

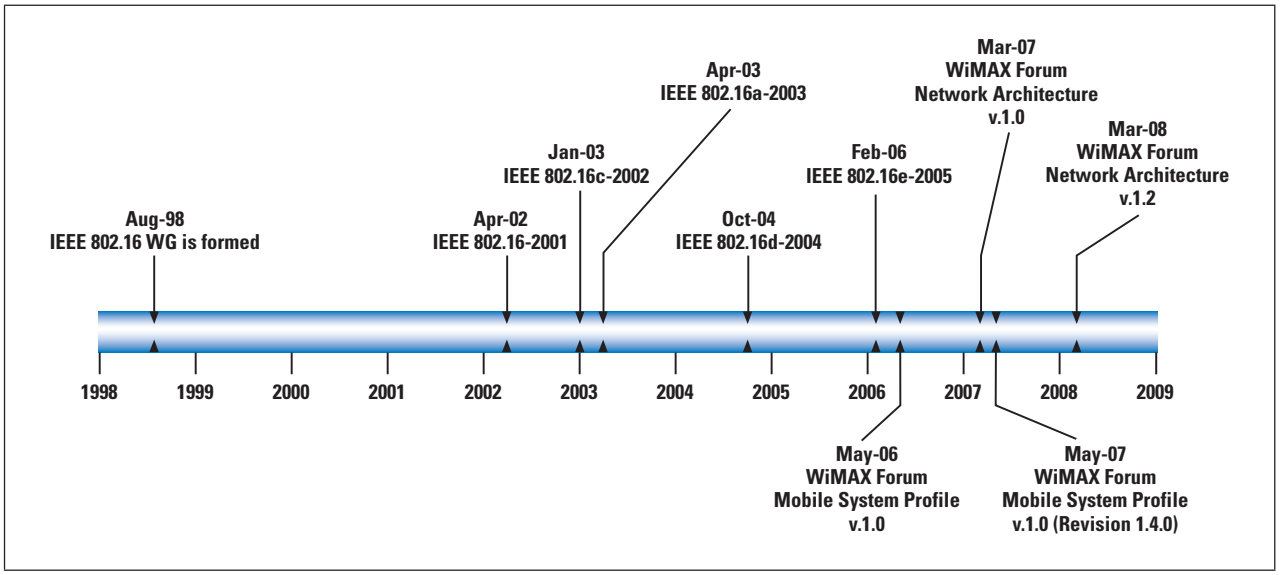
If MDHO and FBSS are supported, the following stages, in addition to those already described in the HHO procedure, must be performed: (a) decision to enable MDHO or FBSS, (b) diversity set update, and (c) anchor BS selection. In macrodiversity communications the MS maintains a connection to one or more serving BSs simultaneously, enabling soft or make-before-break handovers. In [2], the transition of the MS from the air interface of one or more serving BSs to the air interface of one or more target BSs is referred to as a MDHO. The MS and the BS both maintain a list called the *diversity set,* which includes all serving BSs involved in the MDHO communication. The MS maintains both uplink and downlink unicast connections to all the BSs in the diversity set, and one of the serving BSs is defined as the anchor BS. Note that all BSs involved in the diversity set use the same set of CIDs for the connections established between the MS and the serving BSs.

In FBSS, the MS transmits to and receives data from a single serving BS during any frame period. The BS, to which the MS has the connection to at any given frame, is called the *anchor BS*. The MS maintains a diversity set, which includes all active BSs in its range, and can change its anchor BS on a frame-by-frame basis, based on certain criteria. The transition from the serving anchor BS to the target anchor BS in FBSS is done without invocation of the normal handover procedure, and only the anchor BS update procedure is needed. After all, the MS has collected all required information about all BSs during the diversity set update ranging procedures.

Mobile WiMAX vs. HSPA

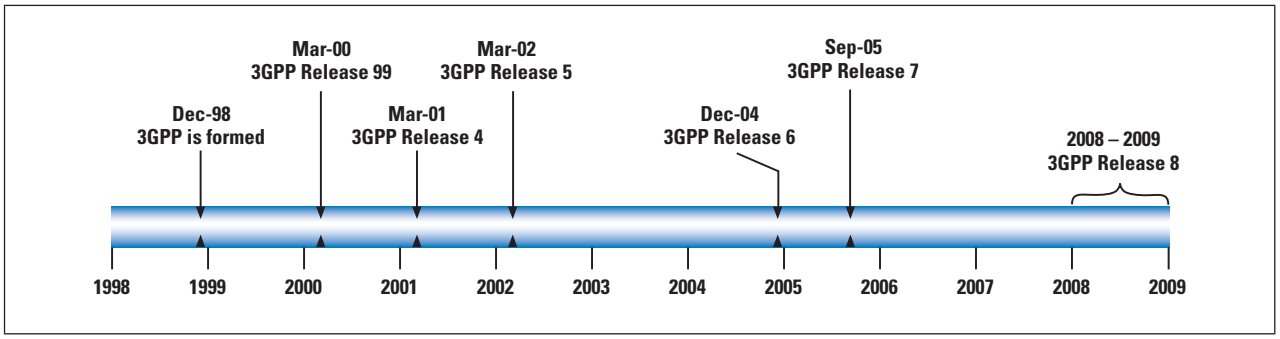
Mobile WiMAX and *High-Speed Packet Access* (HSPA) are expected to be the two major contestants in the rapidly growing wireless broadband market. The two, however, come from different origins. Figure 6 summarizes the evolution toward mobile WiMAX. It all started with the establishment in August 1998 of the IEEE 802.16 working group, which published its first standard (IEEE 802.16-2001) in April 2002. This first version defines a single carrier system operating in the 10- to 66-GHz frequency band and only under *line-of-sight* (LOS) conditions. The IEEE 802.16c-2002 amendment detailed system profiles for the original standard based on the 10- to 66-GHz frequency band. IEEE 802.16a-2003 introduced support for 2- to 11-GHz frequencies and *non-line of sight* (NLOS) operation, and adopted the use of OFDM and OFDMA. IEEE 802.16d-2004[1] consolidated all these previous versions and amendments in a single document, and further enhanced the system. Fixed WiMAX is based on IEEE 802.16d-2004, [3], and [4]. Mobile WiMAX is based on the IEEE 802.16e-2005 amendment[2], which introduced mobility support, as well on [3] and [4].

Figure 6: The Road Toward Mobile WiMAX



HSPA is a set of technological enhancements to the already widely deployed *Wideband Code Division Multiple Access* (WCDMA) cellular networks defined by the *Third Generation Partnership Project* (3GPP). Figure 7 illustrates the WCDMA specification evolution. The origins of HSPA can be traced in the foundation of 3GPP in December 1998. The original aim of 3GPP was to develop a third-generation WCDMA system, and in the process, HSPA was introduced. In March 2000, Release 99, the original standard specifying the WCDMA system, was published. A year later, the first enhancements were published in Release 4, which introduced, among others, an IP-based core network. Release 5 introduced *High-Speed Downlink Packet Access* (HSDPA) and defined the 3GPP *IP Multimedia Subsystem* (IMS). *High-Speed Uplink Packet Access* (HSUPA) and some further improvements to HSDPA were defined in Release 6 (December 2004). Release 7 further enhanced QoS support and defined mechanisms to decrease network latency. Release 8 is expected to be published in 2008, and it will include specifications for the next step, called 3GPP *Long-Term Evolution* (LTE). LTE is meant to deliver maximum cell throughputs an order of magnitude larger than HSPA.

Figure 7: The Evolution of the 3GPP WCDMA Standard



Mobile WiMAX evolved out of a broadband wireless LAN/MAN technology, and vendors currently report that it can deliver maximum cell capacities of 46 and 7 Mbps in downlink and uplink transmissions, respectively. However, mobility management is a later addition and, according to Maravedis, by September 2007 only 12 percent of all deployed *Customer Premises Equipment* (CPE) was IEEE 802.16e-2005-compliant[16]. On the other hand, HSPA is based on a solid foundation of mobility management techniques with wide deployment in cellular networks around the globe, but can currently deliver maximum cell throughputs of only 14.4 and 5.8 Mbps in downlink and uplink transmissions, respectively.

Either commercial or trial networks of both technologies have already been implemented all over the world. However, according to the *Global Mobile Suppliers Association* (GSA), HSPA networks have yet to be deployed in China and India, both of which are large and rapidly growing market areas for wireless communications. According to Maravedis, both India and China have at least WiMAX trial deployments in place.

As mentioned already, the vast majority of current WiMAX deployments do not support mobility. Up to now, fixed WiMAX has been used mainly for last-mile broadband connectivity for sparsely populated rural areas. The largest commercial IEEE 802.16e-2005-compliant system is currently the *Wireless Broadband* (WiBro)[17] network in South Korea, which supports simple mobility up to 60 km/h. Even though WiMAX and WiBro are both based on the same standards, WiBro was developed by the South Korean telecommunications industry before the WiMAX Forum adopted mobility support for its system profiles. WiMAX and WiBro are often cited as separate technologies, even though cooperation is in place in order to assure interoperability between the two.

Summary

In this article we presented an overview of mobile WiMAX, a much-heralded technology for next-generation mobile broadband networks; mobile WiMAX is an intricate system. We introduced WiMAX and the role of the WiMAX Forum, and summarized the important points of the WiMAX network reference model and the PHY and MAC layers. We addressed mobility support, but not the security aspects. Finally, we briefly compared WiMAX with HSPA, presenting their respective evolutions and illustrating their worldwide deployments. We hope that this article will serve as a valuable primer, and we highly recommend that those interested in the mobile WiMAX technology check the bibliography.

Letters to the Editor

IDNs

The DNS protocol is 8-bit clean ("Internationalizing the Domain Name System," IPJ, Volume 11, No. 1, March 2008), even if some DNS clients and servers are not. The hardest thing about changing any Internet protocol is coordinating clients and servers during the transition.

And yet, with the DNS, no transition is needed to support UTF-8 domain names. If you want to publish a UTF-8 domain name, then run a name server that supports UTF-8. If you want to be able to access domain names in your own language, switch to DNS software that supports it. Implementations that are 8-bit clean are already available; ordinary market mechanisms will handle the rest.

Punycode is a gross hack that makes my stomach roil. You know it, I know it, any engineer will agree with you, so how did it get through the IETF?

The argument for where to stop internationalization does not spread to `protocol://` because it's "gobble-de-gook" in English, too. Dots are a completely arbitrary character used to separate the hierarchy. There's plenty of space at the top for UTF-8 names.

The real problem with IDN is homoglyphs.

—Russ Nelson,
`nelson@crynwr.com`

The author responds:

It would certainly make more sense in terms of design elegance and minimalism within the DNS if the label that was stored in the DNS was precisely the same label that was used in the interface between applications and the DNS client software. There is something rather clumsy about the approach that stores an encoded version of a canonical version of the label value, and relies on the application being capable of performing the *stringprep* and encoding functions in consistent and uniform ways. The resultant limitations on what can actually sit in DNS labels on a language-by-language basis are, in part, an outcome of the potential indeterminism of this canonicalization function.

But indeterminism is not a tolerable outcome of the DNS. The DNS is not a guessing game, and inconsistencies in the mapped transforms that are provided by the DNS trigger intolerable insecurities in the networked environment. So the *nameprep* profiles and the related restrictions on allowable Unicode code points are unavoidable if we want to avoid this indeterminism in the DNS.

So if *nameprep* is required in any case, then what we are left with to consider is the decision to use the Punycode *ASCII Compatible Encoding* (ACE) to map Unicode labels into the *Letter-Digit-Hyphen* (LDH) subset of ASCII. But is the Punycode ACE really that much of a problem? Within the overall IDN framework the Punycode algorithm is not so complex that the risk of incorrect implementations is significant, the algorithm is not processor-intensive, and the outcome does not inflate the encoded labels to an impossible length. The advantage of Punycode is that the DNS servers do not require modification, and the clients that manipulate IDNs required additional *nameprep* functions in any case, so Punycode was evidently intended to be the least-impact approach that spared DNS servers from a potential requirement for modification.

To me, this solution appears to be a design tradeoff, in so far as the ACE approach circumvents the observed problem of non-8-bit clean DNS servers sitting within the deployed DNS, and does not in and of itself demand novel roles and functions on the part of the clients of the DNS in addition to what was already necessitated by the IDN *nameprep* function. However, at the same time it creates an annoying inconsistency in the overall framework of the design of the DNS, where certain labels in the DNS are intended to trigger a Punycode transform into an equivalent Unicode string while other labels are meant to be used without further transforms applied.

My judgment of the short-term path of least risk sits with the ACE approach as adopted for IDNs, but at the same time I agree with Russ' discomfort that the path that preserves the long-term essential broad utility and function of the DNS through consistency of design and application sits in an 8-bit clean DNS without the adornment of any form of an ACE.

And, yes, I agree with Russ that the most significant problem with IDNs is homoglyphs, because of continued reliance of an underlying approach of "appearance is everything" in terms of the integrity of the DNS as an identity framework.

—Geoff Huston,
gih@apnic.net

More IDNs

The LDH restriction referred to in "Internationalizing the Domain Name System" (IPJ, Volume 11, No. 1, March 2008) was relaxed in RFC 1123[1] to allow a host name to begin with either a letter or a digit.

—Andrew Friedman

[1] R. Braden, Editor, "Requirements for Internet Hosts – Application and Support," RFC 1123, October 1989.

The author responds:

My thanks to Andrew for pointing this out. It has been commonly recounted that this relaxation of the LDH convention was associated with the successful registration of the DNS name **3com.com** and that the RFC paperwork was revised following this registration. Since then the most visible set of names that used this "liberal" revision of LDH with names that have leading digits were telephone number mapping name sets, including the venerable **tpc.int** domain of the early 1990s and, more recently, ENUM. As for names with leading hyphens, I don't believe that we are at the point of allowing Morse code into the DNS yet, but I'm sure that someone somewhere is working on it!

Fragments

OLSR stands for *Optimized Link State Routing Protocol.*

DUMBO

The *Digital Ubiquitous Mobile Broadband OLSR* (DUMBO) project deploys mobile wireless networks on an ad hoc basis for emergency conditions, such as after a natural disaster when a fixed network infrastructure is not available.

A *Mobile ad hoc Network* (MANET) consists of mobile nodes that automatically cooperate to support the exchange of information through wireless medium. Since the MANET does not rely on fixed telecommunication infrastructure, it is suitable for emergency situations and can be set up in a short amount of time. Using lightweight portable mobile nodes, MANET coverage can penetrate deep into areas not easily accessible by roads or into areas where the telecommunication infrastructure has been destroyed.

DUMBO allows streaming video, *Voice over IP* (VoIP) and short messages to be simultaneously transmitted from a number of mobile laptops to a central command center, or to the other rescuers at the same or different disaster sites. The DUMBO command center has a face recognition module that identifies potential matches between unknown victims' face photos taken from the field and a collection of stored known face images. In addition, sensors can be deployed to measure environmental data such as temperature and humidity. Data from the sensors can be sent to the command center which analyzes or passes it on to the other mobile nodes. The command center can be located either in the disaster area or anywhere with Internet access. DUMBO technology is currently being deployed in cyclone-ravaged Burma. See `http://www.interlab.ait.ac.th/dumbo/` and `http://www.relief.asia/`

Upcoming Events

The *Internet Engineering Task Force* (IETF) will meet in Dublin, Ireland, July 27 – August 1 and in Minneapolis, Minnesota, November 16 – 21, see `http://www.ietf.org/`

APNIC, the *Asia Pacific Network Information Centre,* will hold its Open Policy meeting in Christchurch, New Zealand, August 25 – 29, see `http://www.apnic.net/meetings/26/`

[*Ed.: I will be organizing a pipe organ demonstration event on August 26 as part of the opening reception for APNIC 26, see* `http://organdemo.info`]

The *North American Network Operators' Group* (NANOG) will meet in Los Angeles, California, October 12 – 14. Immediately following the NANOG meeting, the *American Registry for Internet Numbers* (ARIN) will meet in the same location, October 15 – 17. See `http://nanog.org` and `http://arin.net`

The *Internet Corporation for Assigned Names and Numbers* (ICANN) will meet in Paris, France, June 22 – 26, and in Cairo, Egypt, November 2 – 7. See `http://icann.org`

The Internet Protocol Journal

September 2008 Volume 11, Number 3

A Quarterly Technical Publication for Internet and Intranet Professionals

In This Issue

From The Editor

If you are reading the printed version of this journal you will notice a subtle change in the paper. This issue is printed on an uncoated stock, specifically Exact® Offset Opaque White 60#, a recycled paper made by Wausau Paper Corporation. This paper is slightly thinner, and thus lighter, than the paper we have been using. It is also less reflective and easier to write notes on. We invite your feedback on this paper as we experiment with various solutions to reduce our carbon footprint. As always, send your comments to: **ipj@cisco.com**

This journal has a long history of covering existing and emerging technologies that form part of the underlying infrastructure for both the global Internet and private enterprise networks. Recent articles have focused on wireless systems such as WiMAX, and we have other articles on wireless technologies in the pipeline. This time, however, we look at *optical networking*, specifically *Generalized Multiprotocol Label Switching* (GMPLS) as a technology for next-generation internets. The article is by Francesco Palmieri.

The topic of IP Version 4 address exhaustion has been discussed in several articles in this journal, and is currently being heavily debated in the *Regional Internet Registries* (RIRs). As we approach the inevitable date when the IPv4 address pool "runs out," we are returning to this topic with several articles. The first of these articles is included in this issue. Geoff Huston sets the stage by reviewing some of the history and answering the basic question of "why" we find ourselves at a point in history where the IPv4 addresses will run out before we have deployed any significant amount of IPv6 systems. In future issues we will follow Geoff's introduction with several other perspectives on this situation.

Once again, let me remind you to visit our Website at **http://www.cisco.com/ipj**, where you can renew and update your subscription, download back issues, and find additional resources such as our online forum at **http://ipjforum.org**

GMPLS Control Plane Services in the Next-Generation Optical Internet

by Francesco Palmieri, Federico II University of Napoli, Italy

One of the major concerns in the Internet-based information society today is the tremendous demand for more and more bandwidth. Optical communication technology has the potential for meeting the emerging needs of obtaining information at much faster yet more reliable rates because of its potentially limitless capabilities—huge bandwidth (nearly 50 terabits per second[1]), low signal distortion, low power requirement, and low cost. The challenge is to turn the promise of optical networking into reality to meet our Internet communication demands for the next decade. With the deployment of *Dense Wavelength Division Multiplexing* (DWDM) technology, a new and very crucial milestone is being reached in network evolution. The speed and capacity of such wavelength switched networks—with hundreds of channels per fiber strand—seem to be more then adequate to satisfy the medium to long term connectivity demands. In this scenario, carriers need powerful, commercially viable and scalable devices and control plane technologies that can dynamically manage traffic demands and balance the network load on the various fiber links, wavelengths, and switching nodes so that none of these components is over- or underused.

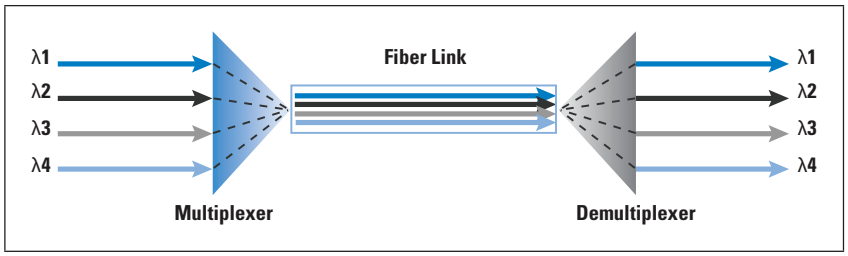
This process of adaptively mapping traffic flows onto the physical topology of a network and allocating resources to these flows—usually referred to as *traffic engineering*—is one of the most difficult tasks facing Internet backbone providers today. *Generalized Multiprotocol Label Switching* (GMPLS) is the most promising technology. GMPLS will play a critical role in future IP pure optical networks by providing the necessary bridges between the IP and optical layers to deliver effective traffic-engineering features and allow for interoperable and scalable parallel growth in the IP and photonic dimension. The GMPLS control plane technology, when fully available in next-generation optical switching devices, will support all the needed traffic-engineering functions and enable a variety of protection and restoration capabilities, while simplifying the integration of new photonic switches and existing label switching routers.

Wavelength Division Multiplexing

Traditional *Electronic Time-Division Multiplexed* (ETDM) networks use an electrical signal form to switch traffic along routes and restore signal strength. These networks do not fully exploit the bandwidth available on optical fibers because only a single frequency (wavelength or *lambda*) of light is used on each fiber to transmit data signals that can be modulated at a maximum bit rate of the order of 40 Gbps. The high bandwidth of optical fibers can be better used through WDM technology by which distinct data signals may share an optical fiber, provided they are transmitted on carriers having different wavelengths[2].

In more detail, the optical transmission spectrum is divided into numerous nonoverlapping wavelengths, with each wavelength supporting a single communication channel. Each channel, which can be viewed as a *light path*, is transmitted at a different wavelength (or frequency). Multiple wavelengths are multiplexed into a single optical fiber and multiple light-path data is transmitted as shown in Figure 1.

Figure 1: WDM Functional Model



Dense WDM (DWDM), an evolution of WDM referring essentially to the closer spacing of channels, is the current favorite multiplexing technology for long-haul communications in modern optical networks. Hence, all the major carriers today devote significant effort to developing and applying DWDM technology in their business.

All-optical networks employing the concept of WDM and wavelength routing are thought to be the transport networks for the future[3]. In such networks, two adjacent nodes are connected by one or multiple fibers, each carrying multiple wavelengths or channels. Each node consists of a dynamically configurable optical switch that supports fiber switching and wavelength switching; that is, the data on a specified input fiber and wavelength can be switched to a specified output fiber on the same wavelength[4]. In order to transfer data between source–destination node pairs, a light path needs to be established by allocating the same wavelength throughout the route of the transmitted data. Benefiting from the development of all-optical amplifiers, light paths can span more than one fiber link and remain entirely optical from end to end. It has been demonstrated that the introduction of wavelength-routing networks not only offers the advantages of higher transmission capacity and routing node throughput, but also satisfies the growing demand for protocol transparency and simplified operation and management[3] [5].

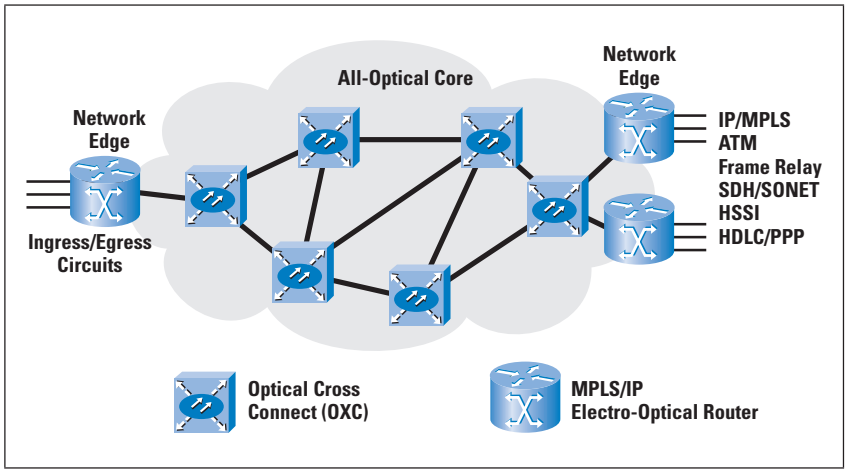
Optical Transport Backbones

The modern Internet transport infrastructure can be physically seen as a very complex mesh of variously interconnected optical or traditional ETDM subnetworks, where each subnetwork consists of several heterogeneous routing and switching devices built by the same or different vendor and operating according to the same control plane protocols and policies. With these very different types of devices, all the forwarding decisions will be based on a combination of packet or cell, timeslot, wavelengths, or physical ports, depending on the position (edge or core) and role (intermediate or termination or gateway node) of the switching devices in the network layout.

In particular, WDM-switched optical subnetworks are typically used as backbone infrastructures to interconnect a large number of different IP as well as other packet networks such as SDH, ATM, and Frame Relay.

New optical devices such as DWDM multiplexers, *Add/Drop Multiplexers* (ADM), and *Optical Cross-Connects* (OXC) are making possible an intelligent all-optical core where packets are routed through the network without leaving the optical domain. The optical network and the surrounding IP networks are independent of each other, and an edge IP router interacts with its ingress switching node only over a well-defined *User-Network Interface* (UNI). Clearly, the optical network is responsible for setting up light paths between the edge IP routers. A light path can be either switched or permanent. Switched light paths are established in real time using proper signaling procedures, and they may last for a short or a long period of time. Permanent light paths are set up administratively by subscription, and they typically last for a very long time. An edge IP router requests a switched light path from its ingress optical switching device using a proper signaling protocol over the UNI. See Figure 2.

Figure 2: The Optical Transport Infrastructure

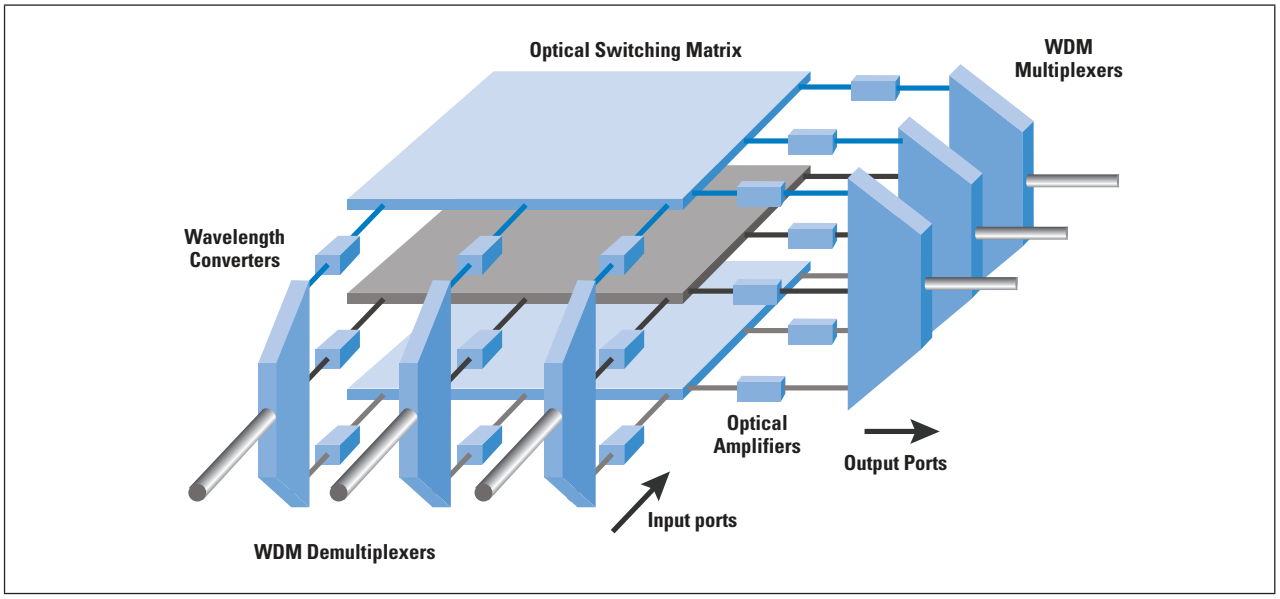


The key concept to guarantee desirable speeds and correct functional behavior in these networks is to maintain the signal in pure optical form, thereby avoiding the prohibitive overhead of conversion to and from electrical form. Such a network would be "optical transparent" in the sense that it would be able to transport client signals with any format and with a wide range of bit rates (at least from about 10 Mbps to more than 10 Gbps). In particular, transparent OXCs, used to selectively switch wavelengths between their input and output ports, are likely to emerge as the preferred option for switching multigigabit or even terabit data streams, because any slow electronic per-packet processing is avoided.

Transparent Optical Switching Nodes

Transparent OXC systems are expected to be the cornerstone of the photonic layer, offering carriers more dynamic and flexible options in building network topologies with enhanced performance and scalability. The development of large and flexible transparent OXCs, now enabled by a new generation of optical components such as optical amplifiers, tunable lasers, and wavelength filters, is still a significant challenge[1]. Their architecture makes use of optical switching fabrics, wavelength multiplexers and demultiplexers, and transparent wavelength converters, which eliminate the need for optoelectronic transponders. A simple and linear architectural model for an optical transparent OXC is shown in Figure 3.

Figure 3: OXC Architectural Model



Here, the WDM demultiplexers separate incoming grouped wavelengths from input ports into individual lambdas. A sufficiently large low-loss connectivity and compact-design, all-optical switching fabric can be realized by using the reflection of light and *Micro-Electromechanical Systems* (MEMS) technology, now widely available on the market. This multilayer switching fabric driven by a micromachined electrical actuator redirects, according to the control plane instructions, each wavelength into appropriate output ports passing through optical amplifiers, typically *Erbium-Doped Fiber Amplifiers* (EDFAs), which boost the signal power in line without the need for any optoelectronic conversion to cope with the effects of light dispersion and attenuation on long distances. The WDM multiplexer then groups the wavelengths from the above multiple layers of cross-connects. Furthermore, the wavelength that arrives into an OXC can be directly passed to the optical switching fabric, to be switched to the appropriate output fiber or previously converted, based on the control plane instructions, to another particular wavelength with the use of a tunable wavelength converter (without being transformed to electricity) if the former output wavelength is not available.

This architecture is transparent; that is, the optical signal does not need to be transformed to electricity at all, implying that this architecture can support any protocol and any data rate. Hence, possible upgrades in the wavelength transport capacity can be accommodated at no extra cost. Furthermore, this architecture decreases the cost because it involves the use of fewer devices than the other architectures. In addition, transparent wavelength conversion eliminates constraints on conversions. In this way the real switching capacity of the OXC is increased, leading to cost reduction. First-generation OXCs require manual configuration. Clearly, an automatic switching capability allowing optical nodes to dynamically modify the network topology based on changing traffic demand is highly desirable.

Automatically Switched Optical Networks

For automatically switched networks, where network nodes may directly initiate or terminate new connections or perform wavelength-level switching in the network, sophisticated and flexible control functions are needed.

The *control plane* supports connection management by clients and also provides protection and restoration services. The control plane of an optical network is also responsible for tracking the network topology and for notifying the state of the network resources. Two families of protocols achieve this task:

- *Routing protocols* are specifically responsible for the reliable advertisement of the optical network topology and the available bandwidth resources within and between network domains. In particular, some areas are relevant within this context: the bundling of links with equivalent or logically bundled characteristics, the definition of the routing areas in an optical domain, the rich specifications of an optical link resource as opposed to a typical advertisement of the up or down interface of IP networks, and the advertisement of the shared risk group (optical fibers flowing in the same cable or duct) to which an optical connection belongs.
- *Signaling protocols* are responsible for provisioning, maintaining, and deleting connections. Optical networks are characterized by connection-oriented paradigms that require a resource reservation protocol. State-of-the-art control plane technologies operating on traditional IP-based networks focus on soft-state protocols that require periodic refresh throughout the participating nodes. In optical networks, where the data plane is separated from the control plane, a possible solution is also to adopt a hard state reservation protocol without periodic refresh to limit the effect caused on the data plane by a failure in the control plane. Furthermore, redundant, generalized label binding is encouraged to reserve protection paths in the mesh network.

Data transport is the most obvious task and the main purpose of an optical network *data plane*. It provides uni- or bidirectional information transport (transmission and switching) between users, detects faults, and monitors signal quality. More specifically, the data plane performs, under the directions of the control plane, data routing to the appropriate ports; channel adds and drops to external, older networks (using the edge interfaces); and label or lambda swapping through an array of WDM demultiplexers, wavelength converters, OXCs, optical amplifiers, and multiplexers.

An important concern that must be addressed in designing an optical network is the cross effect of the failure of a data or control plane. Failures of the data plane are usually addressed by the control plane itself by rerouting the disrupted flows at the appropriate level. The control plane must then advertise quickly the new network state to the neighboring nodes to avoid the presence of stale information in the link databases. A failure of the IP-based control plane usually significantly affects the data plane.

Traffic Engineering in Optical Networks

Traffic engineering should be viewed as assistance to the routing and switching infrastructure that provides additional information used in forwarding traffic along alternate paths across the network, trying to optimize service delivery throughout the network by improving its balanced usage and avoiding congestion caused by uneven traffic distribution. Traffic engineering is required in the modern Internet mainly because the current dynamic routing protocols always use the shortest paths to forward traffic. This practice, obviously, conserves network resources, but it causes some of them to be overused while the other resources remain underused. Furthermore, the routing protocols mentioned earlier never account for specific traffic flow requirements such as bandwidth and *Quality of Service* (QoS) needs. Practitioners in the field often assert that traffic engineering essentially signifies the ability to place traffic where the capacity exists to accommodate it—whereas network engineering denotes the ability to install capacity where the traffic exists.

When a traffic-engineering application implements the right set of features, it should provide precise control over the placement of traffic flows within a routing and switching domain, gaining better network use and realizing a more manageable network. A traffic-engineering solution suitable for transparent optical networks always consists of numerous basic functional components; for example:

- *Traffic monitoring, analysis, and aggregation*—This function collects traffic statistics from the network elements; for example, the OXCs. Then the statistics are analyzed or aggregated to prepare for the traffic engineering and network reconfiguration related to decision making.

- *Bandwidth demand projection*—Bandwidth demand projection estimates the bandwidth requirements in the near future based on past and present measurements and the characteristics of the traffic arrival processes. The bandwidth projections are used for subsequent allocation.
- *Reconfiguration trigger*—This variable consists of a set of policies that decide when a network-level reconfiguration is performed. This decision is based on traffic measurements, bandwidth predictions, and operational areas; for example, to suppress the influence of transitional factors and reserve adequate time for the network to converge.
- *Topology design*—Topology design provides a network topology based on the traffic measurements and predictions. Conceptually this process can be considered as optimizing a graph (that is, OXC connected by light paths at the WDM layer) for specific objectives (for example, maximizing throughput), subject to certain constraints (for example, nodal degree or interface capacity), for a given load matrix (that is, traffic load applied to the network.) This area is, in general, a NP-hard problem. Because reconfiguration is regularly triggered by continually changing traffic patterns, an optimized solution may not be stable. It may be more practical to develop heuristics that place more emphasis on factors such as fast convergence, and less on ongoing traffic, rather than on optimality.
- *Topology migration*—Topology migration consists of algorithms to coordinate the network migration from an old topology to a new one. Because WDM reconfiguration deals with large-capacity channels, changing allocation of channel resources in this coarse granularity significantly affects a large number of end-user flows. Traffic flows have to adapt to the light-path changes at and after each migration step. These effects can potentially spread over the routing pattern of the network, in turn possibly affecting more user flows.

Traditionally, all provisioning and engineering in optical networks has required manual planning and configuration, resulting in setup times of days or even weeks and a marked reluctance among network managers to de-provision resources in case doing so would affect other services. In the last few years, during which control protocols have been deployed to dynamically provide traffic engineering and provisioning or management assistance in optical networks, the control protocols have been proprietary and have greatly suffered from interoperability problems. Consequently, a new standardized control plane framework, supporting evolutionary traffic-engineering features, is needed for automatically switched optical transport networks to foster the expedited development and deployment of a new class of versatile optical switches that specifically address the optical transport needs of the Internet.

The important remaining challenge to be addressed in developing a dynamically reconfigurable optical network is that of controlling the optical resources, especially under distributed control where the network elements exchange information among themselves in a standardized multivendor environment. Performance and reliability requirements make this challenge of paramount importance to photonic networks. Beyond eliminating proprietary "islands of deployment," this common control plane enables independent innovation curves within each product class, and faster service deployment with end-to-end provisioning using a single set of semantics.

The GMPLS Paradigm

GMPLS, the emerging paradigm for the design of control planes for OXCs, aims to address and solve all the challenges mentioned previously, trying to automatically and dynamically configure any kind of network element. It was proposed shortly after *Multiprotocol Label Switching* (MPLS) to extend its packet control plane to encompass time division (for example, for SONET/SDH), wavelength (for optical lambdas) and spatial switching (for example, for incoming port or fiber to outgoing port or fiber). Nongeneralized MPLS overlays a packet-switched IP network to facilitate traffic engineering and allow resources to be reserved and routes predetermined. It provides virtual links or tunnels through the network to connect nodes that lie at the edge of the network. For packets injected into the ingress of an established tunnel, normal IP routing procedures are suspended; instead the packets are label-switched so that they automatically follow the tunnel to its egress.

With the success of MPLS in packet-switched IP networks, optical network providers have accelerated a process to generalize the applicability of MPLS to cover all-optical networks as well. The premise of GMPLS is that the idea of a label can be generalized to be anything that is sufficient to identify a traffic flow. For example, in an optical fiber whose bandwidth is divided into wavelengths, the whole of one wavelength could be allocated to a requested flow. The *Label Switch Routers* (LSRs) at either end of the fiber simply have to agree on which frequency to use. From a control plane perspective, an LSR bases its functions on a table that maintains relations between incoming label or port and outgoing label or port. It should be noted that in the case of the OXC, the table that maintains the relations is not a software entity but it is implemented in a more straightforward way, for example, by appropriately configuring the micro-mirrors of the optical switching fabric.

There are several constraints in reusing the GMPLS control plane. These constraints arise from the fact that LSRs and OXCs use different data technologies. More specifically, LSRs manipulate packets that bear an explicit label, and OXCs manipulate wavelengths that bear the label implicitly; that is, the label value is implicit in the fact that the data is being transported within the agreed frequency band.

Furthermore, because the analogy of a label in the OXC is a wavelength or an optical channel, there are no equivalent concepts of label merging nor label push and pop operations in the optical domain, and label swapping can be realized through wavelength conversion. The transparency and multiprotocol properties of such a control plane approach would allow an OXC to route optical channel trails carrying various types of digital payloads (including IP, ATM, SDH, etc.) coherently and uniformly.

GMPLS Control Plane Functions and Services

GMPLS focuses mainly on the control plane services that perform connection management for the data plane (the actual forwarding logic) for both packet-switched interfaces and non-packet-switched interfaces. The GMPLS control plane essentially facilitates four basic functions:

- *Routing control*—Provides the routing capability, traffic engineering, and topology discovery
- *Resource discovery*—A mechanism to keep track of the system resource availability such as bandwidth, multiplexing capability, and ports
- *Connection management*—Provides end-to-end service provisioning for different services, including connection creation, modification, status query, and deletion
- *Connection restoration*—Implements an additional level of protection to the networks by establishing for each connection one or more presignaled backup paths and enabling very fast switching in case of failure between them.

The fundamental service offered by the GMPLS control plane is dynamic end-to-end connection provisioning. The operators need only to specify the connection parameters and send them to the ingress node. The network control plane then determines the optical paths across the network according to the parameters that the user provides and signals the corresponding nodes to establish the connection. The whole procedure can be done within seconds instead of hours. The other important service is bandwidth on demand, which extends the ease of provisioning even further by allowing the client devices that connect to the optical network to request the connection setup in real time as needed. In order to establish a connection that will be used to transfer data between a source–destination node pair, a light path needs to be established by allocating, in presence of the so-called *continuity constraint,* the same wavelength throughout the route of the transmitted data or selecting the proper wavelength conversion-capable nodes across the path. In fact, if the wavelength continuity constraint is not fully enforced, some wavelength conversion-capable nodes can be placed in the network to reduce the overall blocking probability in case of wavelength resource exhaustion on some nodes. Light paths can span more than one fiber link and remain entirely optical from end to end.

However, according to the mandatory clash constraint, two light paths traversing the same fiber link cannot share the same wavelength on that link. That is, each wavelength on a given fiber is not a sharable resource between light paths.

In general, if there are multiple feasible wavelengths (lambdas) between a source node and a destination node, then a Wavelength Assignment algorithm is required to select a wavelength for a given light path. The wavelength selection can be performed either after an optical route has been determined (in the so-called *decoupled approach*), or in parallel with finding a route. In the latter case, we refer to the coupled approach, in which the entire job is accomplished by a single *Routing and Wavelength Assignment* (RWA) algorithm. When light paths are established and taken down dynamically, routing and wavelength assignment decisions must be made as connection requests arrive to the network. It is possible that, for a given connection request, there may be insufficient network resources to set up a light path, in which case the connection request is blocked. The connection may also be blocked if there is no common wavelength available on all the links along the chosen route. Thus, the objective in the dynamic situation is to choose a route and a wavelength that maximizes the probability of setting up a given connection, while at the same time attempting to minimize the blocking for future connections.

In addition, because the quality of an optical signal degrades as it travels through several optical components and fiber segments, the deployment of "long-distance" light paths may require signal regeneration at strategic locations in a nationwide or global WDM network. As a result, the algorithms performing routing and wavelength assignment, virtual-topology embedding, wavelength conversion, etc. must also be mindful of the locations of the sparse signal regenerators in the network. Such regenerators, which are placed at select locations in the network, "clean up" the optical WDM signal either entirely in the optical domain or through an optoelectronic conversion followed by an electro-optic conversion. Thus the signal from the source travels through the network as far as possible before its quality drops below a certain threshold, thereby requiring it to be regenerated at an intermediate node. The same signal could be regenerated several times in the network before it reaches the destination.

Furthermore, in current multilayer transport networks the bandwidth demanded by traffic typically is orders of magnitude lower than the capacity of lambda links, and the number of available wavelengths per fiber is limited and costly. Hence, it is not worth assigning exclusive end-to-end light paths to these demands, so a better sub-lambda granularity is required. Thus, to increase the throughput of a network with a limited number of lambdas per fiber, *traffic grooming* is required in certain nodes, typically those on the network edge.

The GMPLS control plane ensures traffic-grooming capability on edge nodes by operating on a two-layer model; that is, an underlying pure optical wavelength routed network and an "optoelectronic" time-division multiplexed layer built over it. In the wavelength routed layer, operating exclusively at lambda granularity, when a transparent light path connects two physically adjacent or distant nodes, these nodes will seem adjacent for the upper layer. The upper layer can perform multiplexing of different traffic streams into a single wavelength-based light path through simultaneous time and space switching. Similarly it can demultiplex different traffic streams of a single lambda path. It can also perform remultiplexing: some of the demands demultiplexed can be again multiplexed into some other wavelength paths and handled together along it. This is due to the "generalized" and hence multilayer nature of the GMPLS control plane.

The electronic layer is clearly required for multiplexing packets coming from different ports. This upper electronic layer can be a classical or "next-generation" technology, such as IP/MPLS, but it can also be based on any other networking technology (that is SDH/SONET, ATM, Ethernet, etc.). However, the technology of the upper layer must be unique for all traffic streams that have to be demultiplexed and then multiplexed again, because the network cannot directly multiplex, for example, ATM cells with Ethernet frames.

Another service that gives greatest flexibility to users in handling their own virtual network topologies on the transport core is the *Optical Virtual Private Network* (OVPN), which allows users to have full network resource control of a defined partition of the carrier optical network. Although users have full network resource control of that portion of the network, the OVPN is just a logical network partition and the end users still do not have access and visibility to the carrier's networks. This service can save the carrier's operation resources by allowing end users to perform circuit provisioning and setup procedures.

GMPLS Interfaces

GMPLS encompasses control plane signaling for multiple interface types. The diversity of controlling not only switched packets and cells but also TDM network traffic and optical network components makes GMPLS flexible enough to position itself in the direct migration path from electronic to all-optical network switching. The five main interface types supported by GMPLS follow:

- *Packet Switching Capable* (PSC)—These interfaces recognize packet boundaries and can forward packets based on the IP header or a standard MPLS "shim" header.
- *Layer 2 Switch-Capable* (L2SC)—These interfaces recognize frame and cell headers and can forward data based on the content of the frame or cell header (for example, an ATM LSR that forwards data based on its *Virtual Path Identifier/Virtual Circuit Identifier* (VPI/VCI) value, or Ethernet bridges that forward the data based on the MAC header).

- *Time-Division Multiplexing-Capable* (TDMC)—These interfaces forward the data based on the time slot in a repeating cycle (for example, SDH cross-connect or ADM, interfaces implementing the Digital Wrapper G.709, and *Plesichronous Digital Hierarchy* [PDH] interfaces).
- *Lambda Switch-Capable* (LSC)—These interfaces are for wavelength-based MPLS control of optical devices and wavelength switching devices, such as *optical ADMs* (OADMs) and OXCs, operating at the granularity of the single wavelength or group of wavelengths (waveband). These interfaces forward the optical signal from an incoming optical wavelength to an outgoing optical wavelength. Traffic is forwarded based upon wavelength or waveband.
- *Fiber-Switch-Capable* (FSC)—These interfaces forward the signal from one or more incoming fibers to one or more outgoing fibers for spatial control of interface selection, automated patch panels, and physical fiber switching systems. Traffic is forwarded based on port, fiber, or interface.

These supported interfaces are hierarchal in structure and controlled simultaneously by GMPLS.

Generalized Label

GMPLS defines several new forms of label—the *generalized label* objects. These objects include the generalized label request, the generalized label, the explicit label control, and the protection flag. The generalized label can be used to represent timeslots, wavelengths, wavebands, or space-division multiplexed positions.

With plain MPLS labels embedded in the cell or packet structure for in-band control plane signaling, with the different kinds of interfaces supported by GMPLS it is impossible to embed label-specific information, in terms of fiber port or wavelength switching, into the traffic packet structure. Consequentially, new "virtual" labels have been added to the MPLS label structure. These virtual labels comprise specific indicators that represent wavelengths, fiber bundles, or fiber ports and are distributed to GMPLS nodes through out-of-band GMPLS signaling. GMPLS out-of-band signaling causes a control-channel separation problem.

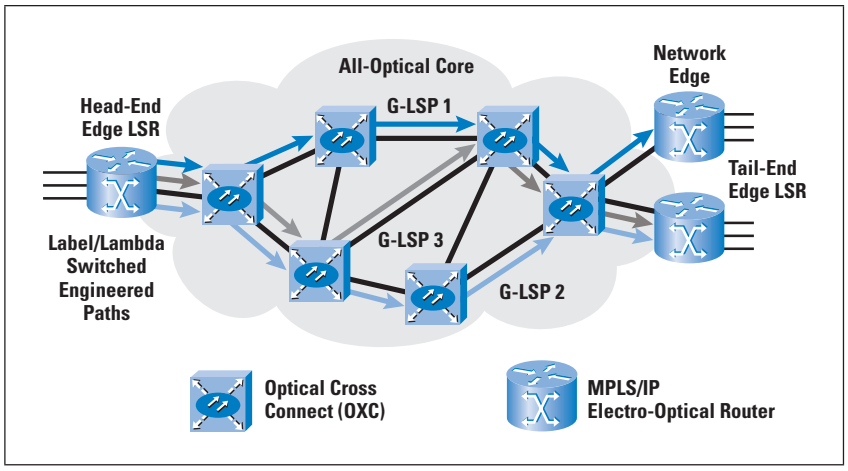
With MPLS, the control information is found in the label, which is directly attached to the data payload. However, when you send the control information out of band, the label is separated from the data that it is attempting to control. GMPLS provides a means for identifying explicit data channels. Having the ability to identify data channels allows the control message to be associated with a particular data flow, whether it is a wavelength, fiber, or fiber bundle.

Generalized Label-Switched Paths

The handling of *label-switched paths* (LSPs) under GMPLS differs from that of MPLS. MPLS does not provide for bidirectional LSPs. Each direction LSP has to be established in turn. Under GMPLS, the LSP can be established bidirectionally. The traffic-engineering requirements for the bidirectional LSP are the same in both directions, and it is established for both directions through only one signaling message, allowing for reductions in latency-related setup time. In the optical environment, OXC translates label assignments into corresponding wavelength assignments and sets up *generalized LSPs* (G-LSPs) using their local control interfaces to the other switching devices. Subsequent to G-LSP setup, no explicit label or lambda lookup or processing operations are performed by the OXC nodes.

GMPLS supports traffic engineering by allowing the node at the network ingress to specify the route that a G-LSP will take by using explicit light-path routing. An explicit route is specified by the ingress as a sequence of hops and wavelengths that must be used to reach the egress, which is different from the hop-by-hop routing that is usually associated with PSC networks.

Figure 4: G-LSPs Ensuring Traffic Engineering



GMPLS also maintains the capability already available with MPLS to nest G-LSPs. Nested G-LSPs make possible the building of a forwarding hierarchy. At the top of this hierarchy are nodes that have FSC interfaces, followed by nodes that have LSC interfaces, followed by nodes that have TDMC interfaces, and followed by nodes with PSC interfaces. Nesting of G-LSPs between interface types increases flexibility in service definition and makes it possible for service providers operating a GMPLS network to deliver both bundled and unbundled services.

Because the deployment of DWDM equipment makes feasible the creation a large number of individual connections between two adjacent nodes, another very useful feature of bundling is the ability to simultaneously handle multiple adjacent links. Link bundling treats the traffic of these links as a single link.

In order for the adjacent links to be bundled, they must be on the same GMPLS segment, they must be of the same type, and they must have the same traffic-engineering requirements. These requirements reduce the amount of link advertisements that need to be maintained throughout the network, thereby increasing the control plane scalability. Just as in MPLS label stacking, GMPLS labels only contain information about a single level of hierarchy. The difference for GMPLS is that this hierarchy can be fiber-, wavelength-, timeslot-, packet- or cell-based.

For instance, if a connection is desired from one PSC interface to another PSC interface, and the traffic traverses physically separate fibers, a unique LSP has to be established for each level in turn. First, the FSC LSP, then the LSC LSP, then the TDMC LSP, and finally the PSC LSP have to be established through GMPLS signaling.

Signaling and Routing Protocols

In order to set up a light path, a signaling protocol is also required to exchange control information among nodes, to distribute labels, and to reserve resources along the path. In our case, the signaling protocol is closely integrated with the routing and wavelength assignment protocols. Suitable GMPLS signaling protocols for the GMPLS control plane include *Resource Reservation Protocol* (RSVP) and *Constraint-Based Label Distribution Protocol* (CR-LDP). Any of the objects that are defined within the GMPLS specification can be carried within the message of either of these signaling protocols that are responsible for all the connection management actions such as setup, modify, or remove the G-LSPs. Clearly, support for provisioning and restoration of end-to-end optical trails within a photonic network consisting of heterogeneous networking elements imposes new requirements for these signaling protocols. Specifically, optical trails require small setup latency (especially for restoration purposes), support for bidirectional trails, rapid failure detection and notification, and fast intelligent trail restoration.

Both RSVP and CR-LDP can be used to reserve a single wavelength for a light path if the wavelength is known in advance. These protocols can also be modified to incorporate wavelength selection functions into the reservation process[7]. In RSVP, signaling takes place between the source and destination nodes. The signaling messages may contain information such as QoS requirements for the carried traffic and label requests for assigning labels at intermediate nodes that reserve the appropriate resources for the path. CR-LDP uses TCP sessions between nodes in order to provide a hop-by-hop reliable distribution of control messages, indicating the route and the required traffic parameters for the route. Each intermediate node reserves the required resources, allocates a label, and sets up its forwarding table before backward signaling to the previous node.

To correctly perform resource reservation, allocation, and topology discovery on the available optical link resources, each node needs to maintain a representation of the state of each link in the network. The link state includes the total number of active channels, the number of allocated channels, and the number of channels reserved for light-path restoration. Additional parameters can be associated with allocated channels; for example, some light paths can be preemptable or have associated hold priorities. When the local inventory is constructed, the node engages in a routing protocol to distribute and maintain the topology and resource information. Standard IP routing protocols, such as *Open Shortest Path First* (OSPF) or *Intermediate System-to-Intermediate System* (IS-IS) with GMPLS Traffic Engineering extensions, can be used to reliably propagate the information.

The extensions to OSPF and IS-IS add additional information about links and nodes into the link-state database. Such information includes the type of LSPs that can be established across a given link (for example, packet forwarding, SONET/SDH trails, wavelengths, or fibers), as well as the current unused bandwidth, the maximum size of G-LSP that can be established, and the administrative groups supported. This information allows the node computing the explicit route for an LSP to do so more intelligently. Furthermore, any switching node cooperating in the GMPLS control plane will maintain a per-interface or per-fiber *Wavelength Forwarding Information Base* (WFIB) because lambdas and channels (labels) are specific to a particular interface or fiber, and the same lambda or channel (label) could be used concurrently on multiple interfaces or fibers.

Link Management Protocol

GMPLS also uses the *Link Management Protocol* (LMP) to communicate proper cross-connect information between the network elements. LMP runs between adjacent systems for link provisioning and fault isolation. It can be used for any type of network element, particularly in natively photonic switches. LMP automatically generates and maintains associations between links and labels for use in label swapping[6]. Automating the labeling process simplifies management and avoids the errors associated with manual label assignment. LMP provides control-channel management, link-connectivity verification, link-property correlation, and fault isolation. Control-channel management establishes and maintains connectivity between adjacent nodes using a keepalive protocol. Link verification verifies the physical connectivity between nodes, thereby detecting loss of connections and misrouting of cable connections. Fault isolation pinpoints failures in both electronic and optical links without regard to the data format traversing the link.

In order for these link bundles to be handled accordingly, GMPLS needed a method to manage the links between adjacent nodes. LMP was developed to address several link-specific problems that surfaced when generalizing the MPLS protocol across different interface types. The main responsibilities of the LMP follow:

- *Control-Channel Management*—Establishment of a control channel is critical to GMPLS signaling. The maintenance of the control channel between adjacent nodes must be able to exchange information related to LSP establishment.
- *Link-Property Correlation*—When link bundling occurs, GMPLS requires a way to verify that all traffic-engineering requirements are similar between links of adjacent nodes. Link-property correlation performs the verification and the aggregation of such links.
- *Link-Connectivity Verification*—This feature is used by GMPLS to verify the connectivity between data links when the control channel is separate from each data link.
- *Fault Management*—Fault management helps the network isolate faults down to the individual link.

Although LMP assumes the messages are IP encoded, it does not dictate the actual transport mechanism used for the control channel. However, the control channel must terminate on the same two nodes that the bearer channels span. Therefore, this protocol can be implemented on any OXC, regardless of the internal switching fabric. A requirement for LMP is that each link has an associated bidirectional control channel and that free bearer channels must be opaque (that is, able to be terminated); however, when a bearer channel is allocated, it may become transparent. Note that this requirement is trivial for optical cross-connects with electronic switching planes, but is an added restriction for photonic switches.

Conclusion

Innovations in the field of optical components will take advantage of the introduction of all-optical networking in all areas of information transport and will offer system designers the opportunity to create new solutions that will allow smooth evolution of all telecommunication networks. A new class of versatile IP-addressable optical switching devices is emerging, operating according to a common GMPLS-based control plane to support full-featured traffic engineering in modern optical transparent infrastructures.

The main advantage of this approach is that it is based on already existing and widely deployed protocols while simplifying network management and engineering tasks that can be performed in a unified way in both the data and the optical domains. Furthermore, it offers a function framework that can accommodate future expectations concerning the way networks will work and the way services will be provided to clients. Thus we envision a horizontal network, harmonized by a common GMPLS-based control plane, where all network elements work as peers to dynamically establish optical paths through the network.

This new photonic internetwork will make it possible to provision high bandwidth in tenths of seconds, and enable new revenue-generating services and dramatic cost savings for service providers.

In the same way that digital communication technologies changed the twentieth century into the "electronic century," the optical technologies discussed in this article will make the next century "the photonic century." All winning strategies must rely on such GMPLS-based photonic infrastructures—an environment in which innovations work at the speed of light.

FRANCESCO PALMIERI holds two Computer Science degrees from Salerno University, Italy. Since 1997, he has led the network management and operation centre of the Federico II University, in Napoli, Italy. He has been closely involved with the development of the Internet in Italy in the last few years, particularly within the academic and research sector, and is actually a member of the Technical Scientific Committee and of the Computer Emergency Response Team of the Italian NREN GARR. He worked for several international companies on a variety of networking-related projects concerned with nationwide communication systems, network management, transport protocols, and IP networking. He is an active researcher in the fields of high-performance, evolutionary networking, and network security. He regularly publishes in leading technical journals and conferences and gives invited talks and keynote speeches. E-Mail: **Francesco.Palmieri@unina.it**

The Changing Foundation of the Internet: Confronting IPv4 Address Exhaustion

by Geoff Huston, APNIC

Throughout its relatively brief history, the Internet has continually challenged our preconceptions about networking and communications architectures. For example, the concepts that the network itself has no role in management of its own resources, and that resource allocation is the result of interaction between competing end-to-end data flows, were certainly novel innovations, and for many they have been very confrontational. The approach of designing a network that is unaware of services and service provisioning and is not attuned to any particular service whatsoever—leaving the role of service support to end-to-end overlays—was again a radical concept in network design. The Internet has never represented the conservative option for this industry, and has managed to define a path that continues to present significant challenges.

From such a perspective it should not be surprising that the next phase of the Internet story—that of the transition of the underlying version of the IP protocol from IPv4 to IPv6—refuses to follow the intended script. Where we are now, in late 2008, with IPv4 unallocated address pool exhaustion looming within the next 18 to 36 months, and IPv6 still largely not deployed in the public Internet, is a situation that was entirely uncontemplated and, even in hindsight, entirely surprising.

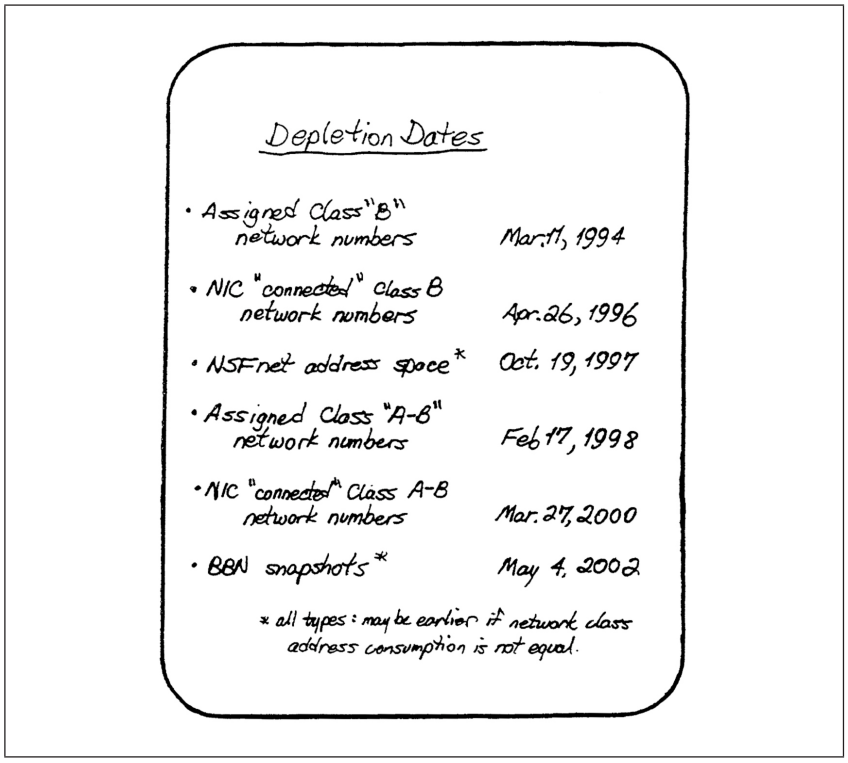
The topic examined here is *why* this situation has arisen, and in examining this question we analyze the options available to the Internet to resolve the problem of IPv4 address exhaustion. We examine the timing of the IPv4 address exhaustion and the nature of the intended transition to IPv6. We consider the shortfalls in the implementation of this transition, and identify their underlying causes. And finally, we consider the options available at this stage and identify some likely consequences of such options.

When?

This question was first asked on the TCP/IP list in November 1988, and the responses included foreshadowing a new version of IP with longer addresses and undertaking an exercise to reclaim unused addresses[1]. The exercise of measuring the rate of consumption of IPv4 addresses has been undertaken many times in the past two decades, with estimates of exhaustion ranging from the late 1990s to beyond 2030. One of the earliest exercises in predicting IPv4 address exhaustion was undertaken by Frank Solensky and presented at IETF 18 in August 1990. His findings are reproduced in Figure 1.

At that time the concern was primarily the rate of consumption of Class B network addresses (or of /16 prefixes from the address block `128.0.0.0/2`, to use current terminology). Only 16,384 such Class B network addresses were within the class-based IPv4 address plan, and the rate of consumption was such that the Class B networks would be fully consumed within 4 years, or by 1994. The prediction was strongly influenced by a significant number of international research networks connecting to the Internet in the late 1980s, with the rapid influx of new connections to the Internet creating a surge in demand for Class B networks.

Figure 1: Report on IPv4 Address Depletion[2]



Successive predictions were made in the context of the *Internet Engineering Task Force* (IETF) in the *Address Lifetime Expectancy* (ALE) Working Group, where the predictive model was refined from an exponential growth model to a logistical saturation function, attempting to predict the level at which all address demands would be met.

The predictive technique described here is broadly similar, using a statistical fit of historical data concerning address consumption into a mathematical model, and then using this model to predict future address consumption rates and thereby predict the exhaustion date of the address pool.

The predictive technique models the IP address distribution framework. Within this framework the pool of unallocated /8 address blocks is distributed by the *Internet Assigned Numbers Authority* (IANA) to the five *Regional Internet Registries* (RIRs). (A "/8 address block" refers to a block of addresses where the first 8 bits of the address values are constant. In IPv4 a /8 address block corresponds to 16,777,216 individual addresses.) Within the framework of the prevailing address distribution policies, each RIR can request a further address allocation from IANA when the remaining RIR-managed unallocated address pool falls below a level required to meet the next 9 months of allocation activity. The amount allocated is the number of /8 address blocks required to augment the RIR's local address pool to meet the anticipated needs of the regional registry for the next 18 months. However, in practice, the RIRs currently request a maximum of 2 /8 address blocks in any single transaction, and do so when the RIR-managed address pool falls below a threshold of the equivalent of 2 /8 address blocks.

As of August 2008 some 39 /8 address blocks are left in IANA's unallocated address pool. A predictive exercise has been undertaken using a statistical modeling of historical address consumption rates, using data gathered from the RIRs' records of address allocations and the time series of the total span of address space announced in the Internet interdomain default-free routing table as basic inputs to the model. The predictive technique is based on a least-squares best fit of a linear function applied to the first-order differential of a smoothed copy of the address consumption data series, as applied to the most recent 1,000 days' data.

The linear function, which is a best fit to the first-order differential of the data series, is integrated to provide a quadratic time-series function to match the original data series. The projection model is further modified by analyzing the day-of-year variations from the smoothed data model, averaged across the past 3 years, and applying this daily variation to the projection data to account for the level of seasonal variations in the total address consumption rate that has been observed in the historical data. The anticipated rate of consumption of addresses from this central pool of unallocated IPv4 addresses is expected to be about 15 /8s in 2009, and slightly more in 2010.

RIR behaviors are modeled using the current RIR operational practices and associated address policies, which are used to predict the times when each RIR will be allocated a further 2 /8s from IANA. This RIR consumption model, in turn, allows the IANA address pool to be modeled.

This anticipated rate of increasing address consumption will see the remaining unallocated addresses that are held by IANA reach the point of exhaustion in February 2011. The most active RIRs are anticipated to exhaust their locally managed unallocated address pools in the months following the time of IANA exhaustion.

The assumptions behind this form of prediction follow:

- The current policy framework relating to the distribution of addresses will continue to apply without any further alteration through to complete exhaustion of the unallocated address pool.
- The demand curves will remain consistent, meaning that there will be no forms of disruption to demand, such as a panic rush on the remaining addresses or some introduced externality that affects total address demand.
- The level of return of addresses to the unallocated address pool will not vary significantly from existing levels of address return.

Although the statistical model is based on a complete data set of address allocations and a detailed hourly snapshot of the address span advertised in the Internet routing table, a considerable level of uncertainty is still associated with this prediction.

First, the behavior of the *Internet Service Provider* (ISP) industry and the other entities that are the direct recipients of RIR address allocations and assignments are not ignorant of the impending exhaustion condition, and there is some level of expectation of some form of last-minute rush or panic on the part of such address applicants when exhaustion of this address pool is imminent. The predictive model described here does not include such a last-minute acceleration of demand.
