The Internet Protocol Journal

June 1998 Volume 1, Number 1

A Quarterly Technical Publication for Internet and Intranet Professionals

In This Issue

From The Editor

Welcome to the first edition of *The Internet Protocol Journal* (IPJ). This publication is designed to bring you in-depth technical articles on current and emerging Internet and intranet technologies. We will publish technology tutorials, as well as case studies on all aspects of internetworking.

Our first article is a detailed look at *Virtual Private Networks* (VPNs). Many organizations are turning to VPNs as a cost-effective way to implement enterprise networking, but the industry has not yet settled for a single approach, nor even a single definition of the VPN concept. The article by Paul Ferguson and Geoff Huston is in two parts. Part II will follow in our second issue, due out in September.

When the Internet Protocol suite (TCP/IP) was first designed, security was not a major consideration. Indeed, the primary goal in the early days of networking was sharing of information among academics and researchers. Today, TCP/IP is being used for mission-critical applications and for the emerging area of electronic commerce. As a result, security mechanisms are being added at all levels of the protocol stack. In this issue, we take a closer look at the *Secure Sockets Layer* (SSL), which is used for Web transactions. William Stallings explains how SSL works and how it is becoming the standard for Web security.

If you want to learn about computer networks, many options are available, including conferences, journals, standards documents, Web sites, glossaries and, of course, books. Our *Fragments* page gives you some pointers for further reading, and every issue will include at least one book review.

A detailed description of the scope of this journal can be found on page 30 in our *Call for Papers*. We want your input in this new publication. Please send comments, suggestions or questions to `ipj@cisco.com`. You may also use this address to request a complimentary copy of the next issue of IPJ. If you would like to write an article, send me e-mail and I will send you author guidelines.

—Ole J. Jacobsen, Editor and Publisher

What Is a VPN? — Part I

by Paul Ferguson, Cisco Systems
and Geoff Huston, Telstra

The term "VPN," or *Virtual Private Network*, has become almost as recklessly used in the networking industry as has "QoS" (Quality of Service) to describe a broad set of problems and "solutions," when the objectives themselves have not been properly articulated. This confusion has resulted in a situation where the popular trade press, industry pundits, and vendors and consumers of networking technologies alike generally use the term VPN as an offhand reference for a set of different technologies. This article provides a common-sense definition of a VPN, and an overview of different approaches to building one.

> "The wonderful thing about virtual private networks is that its myriad definitions give every company a fair chance to claim that its existing product is actually a VPN. But no matter what definition you choose, the networking buzz-phrase doesn't make sense. The idea is to create a private network via tunneling and/or encryption over the public Internet. Sure, it's a lot cheaper than using your own frame relay connections, but it works about as well as sticking cotton in your ears in Times Square and pretending nobody else is around."[1]

A Common-Sense Definition

As *Wired Magazine* notes in the quotation, the myriad definitions of a VPN are less than helpful in this environment. Accordingly, it makes sense to begin this examination of VPNs to see if it is possible to provide a common-sense definition of a VPN. Perhaps the simplest method of attempting to arrive at a definition for VPNs is to look at each word in the acronym individually, and then tie each of them together in a simple, common-sense, and meaningful fashion.

Let's start by examining the word "network." This term is perhaps the least difficult one for us to define and understand, because the commonly accepted definition is fairly uncontroversial and generally accepted throughout the industry. A network consists of any number of devices that can communicate through some arbitrary method. Devices of this nature include computers, printers, routers, and so forth, and they may reside in geographically diverse locations. They may communicate in numerous ways because the electronic signaling specifications, and data-link, transport, and application-layer protocols are countless. For the purposes of simplicity, let's say that a "network" is a collection of devices that can communicate in some fashion, and can successfully transmit and receive data among themselves.

The term "private" is fairly straightforward, and is intricately related to the concept of "virtualization" insofar as VPNs are concerned, as we'll discuss in a moment. In the simplest of definitions, "private" means communications between two (or more) devices is, in some

fashion, secret—that the devices that are not participating in the "private" nature of communications are not privy to the communicated content, and that they are indeed completely unaware of the private relationship altogether. Accordingly, data privacy and security (data integrity) are also important aspects of a VPN that need to be considered when implementing any particular VPN.

Another means of expressing this definition of "private" is through its antonym, "public." A "public" facility is one that is openly accessible, and is managed within the terms and constraints of a common public resource, often via a public administrative entity. By contrast, a private facility is one where access is restricted to a defined set of entities, and third parties cannot gain access. Typically, the private resource is managed by the entities who have exclusive right of access. Examples of this type of private network can be found in any organizational network that is not connected to the Internet, or to any other external organizational network, for that matter. These networks are private because there is no external connectivity, and thus no external network communications.

Another important aspect of privacy in a VPN is through its technical definition. For example, privacy in an addressing and routing system means that the addressing used within a VPN community of interest is separate and discrete from that of the underlying shared network, and from that of other VPN communities. The same holds true for the routing system used within the VPN and that of the underlying shared network. The routing and addressing scheme within a VPN should, in general, be self-contained, but this scenario degenerates into a philosophical discussion of the context of the term "VPN." Also, it is worthwhile to examine the differences between the "peer" and "overlay" models of constructing VPNs—both of which are discussed in more detail later under the heading "Network-Layer VPNs."

"Virtual" is a concept that is slightly more complicated. *The New Hacker's Dictionary* (formerly known as the Jargon File)[2] defines virtual as:

> virtual /adj./ [via the technical term "virtual memory," prob. from the term "virtual image" in optics] 1. Common alternative to {logical}; often used to refer to the artificial objects (like addressable virtual memory larger than physical memory) simulated by a computer system as a convenient way to manage access to shared resources. 2. Simulated; performing the functions of something that isn't really there. An imaginative child's doll may be a virtual playmate. Oppose {real}.

Insofar as VPNs are concerned, the second definition is perhaps the most appropriate comparison for virtual networks. The "virtualization" aspect is one that is similar to what we briefly described previously as private, but the scenario is slightly modified—the private communication is now conducted across a network infrastructure that

is shared by more than a single organization. Thus, the private resource is actually constructed by using the foundation of a logical partitioning of some underlying common, shared resource rather than by using a foundation of discrete and dedicated physical circuits and communications services. Accordingly, the private network has no corresponding private physical communications system. Instead, the private network is a virtual creation that has no physical counterpart.

The virtual communications between two (or more) devices is because the devices that are not participating in the virtual communications are not privy to the content of the data, and they are also altogether unaware of the private relationships between the virtual peers. The shared network infrastructure could, for example, be the global Internet and the number of organizations or other users not participating in the virtual network may literally number into the thousands or even millions.

A VPN can also said to be a discrete network[3]:

> (discrete \dis*crete"\, a. [L. discretus, p.p. of discernere. See Discreet.] 1. Separate; distinct; disjunct).

The discrete nature of VPNs allows both privacy and virtualization. Although VPNs are not completely separate, intrinsically, the distinction is that they operate in a discrete fashion across a shared infrastructure, providing exclusive communications environments that do not share any points of interconnection.

The combination of these terms produces VPN—a private network, where the privacy is introduced by some method of virtualization. A VPN could be built between two end systems or between two organizations, between several end systems within a single organization or between multiple organizations across the global Internet, between individual applications, or any combination.

It should be noted that there is really no such thing as a nonvirtual network, if the underlying common public transmission systems and other similar public infrastructure components are considered to be the base level of carriage of the network. What separates a VPN from a truly private network is whether the data transits a shared versus a nonshared infrastructure. For instance, an organization could lease private line circuits from various telecommunications providers and build a private network on the base of these private circuit leases, but the circuit-switched network owned and operated by the telecommunications companies are actually circuits connected to their *Digital Access and Crossconnect Systems* (DACSs) network and subsequently their fiber-optics infrastructure. This infrastructure is shared by any number of organizations through the use of multiplexing technologies. Unless an organization is actually deploying private fiber and layered transmission systems, any network is layered with "virtualized" connectivity services in this fashion.

A VPN doesn't necessarily mean communications isolation, but rather the controlled segmentation of communications for communities of interest across a shared infrastructure.

The common and somewhat formal characterization of the VPN, and perhaps the most straightforward and strict definition, follows:

> A VPN is a communications environment in which access is controlled to permit peer connections only within a defined community of interest, and is constructed though some form of partitioning of a common underlying communications medium, where this underlying communications medium provides services to the network on a nonexclusive basis.

A simpler, more approximate, and much less formal description follows:

> A VPN is private network constructed within a public network infrastructure, such as the global Internet.

It should also be noted that although VPNs may be constructed to address any number of specific business needs or technical requirements, a comprehensive VPN solution provides support for dial-in access, support for multiple remote sites connected by leased lines (or other dedicated means), the ability of the VPN service provider (SP) to "host" various services for the VPN customers (for example, Web hosting), and the ability to support not just intra-, but also inter-VPN connectivity, including connectivity to the global Internet.

VPN Motivations

There are several motivations for building VPNs, but a common thread is that they all share the requirement to "virtualize" some portion of an organization's communications—in other words, make some portion (or perhaps all) the communications essentially "invisible" to external observers, while taking advantage of the efficiencies of a common communications infrastructure.

The base motivation for VPNs lies in the economics of communications. Communications systems today typically exhibit the characteristic of a high fixed-cost component, and smaller variable-cost components that vary with the transport capacity, or bandwidth, of the system. Within this economic environment, it is generally financially attractive to bundle numerous discrete communications services onto a common, high-capacity communications platform, allowing the high fixed-cost components associated with the platform to be amortized over a larger number of clients. Accordingly, a collection of virtual networks implemented on a single common physical communications plant is cheaper to operate than the equivalent collection of smaller, physically discrete communications plants, each servicing a single network client.

Therefore, if aggregation of communications requirements leads to a more cost-effective communications infrastructure, why not pool all these services into a single public communications system? Why is there still the requirement to undertake some form of partitioning within this common system that results in these "virtual private" networks?

In response to this question, the second motivation for VPNs is that of communications privacy, where the characteristics and integrity of communications services within one closed environment is isolated from all other environments that share the common underlying plant. The level of privacy depends greatly on the risk assessment performed by the subscriber organization—if the requirement for privacy is low, then the simple abstraction of discretion and network obscurity may serve the purpose. However, if the requirement for privacy is high, then there is a corresponding requirement for strong security of access and potentially strong security applied to data passed over the common network.

History

This article cannot do justice to the concept of VPNs without some historical perspective, so we need to look at why VPNs are an evolving paradigm, and why they will continue to be an issue of confusion, contention, and disagreement. This examination is important because opinions on VPN solutions are quite varied, as well as how they should be approached.

Historically, one of the precursors to the VPN was the *Public Data Network* (PDN), and the current familiar instance of the PDN is the global Internet. The Internet creates a ubiquitous connectivity paradigm, where the network permits any connected network entity to exchange data with any other connected entity. The parallels with the global *Public Switched Telephone Network* (PSTN) are, of course, all too obvious—where a similar paradigm of ubiquitous public access is the predominate characteristic of the network.

The Public Data Network has no inherent policy of traffic segregation, and any modification to this network policy of permitting ubiquitous connectivity is the responsibility of the connecting entity to define and enforce. The network environment is constructed using a single addressing scheme and a common routing hierarchy, which allows the switching elements of the network to determine the location of all connected entities. All these connected entities also share access to a common infrastructure of circuits and switching.

However, the model of ubiquity in the "Internet PDN" does not match all potential requirements, especially the need for data privacy. For organizations that wish to use this public network for private purposes within a closed set of participants (for example, connecting a set of geographically separated offices), the Internet is not always a palatable possibility. Numerous factors are behind this mismatch, including issues of Quality of Service (QoS), availability and reliability, use of

public addressing schemes, use of public protocols, site security, and data privacy and integrity (the possibility of traffic interception). Additionally, a corporate network application may desire more stringent levels of performance management than are available within the public Internet, or indeed may wish to define a management regime that differs from that of the underlying Internet PDN.

Service-Level Agreements

It is worthwhile at this point to briefly examine the importance of *Service-Level Agreements* (SLAs) in regards to the deployment of VPNs. SLAs are negotiated contracts between VPN providers and their subscribers; they contain the service criteria to which the subscriber expects specific services to be delivered. The SLA is arguably the only binding tool at the subscriber's disposal with which to ensure that the VPN provider delivers the service(s) to the level and quality as agreed, and it is in the best interest of the subscribers to monitor the criteria outlined in the SLA for compliance. However, SLAs present some challenging technical issues for both the provider and the subscriber.

For the subscriber, the challenge is to devise and operate service measurement tools that can provide a reasonable indication as to what extent the SLA is being honored by the provider. Also, it should be noted that a subscriber may use an SLA to bind one or more providers to a contractual service level, but if the subscriber's VPN spans multiple providers' domains, the SLA must also encompass the issue of provider interconnection and the end-to-end service performance.

For the provider, the challenge lies in honoring multiple SLAs from a number of service providers. In the case of an Internet PDN provider, the common mode of best-effort service levels is not conducive to meeting SLAs, given the unpredictable nature of the host's resource allocation mechanisms. In such environments, the provider either has to ensure that the network is generously engineered in terms of the ratio of subscriber access capacity to internal switching capacity, or the provider can deploy service differentiation structures to ensure that minimum resource levels are allocated to each SLA subscriber. It must be noted that the former course of action does tend to reduce the benefit of aggregation of traffic, which in turn has an ultimate cost implication, while the latter course of action has implications in terms of operational management complexity and scalability of the network.

Alternatives to the VPN

The alternative to using the Internet as a VPN today is to lease circuits, or similar dedicated communications services, from the public network operators (the local telephone company in most cases), and create a completely private network. It is a layering convention that allows us to label this as "completely private," because these dedicated communications services are (at the lower layers of the protocol

stack) again instances of virtual private communications systems constructed atop a common transmission bearer system. Of course, this scenario is not without precedent, and it must be noted that most of the early efforts in data networking, and many of the current data networking architectures, do not assume a deployment model of ubiquitous public access.

It is interesting to note that this situation is odd, when you consider that the inherent value of an architecture where ubiquitous public access over a chaotic collection of closed private networks had been conclusively demonstrated in the telephony marketplace since the start of the 20th century. Although the data communications industry appears to be moving at a considerable technological pace, the level of experiential learning, and consequent level of true progress as distinct from simple motion, still leaves much to be desired!

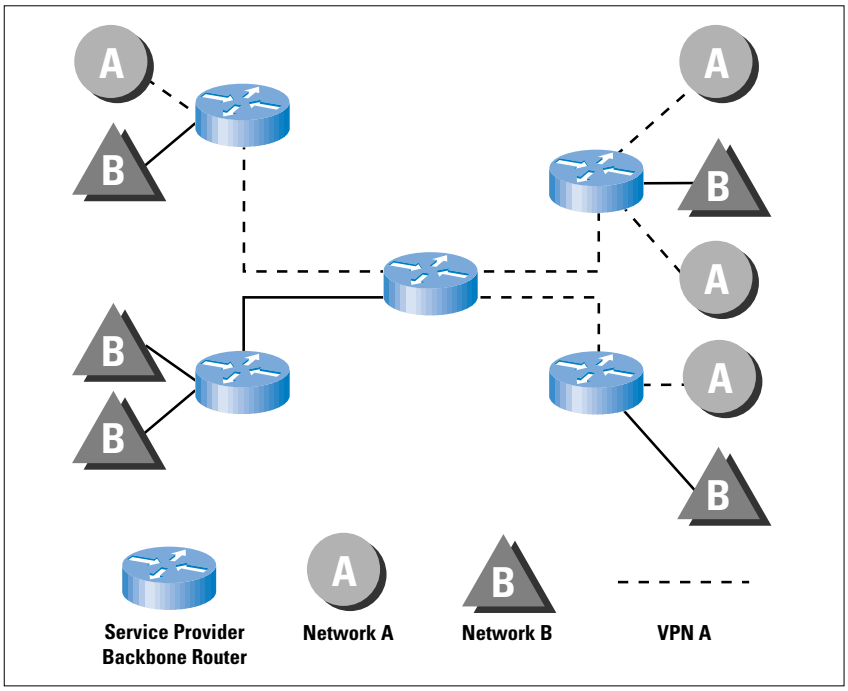
Instead of a public infrastructure deployment, the deployment model used has been that of a closed (or private) network environment where the infrastructure, addressing scheme, management, and services were dedicated to a closed set of subscribers. This model matched that of a closed corporate environment, where the network was dedicated to serve a single corporate entity as the sole client. This precursor to the VPN, which could be called the private data network, was physically constructed using dedicated local office wiring and dedicated leased circuits (or private virtual circuits from an underlying switching fabric such as X.25) to connect geographically diverse sites.

However, this alternative does have an associated cost, in that the client now has to manage the network and all its associated elements, invest capital in network switching infrastructure, hire trained staff, and assume complete responsibility for the provisioning and ongoing maintenance of the network service. Such a dedicated use of transport services, equipment, and staff is often difficult to justify for many small-to-medium sized organizations, and whereas the functionality of a private network system is required, the expressed desire is to reduce the cost of the service through the use of shared transport services, equipment, and management. Numerous scenarios can address this need, ranging from outsourcing the management of the switching elements of the network (managed network services), to outsourcing the capital equipment components (leased network services), to outsourcing the management, equipment, and transport elements to a service provider altogether.

An Example VPN

In the simple example illustrated in Figure 1, Network "A" sites have established a VPN (depicted by the dashed lines) across the service provider's backbone network, where Network "B" is completely unaware of its existence. Both Networks "A" and "B" can harmoniously coexist on the same backbone infrastructure.

Figure 1:
A Virtual Private
Network of
"A" Sites



This type of VPN is, in fact, the most common type of VPN—one that has geographically diverse subnetworks that belong to a common administrative domain, interconnected by a shared infrastructure outside their administrative control (such as the global Internet or a single service provider backbone). The principal motivation in establishing a VPN of this type is that perhaps most of the communications between devices within the VPN community may be sensitive (again, a decision on the level of privacy required rests solely on a risk analysis performed by the administrators of the VPN), yet the total value of the communications system does not justify the investment in a fully private communications system that uses discrete transmission elements.

On a related note, the level of privacy that a VPN may enjoy depends greatly on the technology used to construct the VPN. For example, if the communications between each VPN subnetwork (or between each VPN host) is securely encrypted as it transits the common communications infrastructure, then it can be said that the privacy aspect of the VPN is relatively high.

In fact, the granularity of a VPN implementation can be broken down further to a single end-to-end, one-to-one connectivity scenario. Examples of these types of one-to-one VPNs are single dialup users who establish a VPN connection to a secure application, such as an online banking service, or a single user establishing a secure, encrypted session between a desktop and server application, such as a purchasing transaction conducted on the World Wide Web. This type of one-to-one VPN is becoming more and more prevalent as secure electronic commerce applications become more mature and are further deployed in the Internet. (See article starting on page 20.)

It is interesting to note that the concept of virtualization in networking has also been considered in regard to deploying both research and production services on a common infrastructure. The challenge in the research and education community is one in which there is a need to satisfy both network research and production requirements. VPNs have also been considered as a method to segregate traffic in a network such that research and production traffic behave as "ships in the night," oblivious to one another's existence, to the point that major events (for example, major failures, instability) within one community of interest are completely transparent to the other. This concept is further documented in MORPHnet[4].

It should also be noted that VPNs may be constructed to span more than one host communications network, so that the "state" of the VPN may be supported on one or more VPN provider networks. This scenario is perhaps at its most robust when all the providers explicitly support the resultant distributed VPN environment, but other solutions that do not necessarily involve knowledge of the overlay VPN are occasionally deployed with mixed results.

Types of VPNs

The confusion factor comes into play in the most basic discussions regarding VPNs, principally because there are actually several different types of VPNs, and depending on the functional requirements, several different methods of constructing each type of VPN are available. The process of selection should include consideration of what problem is being solved, risk analysis of the security provided by a particular implementation, issues of scale in growing the size of the VPN, and the complexity involved in implementation of the VPN, as well as ongoing maintenance and troubleshooting.

To simplify the description of the different types of VPNs, they are broken down in this article into categories that reside in the different layers of the TCP/IP protocol suite; Link Layer, Network Layer, Transport Layer, and Application Layer.

Network-Layer VPNs

The network layer in the TCP/IP protocol suite consists of the IP routing system—how reachability information is conveyed from one point in the network to another. There are a few methods to construct VPNs within the network layer—each is examined in the following paragraphs. A brief overview of non-IP VPNs is provided in Part II of this article.

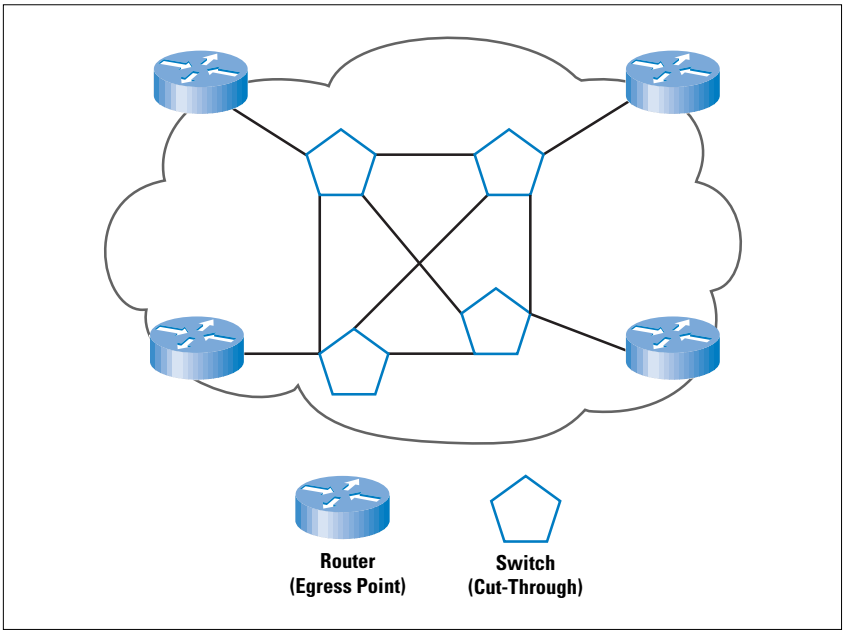
A brief overview of the differences in the "peer" and "overlay" VPN models is appropriate at this point. Simply put, the "peer" VPN model is one in which the network-layer forwarding path computation is done on a hop-by-hop basis, where each node in the intermediate data transit path is a peer with a next-hop node. Traditional routed networks are examples of peer models, where each router in the network

path is a peer with its next-hop adjacencies. Alternatively, the "overlay" VPN model is one in which the network-layer forwarding path is not done on a hop-by-hop basis, but rather, the intermediate link-layer network is used as a "cut-through" to another edge node on the other side of a large cloud. Examples of "overlay" VPN models include ATM, Frame Relay, and tunneling implementations.

Having drawn these simple distinctions between the peer and overlay models, it should be noted that the overlay model introduces some serious scaling concerns in cases where large numbers of egress peers are required because the number of adjacencies increases in direct proportion to the number of peers—the amount of computational and performance overhead required to maintain routing state, adjacency information, and other detailed packet forwarding and routing information for each peer becomes a liability in very large networks. If all the egress nodes in a cut-through network become peers in an effort to make all egress nodes one "Layer 3" hop away from one another, the scalability of the VPN overlay model is limited quite remarkably.

For example, as the simple diagram (Figure 2) illustrates, the routers that surround the interior switched infrastructure represent egress peers, because the switches in the core interior could be configured such that all egress nodes are one Layer 3 hop away from one another, creating what is commonly known as a "cut-through." This scenario forms the foundation of an overlay VPN model.

Figure 2: A Cut-Through VPN



Alternatively, if the switches in the interior are replaced with routers, then the routers positioned at the edge of the cloud become peers with their next-hop router nodes, not other egress nodes. This scenario forms the foundation of the peer VPN model.

Controlled Route Leaking

"Controlled route leaking" (or *route filtering*) is a method that could also be called "privacy through obscurity" because it consists of nothing more than controlling route propagation to the point that only certain networks receive routes for other networks that are within their own community of interest. This model can be considered a "peer" model, because a router within a VPN site establishes a routing relationship with a router within the VPN provider's network, instead of an edge-to-edge routing peering relationship with routers in other sites of that VPN. Although the common underlying Internet generally carries the routes for all networks connected to it, this architecture assumes that only a subset of such networks form a VPN. The routes associated with this set of networks are filtered such that they are not announced to any other set of connected networks, and all other non-VPN routes are not announced to the networks of the VPN. For example, in Figure 1, if the SP routers "leaked" routing information received from one site in Network "A" to only other sites in Network "A," then sites not in Network "A" (for instance, sites in Network "B") would have no explicit knowledge of any other networks which where attached to the service provider's infrastructure (as shown in Figure 3). Given this lack of explicit knowledge of reachability to any location other than other members of the same VPN, privacy of services is implemented by the inability of any of the VPN hosts to respond to packets which contain source addresses from outside the VPN community of interest.

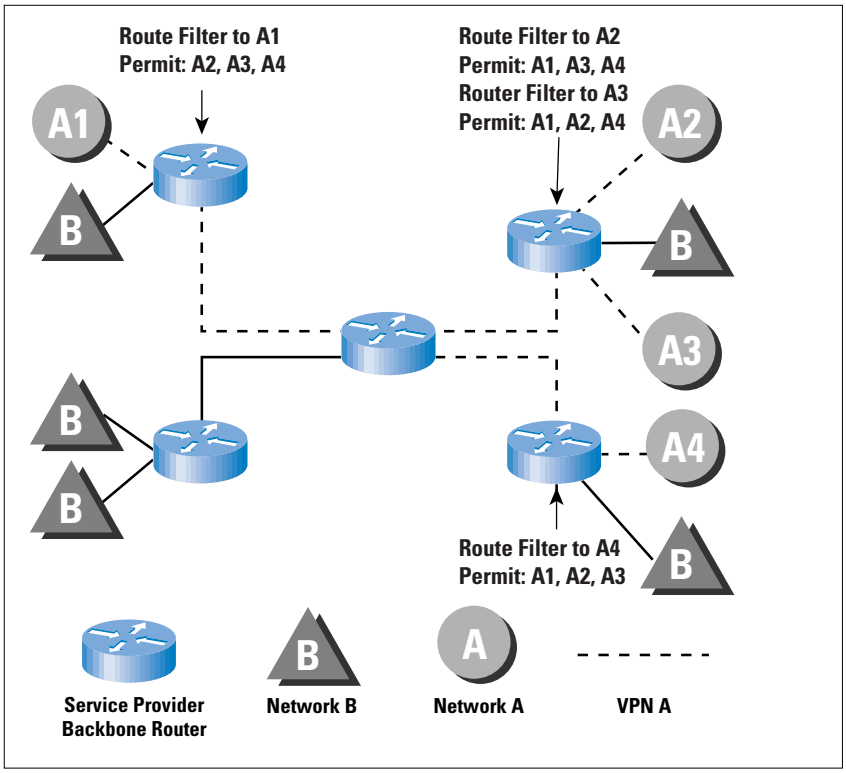


Figure 3: Controlled Route Leaking

This use of partial routing information is prone to many forms of misconfiguration. One potential problem with route leaking is that it is extremely difficult, if not impossible, to prohibit the subscriber networks from pointing default to the upstream next-hop router for traffic destined for networks outside their community of interest. From within the VPN subscriber's context, this action may be reasonable, in that "default" for the VPN is reachability to all other members of the same VPN, and pointing a default route to the local egress path is, within a local context, a reasonable move. Thus, it is no surprise that this is a common occurrence in VPNs in which the customer configures and manages the customer premise equipment (CPE) routers. If the SP manages the configuration of the CPE routers, then this is rarely a problem. Otherwise, the SP might be wise to place traffic filters on first-hop routers to prohibit all traffic destined for networks outside the VPN community of interest.

It should also be noted that this environment implicitly assumes a common routing core. A common routing core, in turn, implies that each VPN must use addresses that do not clash with those of any other VPN on the same common infrastructure, and cannot announce arbitrary private addresses into the VPN. Another, perhaps less obvious, side effect of this form of VPN structure is that it is not possible for two VPNs to have a single point of interconnection, nor is it possible for a VPN to operate a single point of interconnection to the public Internet in such an environment. (This single point would be a so-called "gateway," where all external traffic is passed through a control point that can enforce some form of access policy and record a log of external transactions.) The common routing core uses a single routing paradigm, based solely on destination address.

It should also be noted that this requirement highlights one of the dichotomies of VPN architectures. VPNs must assume that they operate in a mutually hostile environment, where any vulnerability that exposes the private environment to access by external third parties may be exploited in a hostile fashion. However, VPNs rarely are truly isolated communications environments, and typically all VPNs do have some form of external interface that allows controlled reachability to other VPNs and to the broader public data network. The trade-off between secure privacy and the need for external access is a constant feature of VPNs.

Implementation of inter-VPN connectivity requires the network to route externally originated packets to the VPN interconnection point, and if they are admitted into the VPN at the interconnection point, the same packet may be passed back across the network to the ultimate VPN destination address. Without the use of *Network Address Translation* (NAT) technologies at the interconnection point of ingress into the VPN, this kind of communications structure is insupportable within this architecture (Figure 4).

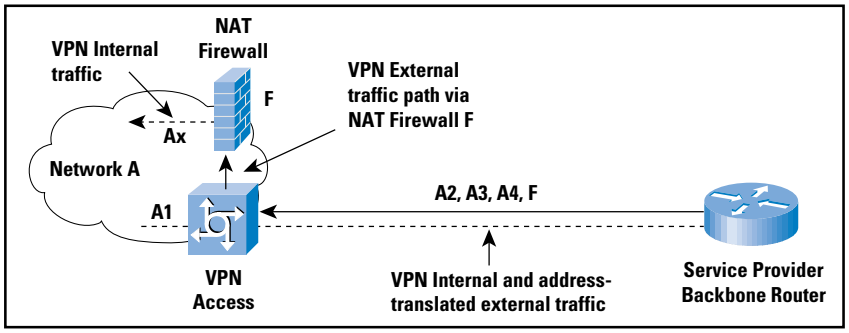

Figure 4: Segregating VPN traffic via address translation

In general, the technique of supporting private communities of interest simply by route filtering can at best be described as a primitive method of VPN construction, which is prone to administrative errors, and admits an undue level of insecurity and network inflexibility. Even with comprehensive traffic and route filtering, the resulting environment is not totally robust. The operational overhead required to support complementary sets of traditional routing and traffic filters is a relevant consideration, and this approach does not appear to possess the scaling properties desirable to allow the number of VPNs to grow beyond the bounds of a few hundred, using today's routing technologies.

Having said that, however, a much more scalable approach is to use *Border Gateway Protocol* (BGP) *communities*[5] as a method to control route propagation. The use of BGP communities scales much better than alternative methods with respect to controlling route propagation and is less prone to human misconfiguration. Briefly, the use of the BGP communities attribute allows a VPN provider to "mark" BGP *Network-Layer Reachability Information* (NLRI) with a community attribute, such that configuration control allows route information to propagate in accordance with a community profile.

Because traffic from different communities of interest must traverse a common shared infrastructure, there is no significant data privacy in the portion of the network where traffic from multiple communities of interest share the infrastructure. Therefore, it can be said that although connected subnetworks—or rather, subscribers to the VPN service—may not be able to detect the fact that there are other subscribers to the service, multiple interwoven streams of subscriber data traffic pass unprotected in the core of the service provider's network.

Tunneling

Sending specific portions of network traffic across a tunnel is another method of constructing VPNs. Some tunneling methods are more effective than others. The most common tunneling mechanisms are *Generic Routing Encapsulation* (GRE)[6] tunneling between a source and destination router, router-to-router or host-to-host tun-neling protocols such as *Layer 2 Tunneling Protocol* (L2TP)[7] and *Point-to-Point Tunneling Protocol* (PPTP)[8], and *Distance Vector Multicast Routing Protocol* (DVMRP)[9] tunnels.

Tunneling can be considered an overlay model, but the seriousness of the scaling impact depends on whether the tunnels are point-to-point or point-to-multipoint. Point-to-point tunnels have fewer scaling problems than do point-to-multipoint tunnels, except in situations where a single node begins to build multiple point-to-point tunnels with multiple endpoints. Although a linear scaling problem is introduced at this point, the manageability of point-to-point tunnels lies solely in the administrative overhead and the number of the tunnels themselves. On the other hand, point-to-multipoint tunnels use "cut-through" mechanisms to make greater numbers of endpoints one hop away from one another and subsequently introduce a much more serious scaling problem.

Although the *Multicast Backbone* (Mbone) itself could literally be considered a global VPN, and although DVMRP tunnels are still widely used by organizations to connect to the Mbone, it really is not germane to the central topic of VPNs, because the focus of this article is on unicast traffic.

Traditional Modes of Tunneling

GRE tunnels, as mentioned previously, are generally configured between a source (*ingress*) router and a destination (*egress*) router, such that packets designated to be forwarded across the tunnel (already formatted with an encapsulation of the data with the "normal" protocol-defined packet header) are further encapsulated with a new header (the GRE header), and placed into the tunnel with a destination address of the tunnel endpoint (the new next-hop). When the packet reaches the tunnel endpoint, the GRE header is stripped away, and the packet continues to be forwarded to the destination, as designated in the original IP packet header (Figure 5).

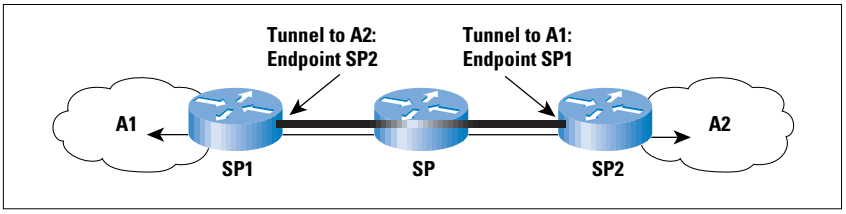

Figure 5: Tunneling across a Service Provider

GRE tunnels are generally point-to-point—that is, there is a single source address for the tunnel and usually only a single destination tunnel endpoint. However, some vendor implementations allow the configuration of point-to-multipoint tunnels—that is, a single source address and multiple destinations. Although this implementation is generally used in conjunction with *Next Hop Resolution Protocol* (NHRP)[10], the effectiveness and utility of NHRP is questionable and should be tested prior to deployment. It is also noteworthy that NHRP is known to produce steady-state forwarding loops when used to establish shortcuts between routers. In the scenario discussed previously, NHRP is used for establishing shortcuts between routers.

Tunnels, however, do have numerous compelling attractions when used to construct VPNs. The architectural concept is to create VPNs as a collection of tunnels across a common host network. Each point of attachment to the common network is configured as a physical link that uses addressing and routing from the common host network, and one or more associated tunnels. Each tunnel endpoint logically links this point of attachment to other remote points from the same VPN. The technique of tunneling uses a tunnel egress address defined within the address space of the common host network, whereas the packets carried within the tunnel use the address space of the VPN, which in turn constrains the tunnel endpoints to be collocated to those points in the network where the VPN and the host network interconnect.

Pros and Cons

The advantage of this approach is that the routing for the VPN is isolated from the routing of the common host network. The VPNs can reuse the same private address space within multiple VPNs without any cross impact, providing considerable independence of the VPN from the host network. This requirement is key for many VPNs in that private VPNs typically may not use globally unique or coordinated address space, and there is often the consequential requirement to support multiple VPNs which independently use the same address block. Such a configuration is not supportable within a controlled route leakage VPN architecture. The tunnel can also encapsulate numerous different protocol families, so that it is possible for a tunnel-based VPN to mimic much of the functionality of dedicated private networks. Again, the need to support multiple protocols in a format which preserves the functionality of the protocol is a critical requirement for many VPN support architectures. This requirement is one in which an IP common network with controlled route leakage cannot provide such services, whereas a tunneling architecture can segment the VPN-private protocol from the common host network. The other significant advantage of the tunneled VPN is the segregation of the common host routing environment with that of the VPN. To the VPN, the common host network assumes the properties of numerous point-to-point circuits, and the VPN can use a routing protocol across the virtual network which matches the administrative requirements of the VPN. Equally, the common host network can use a routing design which matches the administrative requirements of the host network (or collection of host networks), and is not constrained by the routing protocols used by the VPN client networks.

Although it could be said that these advantages indicate that GRE tunneling is the panacea for VPN design, using GRE tunnels as a mechanism for VPNs does have several drawbacks, mostly with regard to administrative overhead, scaling to large numbers of tunnels, and QoS and performance.

Since GRE tunnels must be manually configured, there is a direct relationship to the number of tunnels that must be configured and the amount of administrative overhead required to configure and maintain them—each time the tunnel endpoints must change, and they must be manually reconfigured. Also, although the amount of processing required to encapsulate a packet for GRE handling may appear to be small, there is a direct relationship to the number of configured tunnels and the total amount of processing overhead required for GRE encapsulation. Of course, tunnels can be structured to be triggered automatically, but such an approach has numerous drawbacks that dictate careful consideration of related routing and performance issues. The worst end state of such automatic tunnel generation is that of a configuration loop where the tunnel passes traffic over itself. It is important, once again, to reiterate the impact of a large number of routing peering adjacencies that result from a complete mesh of tunnels; this scenario can result in a negative effect on routing efficiency.

An additional concern with GRE tunneling is the ability of traffic classification mechanisms to identify traffic with a fine enough level of granularity, and not become a hindrance to forwarding performance. If the traffic classification process used to identify packets (that are to be forwarded across the tunnel) interferes with the router's ability to maintain acceptable packet-per-second forwarding rates, then this becomes a performance liability.

Privacy of the network remains an area of concern because the tunnel is still vulnerable—privacy is not absolute. Packets that use GRE formatting can be injected into the VPN from third-party sources. To ensure a greater degree of integrity of privacy of the VPN, it is necessary to deploy ingress filters that are aligned to the configured tunnel structure.

It is also necessary to ensure that the CPE routers are managed by the VPN service provider, because the configuration of the tunnel endpoints is a critical component of the overall architecture of integrity of privacy. However, most VPN service providers are reluctant to add CPE equipment to their asset inventory and undertake remote management of such CPE equipment, due to the high operational overheads and poor capital efficiencies which are typical of CPE deployment. Arguably, one might suggest that having a dedicated CPE router defeats one of the basic premises of constructing a VPN—the use of shared infrastructure as a way to reduce the overall network cost.

It should be noted that VPNs can be constructed using tunnels without the explicit knowledge of the host network provider, and the VPN can span numerous host networks without any related underlying agreements between the network operators to mutually support the overlay VPN. Such an architecture is little different from provider-operated VPN architecture; the major difference lies in the issue of traffic and

performance engineering, and the administrative boundary of the management of the VPN overlay. Independently configured VPN tunnels can result in injection of routes back into the VPN in a remote location, a scenario that can cause traffic to traverse the same link twice, once in an unencapsulated format and again within a tunnel. This situation can then lead to adverse performance impacts.

It is also true that the overlay VPN model has no control over which path is taken in the common host network, nor the stability of that path. This scenario can then lead to adverse performance impacts on the VPN. Aside from the technology aspects of this approach, the major issue is one of whether the VPN management is outsourced to the network provider, or undertaken within administrative functions of the VPN. One of the more serious considerations in building a VPN on tunneling is that there is virtually no way to determine the cost of the route across a tunnel, because the true path is masked by the cut-through nature of the tunnel. This situation could ultimately result in highly suboptimal routing, meaning that a packet could take a path determined by the cut-through mechanism that is excessively suboptimal, while native per-hop routing protocols might find a much more efficient method to forward the packets to their destinations.

Conclusion

So far in our discussion of VPNs, we have introduced a working definition of the term "Virtual Private Network" and discussed the motivations behind the adoption of such networks. We have outlined a framework for describing the various forms of VPNs, and then examined numerous network-layer VPN structures, in particular, that of controlled route leakage and tunneling techniques.

In Part II we will continue this examination of network-layer VPNs, including virtual private dial networks and network-layer encryption. In addition, we will examine link-layer VPNs that use ATM and Frame Relay substrates, and also look at switching and encryption techniques, and issues concerning QoS and non-IP VPNs.

SSL: Foundation for Web Security

by William Stallings

Virtually all businesses, most government agencies, and many individuals now have Web sites. The number of individuals and companies with Internet access is expanding rapidly, and all of them have graphical Web browsers. As a result, businesses are enthusiastic about setting up facilities on the Web for electronic commerce. But the reality is that the Internet and the Web are extremely vulnerable to compromises of various sorts. As businesses utilize the Internet for more than information dissemination, they will need to use trusted security mechanisms.

An increasingly popular general-purpose solution is to implement security as a protocol that sits between the underlying transport protocol (TCP) and the application. The foremost example of this approach is the *Secure Sockets Layer* (SSL) and the follow-on Internet standard of SSL known as *Transport Layer Security* (TLS). At this level, there are two implementation choices. For full generality, SSL (or TLS) could be provided as part of the underlying protocol suite and therefore be transparent to applications. Alternatively, SSL can be embedded in specific packages. For example, Netscape and Microsoft Explorer browsers come equipped with SSL, and most Web servers have implemented the protocol. Although it is possible to use SSL for applications other than Web transactions, its use at present is typically as part of Web browsers and servers and hence limited to Web traffic. Most of this article deals with the technical details of SSL; the status of TLS is described at the end.

If you have viewed an HTML source document, you have seen that the links are referenced with `HREF=<URL>` within an anchor (A) tag. In most cases, the reference is to another document through the use of the *Hyper Text Transfer Protocol*, or HTTP. For this, the browser initiates one or more sessions to the destination port of TCP/80 (the well-known port for HTTP) on the server. In some cases, a plug-in can be called, and data specific to that plug-in can be transferred to or from the browser. For that, the browser would initiate a session to the well-known TCP port of the plug-in. SSL is called when the reference starts like the following: `HREF="https://..` By calling "https" within the browser, it is mandating that the data be transferred through the use of SSL. By clicking on this hot link, the browser initiates a session to the server on port TCP/443. SSL attempts to negotiate a secure link and transfers the data across it. If the negotiation fails, no data is transferred. The browser usually indicates that a secure connection has been requested. Netscape Navigator version 3 indicates this with a blue border around the page and a highlighted key in the lower left corner. Netscape Communicator version 4 displays this with a closed padlock in a lower status window. Microsoft's Internet Explorer indicates it

with a padlock in a lower information window. Display of these signs indicates that the information within the browser window has been delivered through the security of SSL.

SSL was originated by Netscape. Version 3 of the protocol was designed with public review and input from industry and was published as an Internet Draft document. Subsequently, when a consensus was reached to submit the protocol for Internet standardization, the TLS working group was formed within the *Internet Engineering Task Force* (IETF) to develop a common standard. The current work on TLS is aimed at producing an initial version as an Internet Standard. This first version of TLS can be viewed as essentially an SSLv3.1, and is very close to SSLv3. TLS includes a mechanism by which a TLS entity can back down to the SSLv3.0 protocol; in that sense, TLS is backward compatible with SSL.

SSL Architecture

SSL is designed to make use of TCP to provide a reliable end-to-end secure service. SSL is not a single protocol but rather two layers of protocols.

The SSL Record Protocol provides basic security services to various higher-layer protocols. In particular, the HTTP, which provides the transfer service for Web client/server interaction, can operate on top of SSL. Three higher-layer protocols are defined as part of SSL: the *Handshake Protocol*, the *Change CipherSpec Protocol*, and the *Alert Protocol*. These SSL-specific protocols are used in the management of SSL exchanges.

Two important SSL concepts are the SSL session and the SSL connection, which are defined in the specification as follows:

- Connection: A logical client/server link that provides a suitable type of service. For SSL, such connections are peer-to-peer relationships. The connections are transient. Every connection is associated with one session.

- Session: An association between a client and a server. Sessions are created by the Handshake Protocol. Sessions define a set of cryptographic security parameters, which can be shared among multiple connections. Sessions are used to avoid the expensive negotiation of new security parameters for each connection.

Between any pair of parties (applications such as HTTP on client and server), there may be multiple secure connections. In theory, there may also be multiple simultaneous sessions between parties, but this feature is not used in practice.

Several states are associated with each session. When a session is established, there is a current operating state for both read and write (that is, receive and send). In addition, during the Handshake Protocol, pending read and write states are created. Upon successful conclusion of the Handshake Protocol, the pending states become the current states. A session state is defined by the following parameters (definitions taken from the SSL specification):

- Session identifier: An arbitrary byte sequence chosen by the server to identify an active or resumable session state.
- Peer certificate: An X509.v3 certificate of the peer. This element of the state may be null.
- Compression method: The algorithm used to compress data prior to encryption.
- CipherSpec: Specifies the bulk data encryption algorithm (such as DES) and a hash algorithm (such as MD5 or SHA-1). It also defines cryptographic attributes such as the hash size.
- Master secret: 48-byte secret shared between the client and server.
- Is resumable: A flag indicating whether the session can be used to initiate new connections.

A connection state is defined by the following parameters:

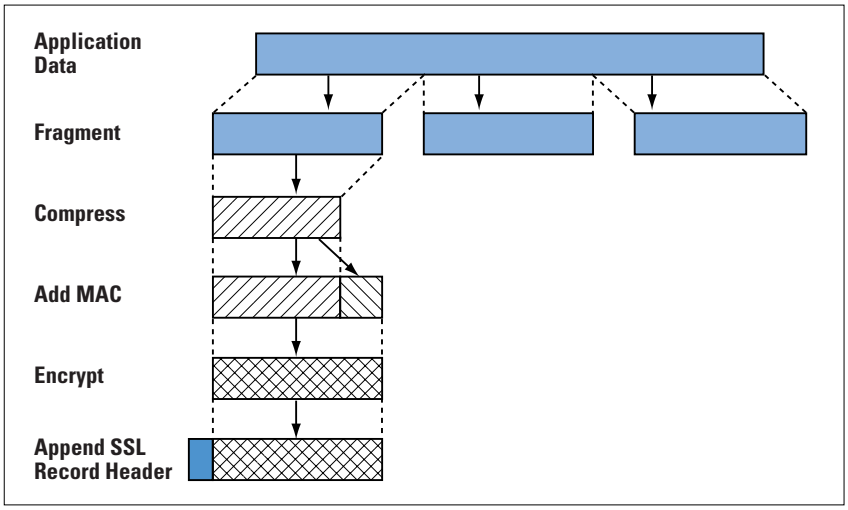
- Server and client random: Byte sequences that are chosen by the server and client for each connection.
- Server write MAC secret: The secret key used in MAC operations on data sent by the server.
- Client write MAC secret: The secret key used in MAC operations on data sent by the client.
- Server write key: The conventional encryption key for data encrypted by the server and decrypted by the client.
- Client write key: The conventional encryption key for data encrypted by the client and decrypted by the server.
- Initialization vectors: When a block cipher in CBC mode is used, an initialization vector (IV) is maintained for each key. This field is first initialized by the SSL Handshake Protocol. Thereafter the final ciphertext block from each record is preserved for use as the IV for the next record.
- Sequence numbers: Each party maintains separate sequence numbers for transmitted and received messages for each connection. When a party sends or receives a change CipherSpec message, the appropriate sequence number is set to zero.

SSL Record Protocol

The SSL Record Protocol provides two services for SSL connections: confidentiality, by encrypting application data; and message integrity, by using a *message authentication code* (MAC). The Record Protocol is a base protocol that can be utilized by some of the upper-layer protocols of SSL. One of these is the handshake protocol which, as described later, is used to exchange the encryption and authentication keys. It is vital that this key exchange be invisible to anyone who may be watching this session.

Figure 1 indicates the overall operation of the SSL Record Protocol. The Record Protocol takes an application message to be transmitted, fragments the data into manageable blocks, optionally compresses the data, applies a MAC, encrypts, adds a header, and transmits the resulting unit in a TCP segment. Received data is decrypted, verified, decompressed, and reassembled and then delivered to the calling application, such as the browser.

Figure 1: SSL Record Protocol Operation



The first step is fragmentation. Each upper-layer message is fragmented into blocks of 2^{14} bytes (16,384 bytes) or less. Next, compression is optionally applied. In SLLv3 (as well as the current version of TLS), no compression algorithm is specified, so the default compression algorithm is null. However, specific implementations may include a compression algorithm.

The next step in processing is to compute a message authentication code over the compressed data. For this purpose, a shared secret key is used. In essence, the hash code (for example, MD5) is calculated over a combination of the message, a secret key, and some padding. The receiver performs the same calculation and compares the incoming MAC value with the value it computes. If the two values match, the receiver is assured that the message has not been altered in transit. An attacker would not be able to alter both the message and the MAC, because the attacker does not know the secret key needed to generate the MAC.

Next, the compressed message plus the MAC are encrypted using symmetric encryption. A variety of encryption algorithms may be used, including the Data Encryption Standard (DES) and triple DES.

The final step of SSL Record Protocol processing is to prepend a header, consisting of the following fields:

- Content Type (8 bits): The higher-layer protocol used to process the enclosed fragment.
- Major Version (8 bits): Indicates major version of SSL in use. For SSLv3, the value is 3.
- Minor Version (8 bits): Indicates minor version in use. For SSLv3, the value is 0.
- Compressed Length (16 bits): The length in bytes of the plain-text fragment (or compressed fragment if compression is used).

The content types that have been defined are change_cipher_spec, alert, handshake, and application_data. The first three are the SSL-specific protocols, mentioned previously. The application-data type refers to the payload from any application that would normally use TCP but is now using SSL, which in turn uses TCP. In particular, the HTTP protocol that is used for Web transactions falls into the application-data category. A message from HTTP is passed down to SSL, which then wraps this message into an SSL record.

Change CipherSpec Protocol

The Change CipherSpec Protocol is one of the three SSL-specific protocols that use the SSL Record Protocol, and it is the simplest. This protocol consists of a single message, which consists of a single byte with the value 1. The sole purpose of this message is to cause the pending state to be copied into the current state, which updates the CipherSuite to be used on this connection. This signal is used as a coordination signal. The client must send it to the server and the server must send it to the client. After each side has received it, all of the following messages are sent using the agreed-upon ciphers and keys.

Alert Protocol

The Alert Protocol is used to convey SSL-related alerts to the peer entity. As with other applications that use SSL, alert messages are compressed and encrypted, as specified by the current state.

Each message in this protocol consists of two bytes. The first byte takes the value "warning" (1) or "fatal"(2) to convey the severity of the message. If the level is fatal, SSL immediately terminates the connection. Other connections on the same session may continue, but no new connections on this session may be established. The second byte contains a code that indicates the specific alert. An

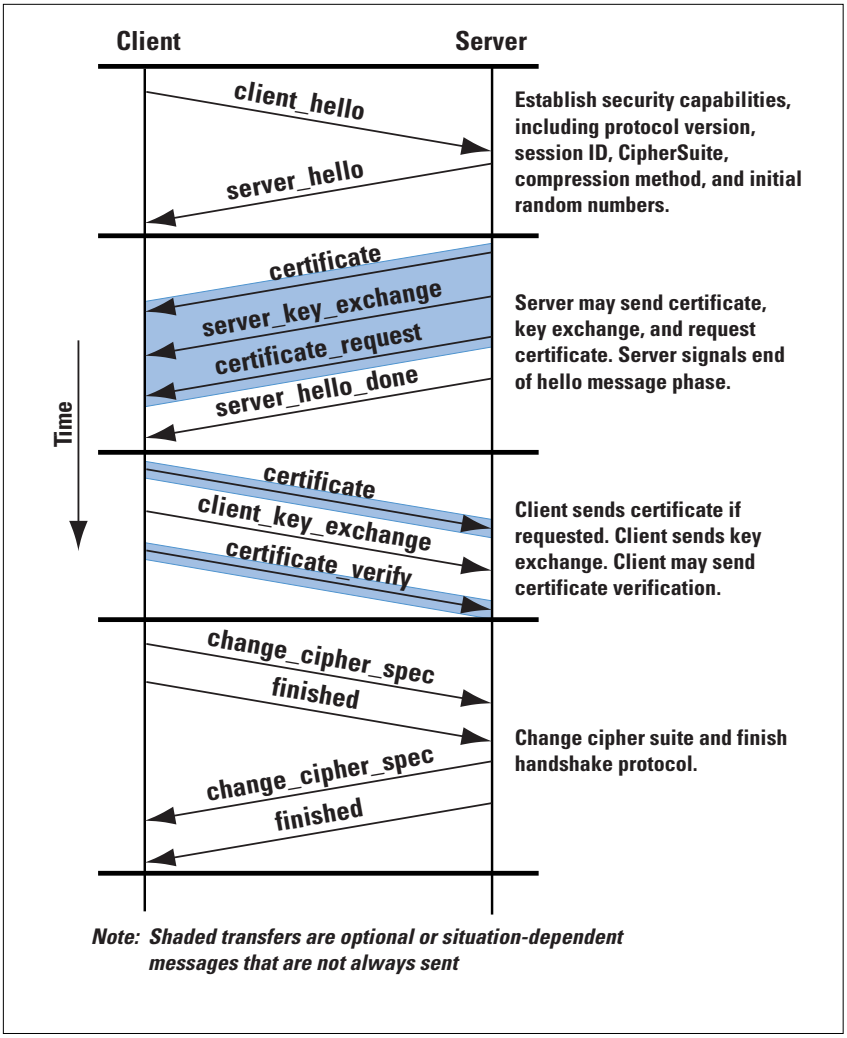
example of a fatal message is illegal_parameter (a field in a handshake message was out of range or inconsistent with other fields). An example of a warning message is close_notify (notifies the recipient that the sender will not send any more messages on this connection; each party is required to send a close_notify alert before closing the write side of a connection).

Handshake Protocol

The most complex part of SSL is the Handshake Protocol. This protocol allows the server and client to authenticate each other and to negotiate an encryption and MAC algorithm and cryptographic keys to be used to protect data sent in an SSL record. The Handshake Protocol is used before any application data is transmitted. The Handshake Protocol consists of a series of messages exchanged by the client and the server.

Figure 2 shows the initial exchange needed to establish a logical connection between the client and the server. The exchange can be viewed as having four phases.

Figure 2: Handshake Protocol Action



Phase 1 is used to initiate a logical connection and to establish the security capabilities that will be associated with it. The exchange is initiated by the client, which sends a client_hello message with the following parameters:

- Version: The highest SSL version understood by the client.
- Random: A client-generated random structure, consisting of a 32-bit timestamp and 28 bytes generated by a secure random number generator. These values serve as nonces and are used during key exchange to prevent replay attacks.
- Session ID: A variable-length session identifier. A nonzero value indicates that the client wishes to update the parameters of an existing connection or create a new connection on this session. A zero value indicates that the client wishes to establish a new connection on a new session.
- CipherSuite: A list that contains the combinations of cryptographic algorithms supported by the client, in decreasing order of preference. Each element of the list (each CipherSuite) defines both a key exchange algorithm and a CipherSpec; these are discussed subsequently.
- Compression Method: A list of the compression methods the client supports.

After sending the client_hello message, the client waits for the server_hello message, which contains the same parameters as the client_hello message. For the server_hello message, the following conventions apply. The Version field contains the lower of the version suggested by the client and the highest version supported by the server. The Random field is generated by the server and is independent of the client's Random field. If the SessionID field of the client was nonzero, the same value is used by the server; otherwise the server's SessionID field contains the value for a new session. The CipherSuite field contains the single CipherSuite selected by the server from those proposed by the client. The Compression field contains the compression method selected by the server from those proposed by the client.

The first element of the CipherSuite parameter is the key exchange method (that is, the means by which the cryptographic keys for conventional encryption and MAC are exchanged). The following key exchange methods are supported:

- RSA: The secret key is encrypted with the receiver's RSA public key. A public-key certificate for the receiver's key must be made available.
- Fixed Diffie-Hellman: This a Diffie-Hellman key exchange in which the server's certificate contains the Diffie-Hellman public parameters

signed by the *certificate authority* (CA). That is, the public-key certificate contains the Diffie-Hellman public-key parameters. The client provides its Diffie-Hellman public key parameters either in a certificate, if client authentication is required, or in a key exchange message. This method results in a fixed secret key between two peers, based on the Diffie-Hellman calculation using the fixed public keys.

- Ephemeral Diffie-Hellman: This technique is used to create ephemeral (temporary, one-time) secret keys. In this case, the Diffie-Hellman public keys are exchanged, and signed using the sender's private RSA or DSS key. The receiver can use the corresponding public key to verify the signature. Certificates are used to authenticate the public keys. This option appears to be the most secure of the three Diffie-Hellman options because it results in a temporary, authenticated key.

- Anonymous Diffie-Hellman: The base Diffie-Hellman algorithm is used, with no authentication. That is, each side sends its public Diffie-Hellman parameters to the other, with no authentication. This approach is vulnerable to man-in-the-middle attacks, in which the attacker conducts anonymous Diffie-Hellman exchanges with both parties.

Following the definition of a key exchange method is the CipherSpec, which indicates the encryption and hash algorithms and other related parameters.

The server begins Phase 2 by sending its certificate, if it needs to be authenticated; the message contains one or a chain of X.509 certificates. The certificate message is required for any agreed-on key exchange method except anonymous Diffie-Hellman. Note that if fixed Diffie-Hellman is used, this certificate message functions as the server's key exchange message because it contains the server's public Diffie-Hellman parameters.

Next, a server_key_exchange message may be sent, if it is required. It is not required in two instances: (1) The server has sent a certificate with fixed Diffie-Hellman parameters; or (2) RSA key exchange is to be used.

Next, a nonanonymous server (server not using anonymous Diffie-Hellman) can request a certicate from the client. The certificate_request message includes two parameters: certificate_type and certificate_authorities. The certificate type indicates the type of public-key algorithm. The second parameter in the certificate_request message is a list of the distinguished names of acceptable certificate authorities.

The final message in Phase 2, and one that is always required, is the server_done message, which is sent by the server to indicate the end of the server hello and associated messages. After sending this message, the server waits for a client response. This message has no parameters.

Upon receipt of the server_done message, the client should verify that the server provided a valid certificate, if required, and check that the server hello parameters are acceptable. If all is satisfactory, the client sends one or more messages back to the server in Phase 3. If the server has requested a certificate, the client begins this phase by sending a certificate message. If no suitable certificate is available, the client sends a no_certificate alert instead.

Next is the client_key_exchange message, which must be sent in this phase. The content of the message depends on the type of key exchange.

Finally, in this phase, the client may send a certificate_verify message to provide explicit verification of a client certificate. This message is only sent following any client certificate that has signing capability (that is, all certificates except those containing fixed Diffie-Hellman parameters).

Phase 4 completes the setting up of a secure connection. The client sends a change_cipher_spec message and copies the pending CipherSpec into the current CipherSpec. Note that this message is not considered part of the Handshake Protocol but is sent using the Change CipherSpec Protocol. The client then immediately sends the finished message under the new algorithms, keys, and secrets. The finished message verifies that the key exchange and authentication processes were successful.

In response to these two messages, the server sends its own change_cipher_spec message, transfers the pending to the current CipherSpec, and sends its finished message. At this point the handshake is complete and the client and server may begin to exchange application layer data.

After the records have been transferred, the TCP session is closed. However, since there is no direct link between TCP and SSL, the state of SSL may be maintained. For further communications between the client and the server, many of the negotiated parameters are retained. This may occur if, in the case of Web traffic, the user clicks on another link that also specifies HTTPs on the same server. If the clients or servers wish to resume the transfer of records, they don't have to again negotiate encryption algorithms or totally new keys. The SSL specifications suggest that the state information be cached for no longer than 24 hours. If no sessions are resumed within that time, all information is deleted and any new sessions have to go through the handshake again. The specifications also recommend that neither the client nor the server have to retain this information, and shouldn't if either of them suspects that the encryption keys have been compromised. If either the client or the server does not agree to resume the session, for any reason, then both will have to go through the full handshake.

Transport Layer Security

TLS is an IETF standardization initiative whose goal is to produce an Internet standard version of SSL. In fact, the charter for the TLS working group states:

> "The TLS working group is a focused effort on providing security features at the transport layer, rather than general purpose security and key management mechanisms. The standard track protocol specification will provide methods for implementing privacy, authentication, and integrity above the transport layer."

This means that TLS can be used to provide security services to any application that uses TCP or the *User Datagram Protocol* (UDP). However, the driving force behind this work is to develop a standardized version of SSL. Microsoft has indicated that TLS will go into the next major version of its browser and Web server products, and Netscape has made a similar commitment. With this kind of support, it is likely that TLS will move quickly along the Internet Standards track.

The current draft version of TLS is very similar to SSLv3. TLS uses slightly different cryptographic algorithms for such things as the MAC function generation of secret keys. TLS also includes more alert codes.

SSL is already widely deployed and, under the name TLS, is moving toward Internet standardization. It is the solution of choice for Web transaction security.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal will carry tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It will provide readers with technology and standardization updates for all levels of the protocol stack and serve as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and quality of service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

Book Reviews

Groupware

Groupware: Collaborative Strategies for Corporate LANs and Intranets, by David Coleman, ISBN 0-13-727728-8, Prentice-Hall PTR, 1997, `http://www.prenhall.com`.

Some areas of science provide very poor training for dealing with primarily human processes. One might think that packet switching would be an exception because it lives on the stochastic nature of bursty communications. Because our knowledge of human and group activity is, at best, characterized by statistical assessments, those working in networking should do well in understanding and dealing with the unpredictable and human nature of communication, especially when it involves using networks.

So much for theory. In general, the world of lower-level networking has done little for the upper strata of computer-mediated human communication, except to provide a platform for the work of others. An apparent exception in the world of Internet technology is e-mail, yet it actually serves more as proof of the problem than as an exception. The basic facilities in Internet e-mail are the same today as they were 25 years ago. As nice as they are, the word "basic" is essential when characterizing them. Almost none of the Internet's standardized e-mail facilities are really targeted at providing automated or structural support for the work of a group.

Groupware Defined

The collection of products and services designed to help people collaborate via computer, by direct interaction, or by information dissemination is called "groupware." Coleman's book is a revision of *Groupware: Technology and Applications*. Written only 15 months earlier, the world changed more than enough in that time to require the revision. The first book had relatively little to say about the Internet, whereas this new book tries mightily to factor it into the equation. The result is a bit erratic, but the digressions serve to highlight how rapidly things are changing, rather than to suggest looking elsewhere for a better source on the topic.

The new book has an entirely different subtitle, giving a reasonable sense that the content targets more an understanding of system organization and function than detailed technical explanation. That's just fine, because the book really is not particularly technical. It covers the requirements and functions for supporting activity by groups.

Downsizing and working remotely are two very strong driving forces for increased use of groupware. This book is essentially an introduction to concepts, functionality, and use of systems that attempt to help staff members work together. Oddly, that does not only mean working together when physically separated, because there is discussion of meeting room assistance, such as with automated sense-of-the-group tallying devices.

Organization

The first two chapters introduce the topic, emphasizing that human and group process concerns dominate the field and are intimately tied to the aggressive efforts that organizations are making to run more productively and, frequently, with fewer people. The third chapter discusses functionality in terms of the World Wide Web. The book reflects the current enthusiasm for the Web, sometimes to the detriment of the appropriate use of messaging technology, although messaging is more prevalent among groupware than other kinds of commercial Internet systems.

The realm of groupware does not have a firm taxonomy. My own synthesis includes: Message (text and document) Exchange, Forms Exchange, Calendaring & Scheduling, Workflow, Presentations and Interactive Meetings, and Document Development and Sharing. The next six chapters cover the functional pieces of this groupware realm.

The next five chapters cover the major vendors of integrated groupware products: Lotus Notes, Novel GroupWise, TeamWARE, Hewlett-Packard, and Oracle Interoffice. HP's chapter discusses "strategy," suggesting the lack of a well-integrated product suite, but one more survey of the terrain is nonetheless useful. And that, perhaps, is the major reason for reading this book: It constantly emphasizes the human and process-oriented aspect of organizational behavior and the need to attend carefully both to the needs of the humans and the nature of the processes. It is easy to understand that an improper travel authorization, will bring an organization to its knees. It is easy to forget that the system is used by humans who well might not want the added complexity or rigidity of the system and who, therefore, must be part of the design and adoption effort. In my opinion, the book takes a rather more negative view about groupware acceptability than is necessary, but then I like such technology, and the average worker in the average organization does not.

The last six chapters of this book intermix case studies and Hahn, of Collabra and Netscape, points the reader to Chapter 17, "Groupware & Reengineering: The Human Side of Change." Although one of the better considerations of these issues in the book, it is far from the only one.

A Useful Survey

If you have little familiarity with these "upper level application" areas of networking, the functionality, products, or use, then this book is a good one to read. You will not learn much about the underlying technology, nor will you be able to qualify as a "certified groupware support engineer," but you will obtain an extremely useful survey of the field, and you will obtain it from the perspective of human and organization use. As the Internet moves into the mass market, that perspective is a good one.

High-Speed Networks

High-Speed Networks: TCP/IP and ATM Design Principles, by William Stallings, ISBN 0-13-525965-7 Prentice-Hall, 1997, `http://www.shore.net/~ws/HsNet.html`

High-speed networks now dominate both the WAN and LAN markets. In the WAN market, data networks have evolved from packet-switching networks to ATM networks operating at 155 Mbps or more. In the LAN market, the staple 10-Mbps Ethernet is being replaced with 100-Mbps Fast Ethernet, Gigabit Ethernet, and even Asynchronous Transfer Mode (ATM) LANs. This book provides a survey of high-speed networks and the design issues related to them. Much of the book is devoted to the study of various techniques aimed at reducing network congestion.

Organization

The book is divided into seven sections. The first section deals with the fundamentals: TCP/IP principles; packet switching and Frame Relay networks; and internetworking principles. The second section provides an overview of ATM and Fast and Gigabit Ethernet. These two sections can easily be torn out of the book and serve as an excellent primer on today's modern networks. I am going to recommend to my employer that they be made mandatory reading.

In the third section of the book, Stallings focuses on one treatment of queueing theory, namely, how it is applied to modeling network behavior. Stallings has an undeniable gift for taking large complicated subjects and teaching the fundamentals, and then some, without belittling the subject at hand or the reader. This book is witness to this gift, and this chapter but one fine example. But once the reader has an understanding of queueing theory, Stallings throws a wrench in the gears. The chapter on self-similarity explains why traditional queuing models are inadequate when trying to predict the performance of Ethernet traffic and other self-similar streams. While this section is by far the most theoretical, it is at the same time necessary for the reader's understanding of network performance, and while many readers may not care to devote the time necessary to gain a complete understanding of self-similarity, astute students are urged to invest in more than a simple gloss-over of this section.

Having understood the basics of self-similarity, I hoped the fifth section of the book, on network traffic management, would be addressed with greater emphasis on delivering quality of service and the problems related to self-similarity. Instead, the material is based on traditional queueing models.

The fourth section, flow control, is divided into two categories. The first, link control mechanisms, focuses on some of the performance issues related to the use of *Automatic Repeat Request* (ARQ) link control protocols. The second category, transport control mechanisms,

concentrates on the TCP flow control mechanism. I expected to find references to bugs in some TCP implementations exposed by high-volume WWW servers, but didn't. Stallings goes on to present an overview of some of the performance issues of TCP over ATM. As institutions begin upgrading their networks, this issue is sure to receive a great deal of interest. The section concludes with a look at the *Real-Time Transport Protocol*, another area sure to spark attention as the need to move large multimedia data across WANs, in real time, becomes more relevant.

The sixth section of the book covers Internet routing protocols and opens with a primer on graph theory. Four routing protocols (RIP, OSPF, BGP, and IDRP) are covered. The section concludes with a discussion of multicasting as an introduction to RSVP. This section sparked my curiosity enough to call for a visit to the WWW site for RSVP development.

Stallings shies away from directly addressing application-driven improvements aimed at increasing network performance. In today's Web/CGI-driven world, I would expect this to be a topic of interest to many. Perhaps this is a subject for another book. But the topic is not entirely avoided. The last section of the book focuses on various lossless and lossy compression techniques. The quirkiness of material covered makes this section a darling.

Recommended

This book rates an A+. Unlike most books about computers being published today, this book is neither superficial nor is it insulting to the reader. It is intended for both professional and academic audiences. Stallings' desire to truly educate is apparent. This is not a book about promoting the hype, this is a book about serious learning.

From The Editor

We begin this issue with Part II of "What Is a VPN?" by Paul Ferguson and Geoff Huston. In Part I they introduced a definition of the term "Virtual Private Network" (VPN) and discussed the motivations behind the adoption of such networks. They outlined a framework for describing the various forms of VPNs, and examined numerous network-layer VPN structures, in particular, that of controlled route leakage and tunneling. In Part II the authors conclude their examination of VPNs by describing virtual private dial networks and network-layer encryption. They also examine link-layer VPNs, switching and encryption techniques, and issues concerning Quality of Service and non-IP VPNs.

IP Multicast is an emerging set of technologies and standards that allow many-to-many transmissions such as conferencing, or one-to-many transmissions such as live broadcasts of audio and video over the Internet. Kenneth Miller describes multicast in general, and reliable multicast protocols and applications in particular. Although multicast applications are primarily used in the research community today, this situation is likely to change as the demand for Internet multimedia applications increases and multicast technologies improve.

Successful deployment of networking technologies requires an understanding of a number of technology options ranging from wiring and transmissions systems via switches, routers, bridges and other pure networking components, to networked applications and services. *The Internet Protocol Journal* (IPJ) is designed to look at all aspects of these "building blocks." This time, Thayumanavan Sridhar details some of the issues in the evolution of Layer 2 and Layer 3 switches.

Interest in the first issue of IPJ has exceeded our expectations, and hard copies are almost gone. However, you can still view and print the issue in PDF format on our Web site at **www.cisco.com/ipj**. The current edition is also available on the Web. If you want to receive our next issue, please complete and return the enclosed card.

We welcome your comments, questions and suggestions regarding anything you read in this journal. We are also actively seeking authors for new articles. The Call for Papers and Author Guidelines can be found on our Web page. Please send your comments to **ipj@cisco.com**

What Is a VPN? — Part II

by Paul Ferguson, Cisco Systems
and Geoff Huston, Telstra

In Part I we introduced a working definition of the term "Virtual Private Network" (VPN), and discussed the motivations behind the adoption of such networks. We outlined a framework for describing the various forms of VPNs, and then examined numerous network-layer VPN structures, in particular, that of controlled route leakage and tunneling techniques. We begin Part II with examining other network-layer VPN techniques, and then look at issues that are concerned with non-IP VPNs and Quality-of-Service (QoS) considerations.

Types of VPNs

This section continues from Part I to look at the various types of VPNs using a taxonomy derived from the layered network architecture model. These types of VPNs segregate the VPN network at the network layer.

Network-Layer VPNs

A network can be segmented at the network layer to create an end-to-end VPN in numerous ways. In Part I we described a controlled route leakage approach that attempts to perform the segregation only at the edge of the network, using route advertisement control to ensure that each connected network received a view of the network (only peer networks). We pick up the description at this point in this second part of the article.

Tunneling

As outlined in Part I, the alternative to a model of segregation at the edge is to attempt segregation throughout the network, maintaining the integrity of the partitioning of the substrate network into VPN components through the network on a hop-by-hop basis. Part I examined numerous tunneling technologies that can achieve this functionality. Tunneling is also useful in servicing VPN requirements for dial access, and we will resume the description of tunnel-based VPNs at this point.

Virtual Private Dial Networks

Although several technologies (vendor-proprietary technologies as well as open, standards-based technologies) are available for constructing a *Virtual Private Dial Network* (VPDN), there are two principal methods of implementing a VPDN that appear to be increasing in popularity—*Layer 2 Tunneling Protocol* (L2TP) and *Point-to-Point Tunneling Protocol* (PPTP) tunnels. From an historical perspective, L2TP is the technical convergence of the earlier Layer 2 Forwarding (L2F)[1] protocol specification and the PPTP protocol. However, one might suggest that because PPTP is now being bundled into the desktop operating system of many of the world's personal computers, it stands to be quite popular within the market.

At this point it is worthwhile to distinguish the difference between "client-initiated" tunnels and "NAS-initiated" (Network Access Server, otherwise known as a Dial Access Server) tunnels. The former is commonly referred to as "voluntary" tunneling, whereas the latter is commonly referred to as "compulsory" tunneling. In voluntary tunneling, the tunnel is created at the request of the user for a specific purpose; in compulsory tunneling, the tunnel is created without any action from the user, and without allowing the user any choice in the matter.

L2TP, as a compulsory tunneling model, is essentially a mechanism to "off-load" a dialup subscriber to another point in the network, or to another network altogether. In this scenario, a subscriber dials into a NAS, and based on a locally configured profile (or a NAS negotiation with a policy server) and successful authentication, a L2TP tunnel is dynamically established to a predetermined endpoint, where the subscriber's *Point-to-Point Protocol* (PPP) session is terminated (Figure 1).

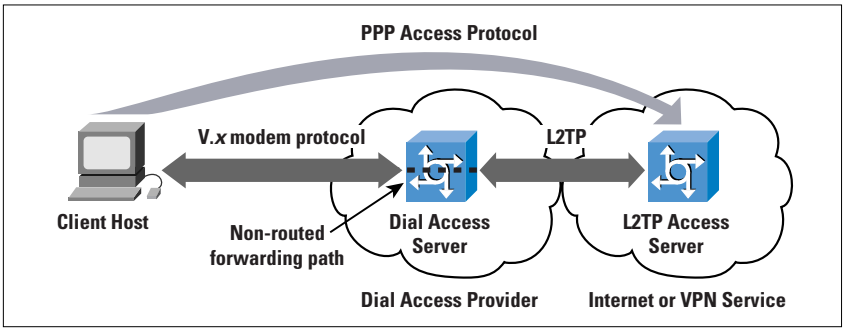

Figure 1: PPP Tunnel Termination Model of L2TP

PPTP, as a voluntary tunneling model, on the other hand, allows end systems (for example, desktop computers) to configure and establish individual discrete point-to-point tunnels to arbitrarily located PPTP servers, without the intermediate NAS participating in the PPTP negotiation and subsequent tunnel establishment. In this scenario, a subscriber dials into a NAS, but the PPP session is terminated on the NAS, as in the traditional Internet access PPP model. The layered PPTP session is then established between the client end system and any upstream PPTP server that the client desires to connect to. The only caveats on PPTP connectivity are that the client can reach the PPTP server via conventional routing processes, and that the user has been granted the appropriate privileges on the PPTP server (Figure 2).

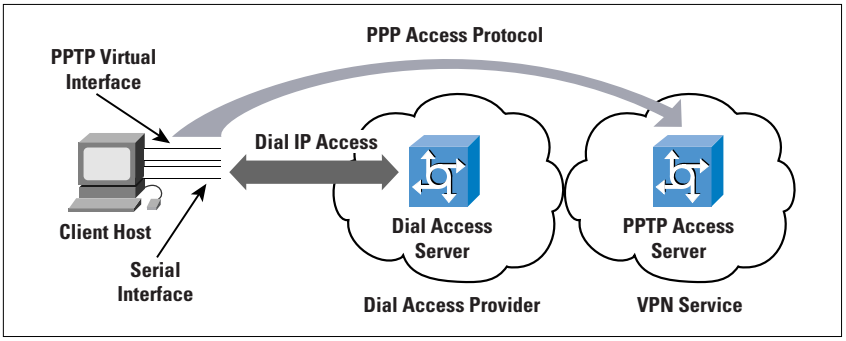

Figure 2: PPP Tunnel Termination Model of PPTP

Although L2TP and PPTP may sound extraordinarily similar, there are subtle differences that deserve further examination. The applicability of both protocols is very much dependent on what problem is being addressed. It is also about control—who has it, and why it is needed. It also depends heavily on how each protocol implementation is deployed—in either the voluntary or the compulsory tunneling models.

With PPTP in a voluntary tunneling implementation, the dial-in user can choose the PPTP tunnel destination (the PPTP server) after the initial PPP negotiation has completed. This feature is important if the tunnel destination changes frequently, because no modifications are needed to the client's view of the base PPP access when there is a change in the server and the transit path to the server. It is also a significant advantage that the PPTP tunnels are transparent to the service provider, and no advance configuration is required between the NAS operator and the overlay dial access VPN. In such a case, the service provider does not house the PPTP server, and simply passes the PPTP traffic along with the same processing and forwarding policies as all other IP traffic. In fact, this feature should be considered a significant benefit of this approach. The configuration and support of a tunneling mechanism within the service provider network would be one less parameter that the service provider has to operationally manage, and the PPTP tunnel can transparently span multiple service providers without any explicit service provider configuration. However, the economic downside to this feature for the service provider, of course, is that a "VPDN-enabled" network service can be marketed to yield an additional source of revenue. Where the client undertakes the VPDN connection, there is no direct service provider involvement and no consequent value added to the base access service.

From the subscriber's perspective, this is a "win-win" situation, because the user is not reliant on the upstream service provider to deliver the VPDN service—at least no more than any user is reliant for basic IP-level connectivity. The other "win" is that the subscriber does not have to pay a higher subscription fee for a VPN service. Of course, the situation changes when the service provider takes an active role in providing the VPDN, such as housing the PPTP servers, or if the subscriber resides within a subnetwork in which the parent organization wants the service provider's network to make the decision concerning where tunnels are terminated. The major characterization of PPTP-based VPDN is one of a roaming client base, where the clients of the VPDN use a local connection to the public Internet data network, and then overlay a private data tunnel from the client's system to the desired remote service point. Another perspective is to view this approach as "on-demand" VPDN virtual circuits.

With L2TP in a "compulsory" tunneling implementation, the service provider controls where the PPP session is terminated. This setup can be extremely important in situations where the service provider to whom

the subscriber is actually dialing into (let's call it the "modem pool provider" network) must transparently hand off the subscriber's PPP session to another network (let's call this network the "content provider"). To the subscriber, it appears as though the local system is directly attached to the content provider's network, when in fact the access path has been passed transparently through the modem pool provider's network to the subscribed content service. Very large content providers, for instance, may outsource the provisioning and maintenance of thousands of modem ports to a third-party access provider, who in turn agrees to transparently pass the subscribers' access sessions back to the content provider. This setup is generally called "wholesale dial." The major motivation for such L2TP-based wholesale dial lies in the typical architecture of the *Public Switched Telephone Network* (PSTN), where the use of wholesale dial facilities can create a more rational PSTN call load pattern with Internet access PSTN calls terminated in the local Central Office.

Of course, if all subscribers who connect to the modem pool provider's network are destined for the same content provider, then there are certainly easier ways to hand this traffic off to the content provider's network—such as simply aggregating all the traffic in the local Central Office and handing the content provider a "big fat pipe" of the aggregated session traffic streams. However, in situations where the modem pool provider is providing a wholesale dial service for multiple upstream "next-hop" networks, the methods of determining how each subscriber's traffic must be forwarded to his/her respective content provider are somewhat limited. Packet forwarding decisions could be made at the NAS, based on the source address of the dialup subscriber's computer. This scenario would allow for traffic to be forwarded along the appropriate path to its ultimate destination, in turn intrinsically providing a virtual connection. However, the use of assigning static IP addresses to dial-in subscribers is highly discouraged because of the inefficiencies in IP address utilization policies, and the critical success of the *Dynamic Host Configuration Protocol* (DHCP).

There are, however, some serious scaling concerns in deploying a large-scale L2TP network; these concerns revolve around the issue of whether large numbers of tunnels can actually be supported with little or no network performance impact. Since there have been no large-scale deployments of this technology to date, there is no empirical evidence to support or invalidate these concerns.

In some cases, however, appearances are everything—some content providers do not wish for their subscribers to know that when they connect to their service, they have instead been connected to another service provider's network, and then passed along ultimately to the service to which they have subscribed. In other cases, it is merely designed to be a matter of convenience, so that subscribers do not need to log into a device more than once.

Regrettably, the L2TP draft does not detail all possible implementations or deployment scenarios for the protocol. The basic deployment scenario is quite brief when compared to the rest of the document, and is arguably biased toward the compulsory tunneling model. Nonetheless, there are implementations of L2TP that follow the voluntary tunneling model. To the best of our knowledge, there has never been any intent to exclude this model of operation. In addition, at various recent interoperability workshops, several different implementations of a voluntary L2TP client have been modeled. Nothing in the L2F protocol would prohibit deploying it in a voluntary tunneling manner, but to date it has not been widely implemented. Further, PPTP has also been deployed using the compulsory model in a couple of specific vendor implementations.

In summary, consideration of whether PPTP or L2TP is more appropriate for deployment in a VPDN depends on whether control needs to lie with the service provider or with the subscriber. Indeed, the difference can be characterized with respect to the client of the VPN, where the L2TP model is one of a "wholesale" access provider who has numerous configured client service providers who appear as VPNs on the common dial access system, whereas the PPTP model is one of distributed private access where the client is an individual end user and the VPN structure is that of end-to-end tunnels. One might also suggest that the difference is also a matter of economics, because the L2TP model allows service providers to actually provide a "value-added" service, beyond basic IP-level connectivity, and charge their subscribers accordingly for the ability to access it, thus creating new revenue streams. By contrast, the PPTP model enables distributed reach of the VPN at a much more basic level, enabling corporate VPNs to extend access capabilities without the need for explicit service contracts with a multitude of network access providers.

Network-Layer Encryption

Encryption technologies are extremely effective in providing the segmentation and virtualization required for VPN connectivity, and they can be deployed at almost any layer of the protocol stack. The evolving standard for network-layer encryption in the Internet is *IP Security* (IPSec)[3, 4]. (IPSec is actually an architecture—a collection of protocols, authentication, and encryption mechanisms. The IPSec security architecture is described in detail in [3].)

While the *Internet Engineering Task Force* (IETF) is finalizing the architecture and the associated protocols of IPSec, there is relatively little network-layer encryption being done in the Internet today. However, some vendor proprietary solutions are currently in use.

Whereas IPSec has yet to be deployed in any significant volume, it is worthwhile to review the two methods in which network-layer encryption is predominantly implemented. The most secure method for network-

layer encryption to be implemented is end-to-end, between participating hosts. End-to-end encryption allows for the highest level of security. The alternative is more commonly referred to as "tunnel mode," in which the encryption is performed only between intermediate devices (routers), and traffic between the end system and the first-hop router is in plaintext. This setup is considerably less secure, because traffic intercepted in transit between the first-hop router and the end system could be compromised.

As a more general observation on this security vulnerability, where a VPN architecture is based on tunnels, the addition of encryption to the tunnel still leaves the tunnel ingress and egress points vulnerable, because these points are logically part of the host network as well as being part of the unencrypted VPN network. Any corruption of the operation, or interception of traffic in the clear, at these points will compromise the privacy of the private network.

In the end-to-end encryption scheme, VPN granularity is to the individual end-system level. In the tunnel mode scheme, the VPN granularity is to the subnetwork level. Traffic that transits the encrypted links between participating routers, however, is considered secure. Network-layer encryption, to include IPSec, is merely a subset of a VPN.

Link-Layer VPNs

One of the most straightforward methods of constructing VPNs is to use the transmission systems and networking platforms for the physical and link-layer connectivity, yet still be able to build discrete networks at the network layer. A link-layer VPN is intended to be a close (or preferably exact) functional analogy to a conventional private data network.

ATM and Frame Relay Virtual Connections

A conventional private data network uses a combination of dedicated circuits from a public carrier, together with an additional private communications infrastructure, to construct a network that is completely self-contained. Where the private data network exists within private premises, the network generally uses a dedicated private wiring plant to carry the VPN. Where the private data network extends outside the private boundary of the dedicated circuits, it is typically provisioned for a larger public communications infrastructure by using some form of time-division or frequency-division multiplexing to create the dedicated circuit. The essential characteristic of such circuits is the synchronization of the data clock, such that the sender and receiver pass data at a clocking rate that is fixed by the capacity of the dedicated circuit.

A link-layer VPN attempts to maintain the critical elements of this self-contained functionality, while achieving economies of scale and operation, by utilizing a common switched public network infrastructure. Thus, a collection of VPNs may share the same infrastructure for connectivity, and share the same switching elements within the interior of

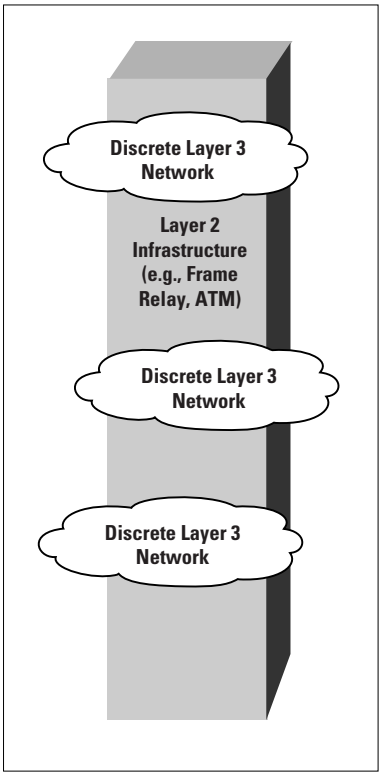

Figure 3: Conceptualization of Discrete Layer 3 Networks on a Common Layer 2 Infrastructure

the network, but explicitly must have no visibility, either direct or inferred, of one another. Generally, these "networks" operate at Layer 3 (the network layer) or higher in the OSI Reference Model, and the "infrastructure" itself commonly consists of either a *Frame Relay* or *Asynchronous Transfer Mode* (ATM) network (Figure 3). The essential difference here between this architecture of virtual circuits and that of dedicated circuits is that there is now no synchronized data clock shared by the sender and receiver, nor necessarily is there a dedicated transmission path that is assigned from the underlying common host network. The sender generally has no a priori knowledge of the available capacity of the virtual circuit, because the capacity varies in response to the total demand placed on it by other simultaneous transmission and switching activity. Instead, the sender and receiver can use adaptive clocking of data, where the sender can adjust the transmission rate to match the requirements of the application and any signaling received from the network and the receiver. It should be noted that a dedicated circuit system using synchronized clocking cannot be oversubscribed, whereas the virtual circuit architecture (where the sender does not have a synchronized end-to-end data clock) can indeed be oversubscribed. It is the behavior of the network when it transitions into this oversubscribed state that is of most interest here.

One of the nice things about a public switched wide-area network that provides virtual circuits is that it can be extraordinarily flexible. Most subscribers to Frame Relay services, for example, have subscribed to the service for economic reasons—it is cheap, and the service provider usually adds a *Service-Level Agreement* (SLA) that "guarantees" some percentage of frame delivery in the Frame Relay network itself.

The remarkable thing about this service offering is that the customer is generally completely unaware of whether the service provider can actually deliver the contracted service at all times and under all possible conditions. The Layer 2 technology is not a synchronized clock blocking technology in which each new service flow is accepted or denied based on the absolute ability to meet the associated resource demands. Each additional service flow is accepted into the network and carried on a best-effort basis. Admission functions provide the network with a simple two-level discard mechanism that allows a graduated response to instances of overload; however, when the point of saturated overload is reached within the network, all services will be affected.

This situation brings up several other important issues: The first concerns the engineering practices of the Frame Relay service provider. If the Frame Relay network is poorly engineered and is constantly congested, then obviously the service quality delivered to the subscribers will be affected. Frame Relay uses a notion of a per-virtual circuit *Committed Information Rate* (CIR), which is an ingress function associated with Frame Relay that checks the ingress traffic rate against the CIR.

Frames that exceed this base rate are still accepted by the Frame Relay network, but they are marked as *discard eligible* (DE). Because the network can be oversubscribed, the data rate within a switch will at times exceed both the egress transmission rate and the local buffer storage. When this situation occurs, the switch will begin to discard data frames, and will do so initially for frames with the DE marker present. This scenario is essentially a two-level discard precedence architecture. It is an administrative decision by the service provider as to the relative levels of provisioning of core transmission and switching capacity, and the ratio of network ingress capacity used by subscribers. The associated CIRs of the virtual circuits against this core capacity are critical determinants of the resultant deliverable quality of performance of the network and the layered VPNs.

For example, at least one successful (and popular) Frame Relay service provider provides an economically attractive Frame Relay service that permits a zero-rate CIR on PVCs, combined with an SLA that ensures that at least 99.8 percent of all frame-level traffic presented to the Frame Relay network will be delivered successfully. If this SLA is not met, then the subscriber's monthly service fee will be appropriately prorated the following month. The Frame Relay service provider provides frame level statistics to each subscriber every month, culled from the Frame Relay switches, to measure the effectiveness of this SLA "guarantee." This particular Frame Relay service provider is remarkably successful in honoring the SLAs because they conduct ongoing network capacity management on a weekly basis, provisioning new trunks between Frame Relay switches when trunk utilization exceeds 50 percent, and ensuring that trunk utilization never exceeds 75 percent. In this fashion, traffic on PVCs with a zero-rate CIR can generally avoid being discarded in the Frame Relay network.

Having said that, the flexibility of PVCs allows discrete VPNs to be constructed across a single Frame Relay network. And in many instances, this scenario lends itself to situations where the Frame Relay network provider also manages each discrete VPN via a telemetry PVC. Several service providers have *Managed Network Services* (MNS) that provide exactly this type of service.

Whereas the previous example revolves around the use of Frame Relay as a link-layer mechanism, essentially the same type of VPN mechanics hold true for ATM. As with Frame Relay, there is no data clock synchronization between the sender, the host network, and the receiver. In addition, the sender's traffic is passed into the ATM network via an ingress function, which can mark cells with a *Cell Loss Priority* (CLP) indication. And, as with Frame Relay, where a switch experiences congestion, the switch will attempt to discard marked (CLP) cells as the primary load shedding mechanism, but if this step is inadequate, the network must shed other cells that are not so marked. Once again, the quality of the service depends on proper capacity engineering of the network, and there is no guarantee of service quality inherently in the technology itself.

The generic observation is that the engineering of Frame Relay and ATM common carriage data networks is typically very conservative. The inherent capabilities of both of these link-layer architectures do not permit a wide set of selective responses to network overload, so that in order for the network to service the broadest spectrum of potential VPN clients, the network must provide high-quality carriage and very limited instances of any form of overload. In this way, such networks are typically positioned as a high-quality alternative to dedicated circuit private network architectures, which are intended to operate in a very similar manner (and, not surprisingly, are generally priced as a premium VPN offering). Technically, the architecture of link-layer VPNs is almost indistinguishable from the dedicated circuit private data network—the network can support multiple protocols, private addressing, and routing schemes, because the essential difference between a dedicated circuit and a virtual link-layer circuit is the absence of synchronized clocking between the sender and the receiver. In all other aspects, the networks are very similar.

These approaches to constructing VPNs certainly involve scaling concerns, especially with regard to configuration management of provisioning new *Virtual Connections* (VCs) and routing issues. Configuration management still tends to be one of the controversial points in VPN management—adding new subscribers and new VPNs to the network requires VC path construction and provisioning, a tedium that requires ongoing administrative attention by the VPN provider. Also, as already mentioned, full mesh networks encounter scaling problems, in turn resulting in construction of VPNs in which partial meshing is done to avoid certain scaling limitations. The liabilities in these cases need to be examined closely, because partial meshing of the underlying link-layer network may contribute to suboptimal routing (for example, extra hops caused by hub-and-spoke issues, or redirects).

These problems apply to all types of VPNs built on the "overlay" model—not just ATM and Frame Relay. Specifically, the problems also apply to *Generic Routing Encapsulation* (GRE) tunnels.

MPOA and the "Virtual Router" Concept

Another unique model of constructing VPNs is the use of *Multiprotocol over ATM* (MPOA)[5], which uses RFC 1483 encapsulation[6]. This VPN approach is similar to other "cut-through" mechanisms in which a particular switched link layer is used to enable all "Layer 3" egress points to be only a single hop away from one another.

In this model, the edge routers determine the forwarding path in the ATM switched network, because they have the ability to determine which egress point packets need to be forwarded to. After a network-layer reachability decision is made, the edge router forwards the packet onto a VC designated for a particular egress router. However, since the egress routers cannot use the *Address Resolution Protocol* (ARP) for destination address across the cloud, they must rely on an external server for address resolution (ATM address to IP address).

The first concern here is a sole reliance on ATM—this particular model does not encompass any other types of data link layer technologies, rendering the technology less than desirable in a hybrid network. Whereas this scenario may have some domain of applicability within a homogenous ATM environment, when looking at a broader VPN environment that may encompass numerous link-layer technologies, this approach offers little benefit to the VPN provider.

Secondly, there are serious scaling concerns regarding full mesh models of connectivity, where suboptimal network-layer routing may result because of cut-through. And the reliance on address resolution servers to support the ARP function within the dynamic circuit framework brings this model to the point of excessive complexity.

The advantage of the MPOA approach is the use of dynamic circuits rather than more cumbersome, statically configured models. The traditional approach to supporting private networks involves extensive manual design and operational support to ensure that the various configurations on each of the bearer switching elements are mutually consistent. The desire within the MPOA environment is to attempt to use MPOA to govern the creation of dynamically controlled, edge-to-edge ATM VCs. Although this setup may offer the carrier operator some advantages in reduced design and operational overhead, it does require the uniform availability of ATM, and in many heterogeneous environments this scenario is not present.

In summary, this model is another overlay model, with some serious concerns regarding the ability of the model to withstand scale.

"Peer" VPN models that allow the egress nodes to maintain separate routing tables have also been introduced—one for each VPN—effectively allowing separate forwarding decisions to be made within each node for each distinctive VPN. Although this is an interesting model, it introduces concerns about approaches in which each edge device runs a separate routing process and maintains a separate *Routing Information Base* (RIB, or routing table) process for each VPN community of interest. It also should be noted that the "virtual router" concept requires some form of packet labeling, either within the header or via some lightweight encapsulation mechanism, in order for the switch to be able to match the packet against the correct VPN routing table. If the label is global, the issue of operational integrity is a relevant concern, whereas if the label is local, the concept of label switching and maintenance of edge-to-edge label switching contexts is also a requirement.

Among the scaling concerns are issues regarding the number of supported VPNs in relation to the computational requirements, and stability of the routing system within each VPN (that is, instability in one VPN affecting the performance of other VPNs served by the same device). The aggregate scaling demands of this model are also significant. Given a change in the underlying physical or link-layer topology, the consequent

requirement to process the routing update on a per-VPN basis becomes a significant challenge. Use of distance vector protocols to manage the routing tables would cause a corresponding sudden surge in traffic load, and the surge grows in direct proportion to the number of supported VPNs. The use of link-state routing protocols would require the consequent link-state calculation to be repeated for each VPN, causing the router to be limited by available CPU capacity.

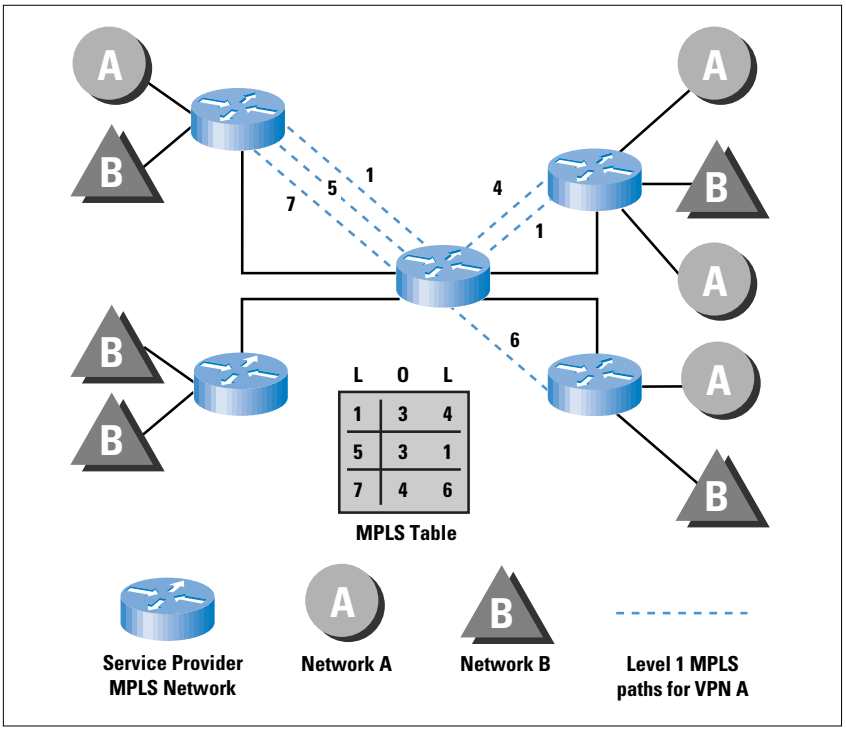
Multiprotocol Label Switching

One method of addressing these scaling issues is to use VPN labels within a single routing environment, in the same way that packet labels are necessary to activate the correct per-VPN routing table. The use of local label switching effectively recreates the architecture of a Multiprotocol Label Switching VPN. It is perhaps no surprise that when presented with two basic approaches to the architecture of the VPN—the use of network-layer routing structures and per-packet switching, and the use of link-layer circuits and per-flow switching—the industry would devise a hybrid architecture that attempts to combine aspects of these two approaches. This hybrid architecture is referred to as *Multiprotocol Label Switching* (MPLS)[7, 8].

The architectural concepts used by MPLS are generic enough to allow it to operate as a peer VPN model for switching technology for a variety of link-layer technologies, and in heterogeneous Layer 2 transmission and switching environments. MPLS requires protocol-based routing functionality in the intermediate devices, and operates by making the interswitch transport infrastructure visible to the routing. In the case of IP over ATM, each ATM bearer link becomes visible as an IP link, and the ATM switches are augmented with IP routing functionality. IP routing is used to select a transit path across the network, and these transit paths are marked with a sequence of labels that can be thought of as locally defined forwarding path indicators. MPLS itself is performed using a label swapping forwarding structure. Packets entering the MPLS environment are assigned a local label and an outbound interface based on a local forwarding decision. The local label is attached to the packet via a lightweight encapsulation mechanism. At the next MPLS switch, the forwarding decision is based on the incoming label value, where the incoming label determines the next hop interface and next hop label, using a local forwarding table indexed by label. This lookup table is generated by a combination of the locally used IP routing protocol, together with a label distribution protocol, which creates end-to-end transit paths through the network for each IP destination. It is not our intention to discuss the MPLS architecture in detail, apart from noting that each MPLS switch uses a label-indexed forwarding table, where the attached label of an incoming packet determines the next-hop interface and the corresponding outgoing label.

The major observation here is that this lightweight encapsulation, together with the associated notion of boundary-determined transit paths, provides many of the necessary mechanisms for the support of VPN structures[9]. MPLS VPNs have not one, but three key ingredients: (1) constrained distribution of routing information as a way to form VPNs and control inter-VPN connectivity; (2) the use of VPN-IDs, and specifically the concatenation of VPN-IDs with IP addresses to turn (potentially) nonunique addresses into unique ones; and (3) the use of label switching (MPLS) to provide forwarding along the routes constructed via (1) and (2). The generic architecture of deployment is that of a label-switched common host network and a collection of VPN environments that use label-defined virtual circuits on an edge-to-edge basis across the MPLS environment. An example is indicated in Figure 4, which shows how MPLS virtual circuits are constructed.

Figure 4: MPLS "Tunnels," or VPNs



Numerous approaches are possible to support VPNs within an MPLS environment. In the base MPLS architecture, the label applied to a packet on ingress to the MPLS environment effectively determines the selection of the egress router, as the sequence of label switches defines an edge-to-edge virtual path. The extension to the MPLS local label hop-by-hop architecture is the notion of a per-VPN global identifier (or *Closed User Group* (CUG) identifier, as defined in [5]), which is used effectively within an edge-to-edge context. This global identifier could be assigned on ingress, and is then used as an index into a per-VPN routing table to determine the initial switch label. On egress from the MPLS environment, the CUG identifier would be used again as an index into a per-VPN global identifier table to undertake next-hop selection.

Routing protocols in such an environment need to carry the CUG identifier to trigger per-VPN routing contexts, and a number of suggestions are noted in [5] as to how this could be achieved.

It should be stressed that MPLS itself, as well as the direction of VPN support using MPLS environments, is still within the area of active research, development, and subsequent standardization within the IETF, so this approach to VPN support is still somewhat speculative in nature.

Link-Layer Encryption

As mentioned previously, encryption technologies are extremely effective in providing the segmentation and virtualization required for VPN connectivity, and can be deployed at almost any layer of the protocol stack. Because there are no intrinsically accepted industry standards for link-layer encryption, all link-layer encryption solutions are generally vendor specific and require special encryption hardware.

Although this scenario can avoid the complexities of having to deal with encryption schemes at higher layers of the protocol stack, it can be economically prohibitive, depending on the solution adopted. In vendor proprietary solutions, multivendor interoperability is certainly a genuine concern.

Transport and Application-Layer VPNs

Although VPNs can certainly be implemented at the transport and application layers of the protocol stack, this setup is not very common. The most prevalent method of providing virtualization at these layers is to use encryption services at either layer; for example, encrypted e-mail transactions, or perhaps authenticated *Domain Name System* (DNS) zone transfers between different administrative name servers, as described in DNSSec (*Domain Name System Security*)[10].

Some interesting, and perhaps extremely significant, work is being done in the IETF to define a *Transport Layer Security* (TLS) protocol[11], which would provide privacy and data integrity between two communicating applications. The TLS protocol, when finalized and deployed, would allow applications to communicate in a fashion that is designed to prevent eavesdropping, tampering, or message forgery. It is unknown at this time, however, how long it may be before this work is finalized, or if it will be embraced by the networking community as a whole after the protocol specification is completed.

The significance of a "standard" transport-layer security protocol, however, is that when implemented, it could provide a highly granular method for virtualizing communications in TCP/IP networks, thus making VPNs a pervasive commodity, and native to all desktop computing platforms.

Non-IP VPNs

Although this article has focused on TCP/IP and VPNs, it is recognized that multiprotocol networks may also have requirements for VPNs. Most of the same techniques previously discussed can also be applied to multiprotocol networks, with a few obvious exceptions—many of the techniques described herein are solely and specifically tailored for TCP/IP protocols.

Controlled route leaking is not suitable for a heterogeneous VPN protocol environment, in that it is necessary to support all protocols within the common host network. GRE tunnels, on the other hand, are constructed at the network layer in the TCP/IP protocol stack, but most routable multiprotocol traffic can be transported across GRE tunnels (for example, IPX and AppleTalk). Similarly, the VPDN architectures of L2TP and PPTP both provide a PPP end-to-end transport mechanism that can allow per-VPN protocols to be supported, with the caveat that it is a PPP-supported protocol in the first place.

The reverse of heterogeneous VPN protocol support is also a VPN requirement in some cases, where a single VPN is to be layered above a heterogeneous collection of host networks. The most pervasive method of constructing VPNs in multiprotocol networks is to rely upon application-layer encryption, and the resulting VPNs are generally vendor proprietary, although some would contend that one of the most pervasive examples of this approach was the mainstay of the emergent Internet in the 1970s and 1980s—that of the UNIX-to-UNIX Copy Program (UUCP) network, which was (and remains) an open technology.

Quality-of-Service Considerations

In addition to creating a segregated address environment to allow private communications, the expectation that the VPN environment will be in a position to support a set of service levels also exists. Such per-VPN service levels may be specified either in terms of a defined service level that the VPN can rely upon at all times, or in terms of a level of differentiation that the VPN can draw upon the common platform resource with some level of priority of resource allocation.

Using dedicated leased circuits, a private network can establish fixed resource levels available to it under all conditions. Using a shared switched infrastructure, such as Frame Relay virtual circuits or ATM virtual connections, a quantified service level can be provided to the VPN through the characteristics of the virtual circuits used to implement the VPN.

When the VPN is moved away from such a circuit-based switching environment to that of a general Internet platform, is it possible for the Internet Service Provider to offer the VPN a comparable service level that attempts to quantify (and possibly guarantee) the level of resources that the VPN can draw upon from the underlying host Internet?

This area is evolving rapidly, and much of it remains within the realm of speculation rather than a more concrete discussion about the relative merits of various Internet QoS mechanisms. Efforts within the *Integrated Services Working Group* of the IETF have resulted in a set of specifications for the support of guaranteed and controlled load end-to-end traffic profiles using a mechanism that loads per-flow state into the switching elements of the network[12, 13]. There are numerous caveats regarding the use of these mechanisms, in particular relating to the ability to support the number of flows that will be encountered on the public Internet[14]. Such caveats tend to suggest that these mechanisms will not be the ones that are ultimately adopted to support service levels for VPNs in very large networking environments.

If the scale of the public Internet environment does not readily support the imposition of per-flow state to support guarantees of service levels for VPN traffic flows, the alternative query is whether this environment could support a more relaxed specification of a differentiated service level for overlay VPN traffic. Here, the story appears to offer more potential, given that differentiated service support does not necessarily imply the requirement for per-flow state, so stateless service differentiation mechanisms can be deployed that offer greater levels of support for scaling the differentiated service[15]. However, the precise nature of these differentiated service mechanisms, and their capability to be translated to specific service levels to support overlay VPN traffic flows, still remain in the area of future activity and research.

Conclusions

So what is a virtual private network? As we have discussed, a VPN can take several forms. A VPN can be between two end systems, or it can be between two or more networks. A VPN can be built using tunnels or encryption (at essentially any layer of the protocol stack), or both, or alternatively constructed using MPLS or one of the "virtual router" methods. A VPN can consist of networks connected to a service provider's network by leased lines, Frame Relay, or ATM, or a VPN can consist of dialup subscribers connecting to centralized services or other dialup subscribers.

The pertinent conclusion here is that although a VPN can take many forms, a VPN is built to solve some basic common problems, which can be listed as virtualization of services and segregation of communications to a closed community of interest, while simultaneously exploiting the financial opportunity of economies of scale of the underlying common host communications system.

To borrow a popular networking axiom, "When all you have is a hammer, everything looks like a nail." Every organization has its own problem that it must solve, and each of the tools mentioned in this article can be used to construct a certain type of VPN to address a particular set of functional objectives. More than a single "hammer" is

available to address these problems, and network engineers should be cognizant of the fact that VPNs are an area in which many people use the term generically—there is a broad problem set with equally as many possible solutions. Each solution has numerous strengths and also numerous weaknesses and vulnerabilities. No single mechanism for VPNs that will supplant all others in the months and years to come exists, but instead a diversity of technology choices in this area of VPN support will continue to emerge.

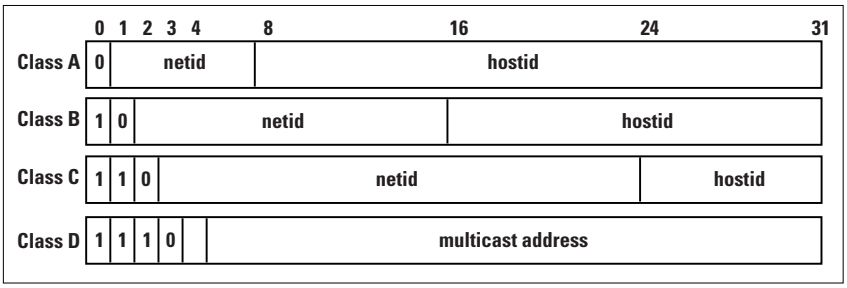
Reliable Multicast Protocols and Applications

by C. Kenneth Miller, StarBurst Communications

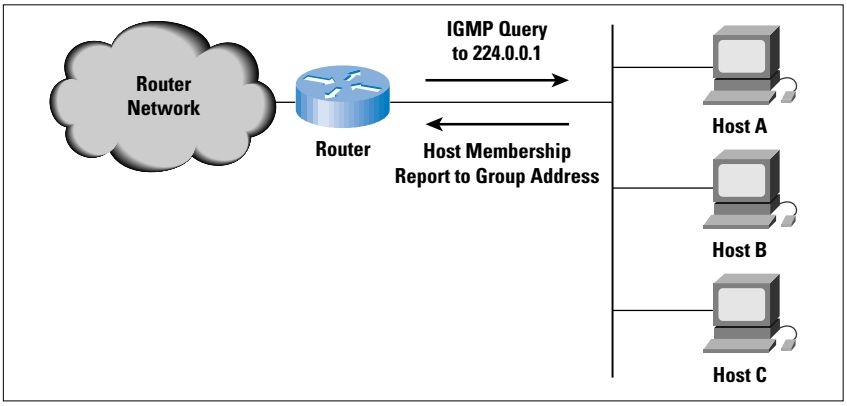
Multicast IP network services offer new opportunities to provide value-added applications that involve many-to-many transmission such as conferencing or network gaming, or one-to-many transmission such as multimedia events, tickertape feeds, and file transfer, where the many could be thousands or even conceivably millions. Multicast IP services use a different kind of IP address, called Class D. In contrast to individual host addresses (Classes A–C), which include a host and a network component and usually are semipermanent, Class D multicast addresses may by design be used only for a particular session, or can be semipermanent, as multicast groups may be set up and torn down relatively quickly, on the order of seconds. The IP address structure is shown in Figure 1.

Figure 1: IP Address Types



Hosts join groups at the receiver's initiation using the *Internet Group Management Protocol* (IGMP). When a host joins a group, it notifies the nearest multicast subnet router of its presence in the group, as shown in Figure 2. First defined in RFC 1112[1], IGMPv1 is still the version of IGMP most widely supported. IGMPv2 has recently been documented as an official RFC (RFC 2236[2]). The main feature that IGMPv2 brings is reduced latency for leaving groups. In IGMPv1, the designated multicast router for the subnet polls for multicast group members; no response between polls indicates that all hosts in a particular multicast group have left the group, and that the routers can prune back the multicast routing tree.

Figure 2: IGMPv1 Dialog



Network infrastructure devices, for example, routers, need to provide a routing protocol to forward multicast packets to group members, in a fashion similar to that performed for unicast routing. Multicast IP packet forwarding is best effort, just as it is with unicast packet forwarding. However, most unicast applications use TCP as a transport layer to provide guaranteed packet ordering and delivery. Some examples of applications that use TCP are the *File Transfer Protocol* (FTP) for file transfer and the *Hypertext Transfer Protocol* (HTTP) for Web access.

However, TCP is a unicast (point-to-point) only transport protocol. Thus, all multicast applications must run on top of the *User Datagram Protocol* (UDP) or alternatively, interface directly to IP via "raw" sockets and provide their own customized transport layer, as shown in Figure 3. UDP provides only minimal transport-layer services, error detection, and port multiplexing. Thus, if any errors or packet loss due to congestion occur, packets are simply lost to the application, and they are not recoverable. Thus, *all multicast applications must have a specific transport-layer service to support that particular application*. When that transport layer operates over UDP, it operates in the application layer with the application. When it interfaces directly to IP using "raw" sockets, the specialized transport layer operates at the transport layer, but is specialized to the particular application that uses it.

It should be noted that TCP supports only data reliability; it is not suited for transport of multimedia streams, which require consistent time delivery at the receiver and only need to be semireliable. Thus, multimedia streaming applications need a specialized transport layer such as the *Real-Time Transport Protocol* (RTP)[3] for unicast as well as multicast transmissions.

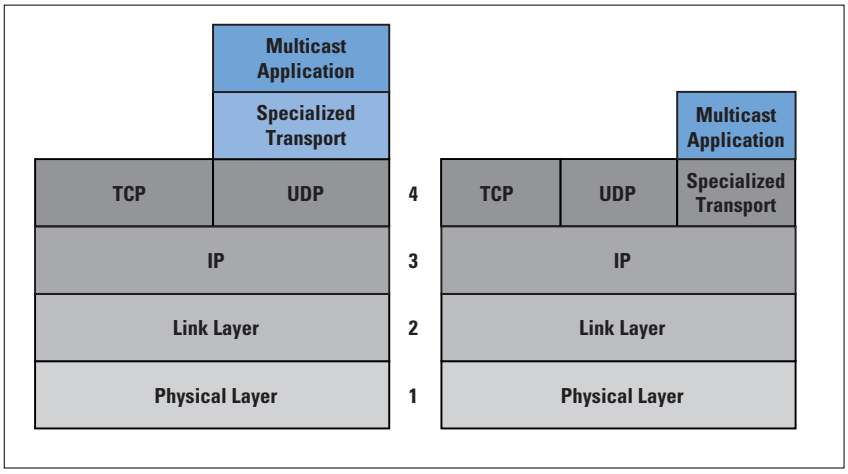


Figure 3: Specialized Multicast Transport Protocols Operate over UDP or IP

Many equate multicast with multimedia, thinking that the Internet and private intranets will become an alternative entertainment media to television by using multicast IP network services and multimedia streaming technology. However, numerous other multicast applications require reliability rather than timeliness; they are multicast applications that are similar to those unicast applications that operate over TCP, except that delivery is to many recipients rather than just one.

Reliable Multicast Application Categories and Requirements

Reliable multicast applications come in three basic categories with differing requirements, as shown in Figure 4.

Figure 4: Reliable Multicast Application Categories

Application Type	Latency Req.	Reliability	Scalability
Collaborative	Low	Semi/Strict	<100
Message Str.	Low/Medium	Semi/Strict	to Millions
Bulk Data	Not Real Time	Strict	to Millions

Collaborative applications such as data conferences (whiteboarding) and network-based games are many-to-many applications with modest scaling requirements of less than 100 participants. This kind of application requires low latency of less than 400 msec so that responses do not cause discomfort to the human participants. Transmission does not always need strict reliability; for example, refresh of background information for a network game could wait for the next refresh.

Message streaming applications such as tickertape and news feeds also often require low latency. Tickertape feeds to brokerage houses need to be very timely because the information loses value greatly with time. Time is very much money in this application, and there is also a need for strict reliability.

Tickertape feeds to consumers are purposely delayed by minutes because they are usually transmitted without charge, but they cannot be so stale as to be viewed as "old" information. This data does not have a strict reliability requirement because the next trade of a particular security refreshes the data. News feeds likewise have only a moderate latency requirement. If the news feeds are sent in a carousel fashion, that is, each news story is repeated, strict reliability may not be needed because it is refreshed in the next transmission of the same story.

Bulk data delivery has no specific latency requirement. Often there is a desire to schedule delivery during the night, when there is less network traffic. At other times, the desire is to receive the data almost

immediately. However, at all times the entire "file" or piece of data needs to be received to be complete. Strict reliability is the rule; for example, if any bit of a software image is lost, the data is worthless.

Message streaming and bulk data application scaling requirements span the gamut from tens to possibly even millions.

Reliable multicast transport protocols, in contrast to multimedia streaming transport protocols, have not yet been standardized. However, numerous reliable multicast protocols exist; some have been used only for research, while others have been commercialized.

The *Reliable Multicast Research Group* (RMRG) in the *Internet Research Task Force* (IRTF) is now studying reliable multicast. It is chartered to recommend techniques for a working group in the *Internet Engineering Task Force* (IETF) to create a set of reliable multicast standards.

Standardization Effort

The standardization effort has been started in an IRTF research group to study the problems and possible solutions by Internet researchers. This effort was first placed in the hands of researchers because the problems were considered very difficult to solve in the global Internet. Some of the concerns about reliable multicast were discussed in an expired Internet Draft published in November 1996 by the Transport Area Directors of IETF.

These concerns formed the basis for the work of the RMRG, which was formed in early 1997. The concerns from that document follow:

"A particular concern for the IETF (and a dominant concern for the Transport Services Area) is the impact of reliable multicast traffic on other traffic in the Internet in times of congestion (more specifically, the effect of reliable multicast traffic on competing TCP traffic). The success of the Internet relies on the fact that best-effort traffic responds to congestion on a link (as currently indicated by packet drops) by reducing the load presented on that link. Congestion collapse in today's Internet is prevented only by the congestion control mechanism in TCP.

There are a number of reasons to be particularly attentive to the congestion-related issues raised by reliable multicast proposals. Multicast applications in general have the potential to do more congestion-related damage to the Internet than do unicast applications. This is because a single multicast flow can be distributed along a large, global multicast tree reaching throughout the entire Internet.

> Further, reliable multicast applications have the potential to do more congestion-related damage than do unreliable multicast applications. First, unreliable multicast applications such as audio and video are, at the moment, usually accompanied by a person at the receiving end, and people typically unsubscribe from a multicast group if congestion is so heavy that the audio or video stream is unintelligible. Reliable multicast applications such as group file transfer applications, on the other hand, are likely to be between computers, with no humans in attendance monitoring congestion levels.
>
> In addition, reliable multicast applications do not necessarily have the natural time limitations typical of current unreliable multicast applications. For a file transfer application, for example, the data transfer might continue until all of the data is transferred to all of the intended receivers, resulting in a potentially-unlimited duration for an individual flow. Reliable multicast applications also have to contend with a potential explosion of control traffic (e.g., ACKs, NAKs, status messages), and with control traffic issues in general that may be more complex than for unreliable multicast traffic.
>
> The design of congestion control mechanisms for reliable multicast for large multicast groups is currently an area of active research. The challenge to the IETF is to encourage research and implementations of reliable multicast, and to enable the needs of applications for reliable multicast to be met as expeditiously as possible, while at the same time protecting the Internet from the congestion disaster or collapse that could result from the widespread use of applications with inappropriate reliable multicast mechanisms. Because of the setbacks and costs that could result from the widespread deployment of reliable multicast with inadequate congestion control, the IETF must exercise care in the standardization of a reliable multicast protocol that might see widespread use."

One of the statements in this document is very specious:

> "First, unreliable multicast applications such as audio and video are, at the moment, usually accompanied by a person at the receiving end, and people typically unsubscribe from a multicast group if congestion is so heavy that the audio or video stream is unintelligible. Reliable multicast applications such as group file transfer applications, on the other hand, are likely to be between computers, with no humans in attendance monitoring congestion levels."

This statement is a very weak argument; it is not reliable to depend on a human to turn off a nonfunctioning event. Do we typically turn off the television when we leave the house? Or leave the room to do something else?

In contrast, some of the reliable multicast protocols such as the *Multicast File Transfer Protocol* (MFTP) have the sense of a finite session, and automatically time out and leave a group, even if all group members did not receive all the content.

Essentially what is desired is a reliable multicast protocol that behaves like TCP in that it backs off in the face of congestion approximately the same way as TCP and shares the bandwidth with TCP traffic "fairly." This feature is of prime importance to Internet researchers who wish to specify protocols that can scale to the global Internet and not cause harm to the traffic already present.

Two additional significant problems need to be solved: scalability and the ability to operate with scalability over many different network infrastructures.

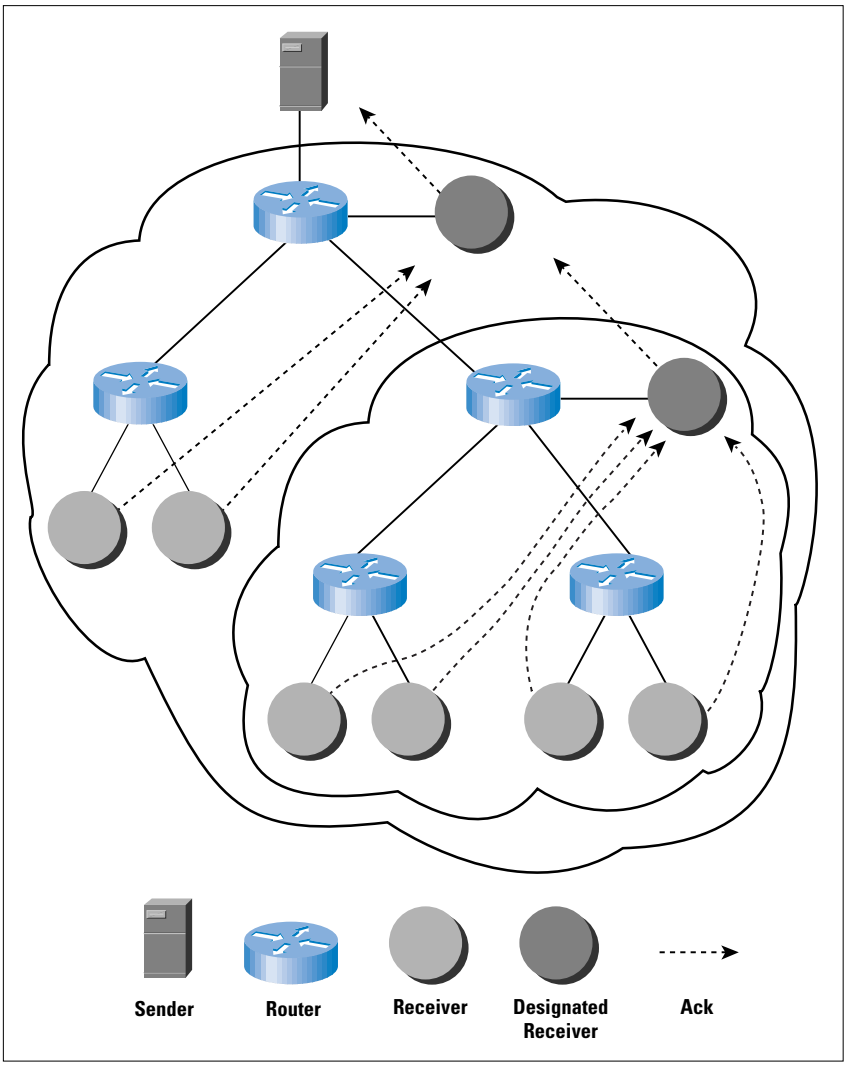
Scaling Issues and How Current Reliable Multicast Protocols Solve Them

Two primary issues are related to scaling, that is, the ability to handle large groups. The first and most significant is widely known as acknowledgment/negative acknowledgment (ACK/NAK) implosion. As the number of receivers grows, the amount of back traffic to the sender eventually overwhelms its capacity to handle them. Additionally, the network at the sender site becomes congested from the cumulative back traffic from the receivers.

The second issue is one of retransmissions (often referred to as "repairs"). If the packet loss is uncorrelated at the receivers, retransmissions grow, so the data may need to be sent multiple times to satisfy all the receivers. Measurements of the *Multicast backbone* (Mbone) have shown that loss consists of both correlated and uncorrelated parts[4]. Satellite networks will also exhibit mostly uncorrelated loss, unless receivers are geographically close.

Various methods have been used to achieve scaling by reducing the amount of ACK/NAK administrative traffic while still retaining reliability. A straightforward approach is to simply deploy repeaters/aggregators in the network, as shown in Figure 5. This approach is provided by the *Reliable Multicast Transport Protocol* (RMTP)[5]. RMTP provides for *designated receivers* (DRs) that collect status messages from nodes in a local RMTP domain and provide repairs (retransmissions of missing data), if available. Receivers direct the administrative messages to the DR by unicast. Thus, the DR provides both local recovery and consolidation of control traffic to the next DR in the hierarchy if the data requested is not available.

Figure 5:
RMTP Designated
Receivers



A second approach is to allow any receiver to provide the repair, biasing the request to the nearest receiver that has the requested data. This approach, called *Scalable Reliable Multicast* (SRM)[6], depends on the concept of repair by any receiver that has the data to gain scalability in reducing administrative back traffic to the source, putting the onus of responsibility on receivers to ensure that they get missed data.

Group members in SRM send low-frequency *session* messages to the group so that their neighbors can learn their status, measure the delay among group members and learn group membership, and detect the last packet in a burst. Session messages are designed to take only about five percent of the traffic in the session.

Receivers with missing data wait a random time period before issuing repair requests, allowing suppression of duplicate requests similar to the mechanism that IGMP uses on its subnet. A similar process occurs for making the actual repairs. The random backoff time for both repair requests made by receivers and repairs made by senders is a

function of "closeness" to the sender and requesting receiver. Thus, those closest to each other time out first and make the repair request or the actual repair in an attempt to keep repairs as local as possible. A receiver that sees the first request and determines that it is the same request that it would have made simply stays silent, reducing potential redundant requests. The requester continues to send repair requests until the repair is received.

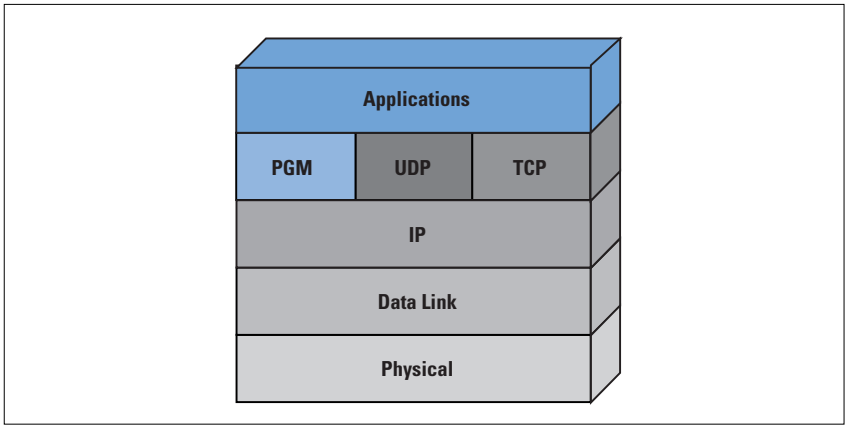
Any receiver may satisfy the repair request, because all receivers are required to cache previously sent data. Any receiver that can satisfy the request is prepared to do so; a random backoff timer is used before a repair is sent, and if it sees the repair being sent by another group member, it stays silent to reduce the probability of sending duplicate repairs.

SRM was first developed to be the reliable multicast protocol to operate with the *wb* whiteboard data conferencing tool developed by Lawrence Berkeley Labs (LBL) researchers, SRM is currently operational over the Mbone, the experimental multicast network of the Internet.

A third approach is to have the network infrastructure, that is, routers, help in providing scaling. This approach, called *Pretty Good Multicast* (PGM)[7], is a new proposal that was first publicly presented to the RMRG meeting held in February 1998.

One design goal of the creators of PGM was simplicity and the ability to optimally leverage routers in the network to provide scalability. PGM is an example of a protocol that bypasses UDP and interfaces directly to IP via "raw" sockets, as shown in Figure 6.

Figure 6: PGM Interfaces Directly to IP



PGM provides no notion of group membership; it simply provides reliability within a source's transmit window from the time a receiver joins a group until it departs.

PGM has only a few data packets that are defined:

ODATA: original content data

NAK: selective negative acknowledgment

NCF: NAK confirmation

RDATA: retransmission (repair)

SPM: source path message

Each PGM packet contains a *Transport Session Identifier* (TSI) to identify the session and source of that data, so multiple sessions may be easily identified by PGM-aware routers and receivers. ODATA, NCF, RDATA, and SPM packets flow downstream in the distribution tree, and NAK packets flow upstream toward the source.

PGM is designed for scalability as well as the ability to serve real-time applications. Thus there is a need for timeliness. This need is handled by the *transmit window*, which defines a sliding window of data such that if no NAKs are received by the sender or a designated local retransmitter by the time the window is up, the data is simply not available for repairs.

PGM is totally NAK based, so the scaling issue is to reduce the number of NAKs sent back to the source, while at the same time protecting against lost NAKs. Enter here the router assist, as shown in Figure 7.

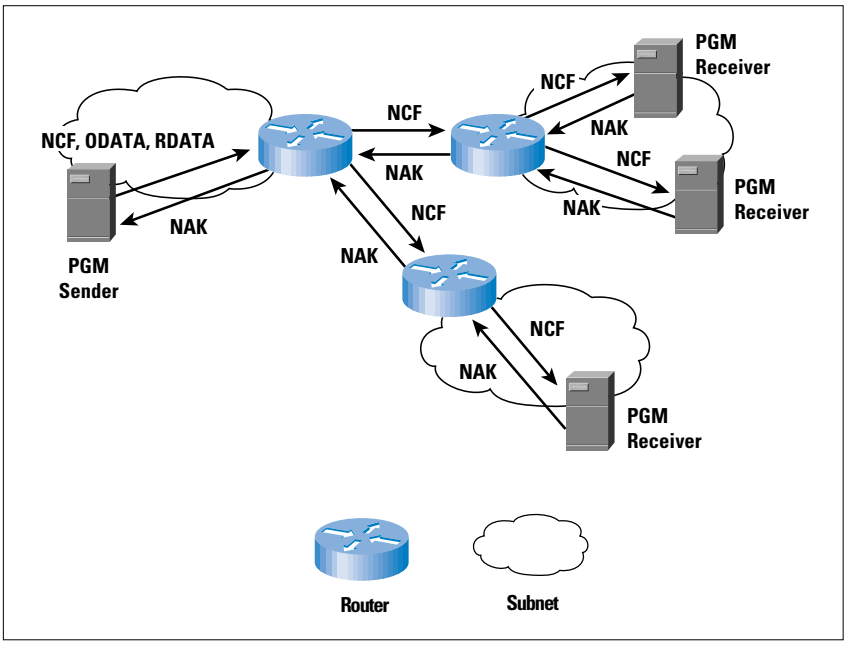


Figure 7: PGM NAK/NCF Dialog

NAKs are unicast from PGM-router to PGM-router, initiated by the receiver that lost data sending a NAK to its nearest PGM-aware router. Each PGM-aware router keeps forwarding NAKs until it sees an NCF or RDATA, which indicates that a repair is being sent. NAK *suppres-*

sion is provided by a receiver's subnet PGM-aware router, and all PGM-aware routers *eliminate* duplicate NAKs all the way upstream to the source.

The unicast path back to the source must be the same path as the downstream multicast tree. SPMs are sent downstream interleaved with ODATA packets to establish a source path state for a given source and session. PGM-aware routers use this information to determine the unicast path back to the source for forwarding NAKs. SPMs also alert receivers that the oldest data in the transmit window is about to be retired from the window and will thus no longer be available for repairs from the source. SPMs are sent by a source at a rate that is at least the rate at which the transmit window is advanced. This rate provokes "last call" NAKs from receivers and updates the receive window state at receivers.

PGM-aware routers also keep state on where the NAKs come from in the distribution tree so that they may constrain the forwarding of RDATA repairs to only those ports from which NAKs requesting that repair were received. This scenario eliminates the transmission of repair data to parts of the distribution tree where the repair is not needed.

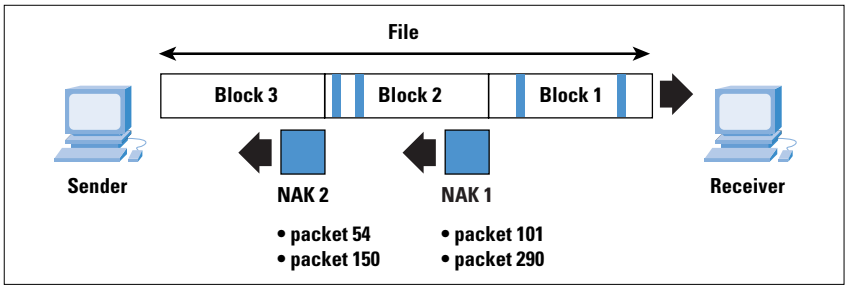
The PGM feature can also optionally redirect NAKs to a *designated local retransmitter* (DLR) rather than the source. A DLR announces its presence to provoke the redirection of NAKs for that session and source.

A fourth approach is to not have a low-latency requirement (that is, only serve "bulk data" delivery applications) and use this feature to advantage to gain scalability. MFTP was first published as an Internet Draft in February 1997, and an update was submitted in April 1998[8].

MFTP also has a provision for sender-based group creation, with different group models, and the group setup protocol to notify receivers to join the group. Group creation is discussed later in this article.

The basic MFTP protocol breaks the data entity to be sent into maximum size "blocks," where a block by default consists of thousands or tens of thousands of packets, depending on packet size used. This setup is shown in Figure 8.

Figure 8: MFTP Blocks



MFTP is a "NAK-only" protocol; that is, if data is received correctly in a block, nothing is sent back to the sender. If one or more packets are in error or missing in a block, receivers respond with a NAK that consists of a bit map of the bad packets in the block. It is thus a *selective reject* mechanism. In this respect, MFTP is similar to RMTP; the main difference is that MFTP explicitly attempts to make the block as large as possible for scaling purposes.

NAKs are normally sent unicast back to the source, unless aggregation to improve scaling using enabled network routers is used. In this case, the NAKs are sent multicast to a special administrative traffic group address.

MFTP does not repair after each block, however; it takes advantage of the non-real time nature of the application for benefit. The data entity, such as a file, is sent initially in its entirety in a *first pass*. The sender collects the NAK packets for a block from all the receivers. One NAK packet from a receiver can represent thousands or even tens of thousands of bad packets, reducing NAK implosion by orders of magnitudes. The collection of NAKs received by the sender from all the receivers is logically OR-ed together to represent the collective need for repairs for the receiving group. These repairs are sent by the sender in a *second pass* to the group. If certain receivers already have the repair, it is simply ignored. This scenario is repeated, if necessary, until all repairs are received by all receivers or until a configurable timeout occurs.

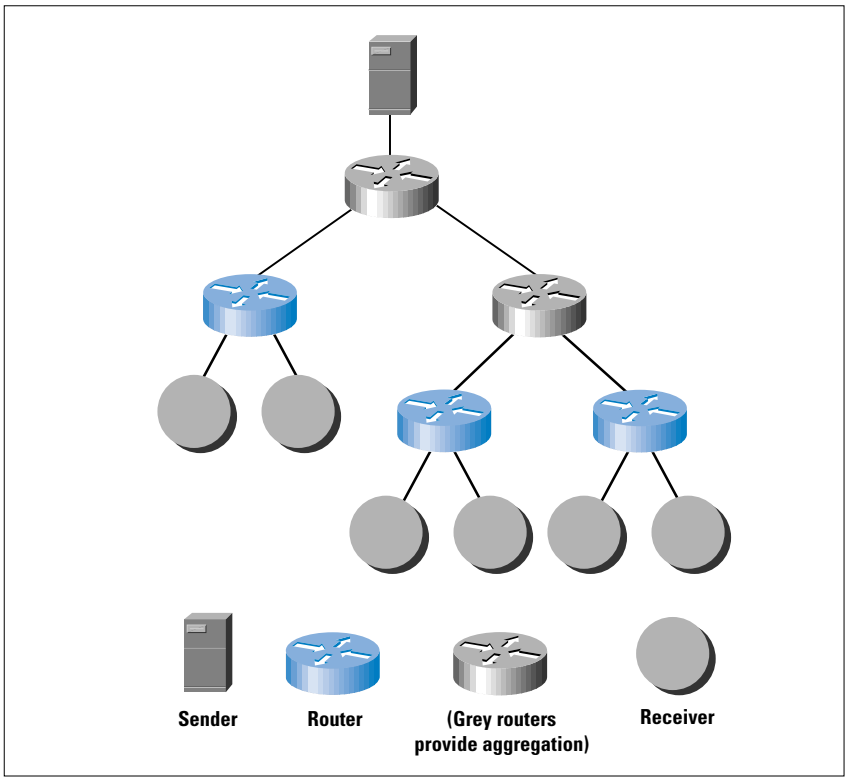
Thus, packet ordering services are not provided, and holes in the data caused by dropped packets or packets in error are filled in as they are received.

The sender is *rate based;* in other words, it transmits at a data rate set by the operator to be less than or equal to what the network can handle. The protocol is thus very efficient with high-latency networks such as satellites, and it is impervious to network asymmetry. It also attempts to be as scalable as possible on one-hop networks such as satellite networks, and it provides for extensions so that network elements may aggregate downstream responses to increase scalability further, depending on the network configuration.

This aggregation capability is shown in Figure 9. The network element, which can be a router, collects MFTP administrative back traffic routers are members. These routers aggregate back traffic from all nodes downstream in the multicast tree from the source, including registrations, NAKs, and dones. Registration and done messages are used by MFTP's group setup protocol, and they are described later in this article.

Depending on the network configuration, this aggregation capability can further improve the scalability of MFTP by orders of magnitudes.

Figure 9: Routers as Network Aggregators



The upper limit to scalability with no network aggregation of administrative traffic is in the tens of thousands of receivers. For example, for a *Maximum Transmission Unit* (MTU) of 1500 bytes (the Ethernet maximum), the default block size is over 11,000 packets. If the number of receivers is 10,000 and each receiver has at least one bad packet per block, then there will be a total of 10,000 NAK packets coming back to the sender from the group about that block, approximately the same number of packets as were sent in the forward direction in that block. MFTP provides for a NAK backoff timer to spread the NAKs out in time to the sender to avoid bursts. If the bandwidth is symmetric at the sender, the sender should be able to handle this maximum NAK. In many situations, the amount of back traffic could exceed forward traffic.

MFTP also has provision for a crude congestion control mechanism. The sender at the beginning of a session sends *announce* messages. These messages are used for many functions, including the setting up of groups. Additionally, it conveys a packet loss parameter to all receivers. This packet loss threshold parameter may be used by receivers to leave the group if the packet loss exceeds the threshold. Leaving the group prunes the distribution tree, relieving the congestion in that section of the tree.

Commercial Usage

The reliable multicast protocols previously discussed are the most prominent ones on the market today. RMTP has been deployed in its message streaming version for a billing record distribution application within a very large telecommunications carrier, but it has had generally limited deployment. It also does not scale over satellite networks, where most of the early multicast deployments reside.

SRM has been used by the research community only over the Mbone, and it is still being refined. Another problem with SRM is that in its current incarnation, it supports neither asymmetric nor satellite networks. Some early Internet Service Provider (ISP) multicast implementations, offer multicast support in only one direction; SRM requires total multicast support.

PGM is new and offers promise, but there is no deployment yet, and it likely will not occur until early 1999. PGM also requires router support in a terrestrial land-line network to gain scaling.

MFTP has the limitation that it supports only bulk transfer applications. However, one trade-off is that it can support all network infrastructures, including satellite infrastructures with scaling. MFTP has also been available commercially in products with the longest application support, dating back to 1995. Thus, MFTP-based products have the largest installed base of any reliable multicast-based product being used over WANs. The largest commercial installation of over 8,500 remote sites in the group is the General Motors[9] dealer network. Several other commercial installations of MFTP-based applications number over 1,000 group members.

Advanced Research Topics Discussed in Reliable Multicast Research Group

A promising technique to reduce the amount of repair data that needs to be retransmitted is called *erasure correction*. This technique can significantly reduce the amount of repairs that need to be resent if the packet loss is largely uncorrelated at the receivers. It uses a *forward error correction* (FEC) code to generate parity packets to be used for repairs only. This setup provides benefit if errors at receivers are uncorrelated. For example, suppose 16 receivers each have one missing packet, but they are all different. Rather than send all 16 original data packets, one FEC packet could be sent that could correct the one missing packet at all 16 receivers, requiring retransmission of only one packet rather than 16.

If the loss is correlated, then many of the receivers lose the same data, and erasure correction is of no benefit. However, there is also no penalty, except for the need for computing power at both the sender and the receivers to perform the FEC correction calculations. Simulations have show[10] that there is a greater than 2:1 reduction in the number of repairs needed to be sent with our example of 10,000 receivers. This benefit will be even larger when group sizes become larger than tens of thousands.

Perhaps a more significant application for FEC is a congestion control technique known as *layering*[11,12]. With layering, numerous groups are set up by the sender, all with different rates. Receivers that can receive at the highest rate join all the "layer" groups. Those receivers that cannot receive at the highest rate simply leave "layers" until congestion is relieved, and they take longer to receive the data. For this to work without sending data redundantly, the number of parity packets created must be very large compared to the number of data packets.

There are some further issues that have been pointed out by the researchers with the Other issues with the layering approaches have been pointed out by the researchers, however. For layering to be effective, the routing tree should be identical for the different groups; otherwise congestion will not be relieved on a part of the tree. This may not always be the case, especially in sparse mode routing protocols, where selection of the rendezvous point or core is based on group address.

Even if the same distribution tree is used for the different layers, it has been pointed out[12] that leaves of hosts downstream from a congested link should be coordinated; otherwise the action of less than all of them has no effect on congestion. Additionally, a receiver could cause congestion by adding a layer that another receiver could interpret as congestion, causing it to drop a layer with no effect.

Thus, layering using FEC techniques is an interesting technique that shows promise for use in congestion control. However, there are issues associated with this type of layering that researchers still need to address.

Another technique that has been proposed for congestion control is bulk feedback to the sender[13]. If the sender receives an excessive number of NAKs from receivers, it drops the sender's transmission rate with an algorithm that attempts to emulate the behavior of TCP. This approach is an obvious one because it is an extension of the process in which TCP falls back in the face of congestion.

This approach, however, has two basic problems. The first is that there is delay, because the sender needs to get feedback from the multitude of receivers before it acts. This delay can be considerably longer than in the case of TCP, which needs feedback from only one receiver.

The second flaw is that one errant receiver can effectively penalize the whole group, because the sender reduces the rate to the total group.

This approach is not viewed as a viable solution for these reasons. In fact, the general consensus is that congestion control decision making will be required at the multiple receivers rather than at the sender for both scaling and timeliness reasons.

Another idea that is now receiving intense study by researchers is that of "subcasting"[14,15,16]. The key idea in subcasting is to optimize local repair to be a retransmitter that may be just above a link congestion point, as shown in Figure 10. The problem is to gain knowledge of the network topology so as to locate a receiving host that is willing to retransmit and that has the repair data.

Then the repairs need to be contained within only the region of the network that lost the original transmission, that is, the "subcast" region.

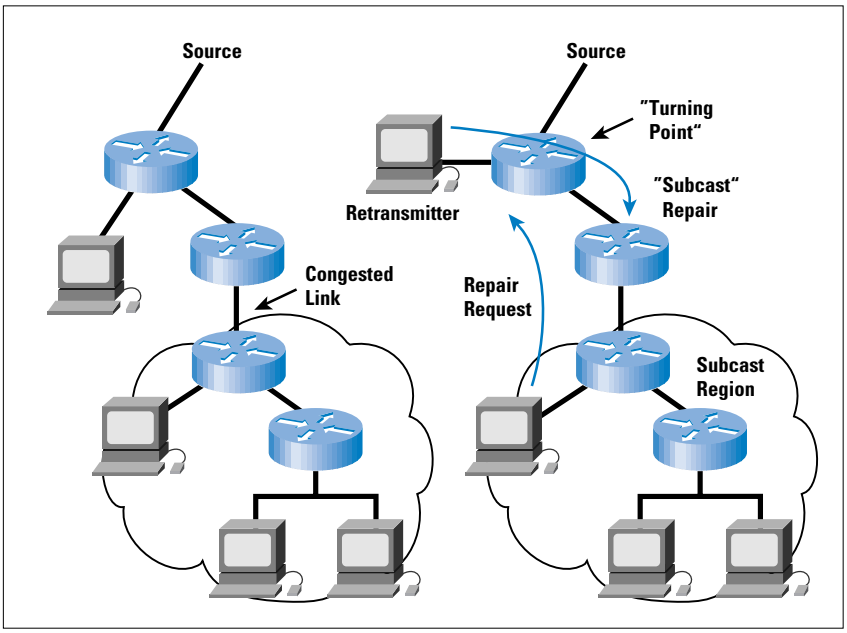


Figure 10: Optimized Local Repair

One proposal is to ask for assistance from the network routers. They know the topology and could be used to find the closest willing retransmitter that has the repair. The router could also direct the repair to only the affected region: the *subcast*.

This technique can be viewed as an extension of concepts originally proposed in SRM to provide local recovery. It assumes that most loss is caused by congested links, and that uncorrelated loss is caused by a series of mildly congested links with few group members. This model is probably the right one for many land-line routed networks; it is problematical with other network infrastructures.

Nevertheless, it is an interesting proposal that merits further research effort. Local repair is destined to be an important tool to meet the goal of improved scalability with minimal traffic overhead.

Group Creation and Destruction

The process of joining a group and leaving a group in IP multicast is left to a potential group member that uses IGMP to notify the nearest multicast router of its membership state. However, mechanisms need to be in place to allow potential members of a group to gain the information needed to decide to join the group.

There are two basic ways to accomplish this scenario for one-to-many sessions. The first and most common is the "broadcast TV" model. The *Multiparty Multimedia Session Control* (MMUSIC) working group of the IETF has developed some protocols that can be used to advertise content. The *Session Announcement Protocol* (SAP)[17] provides the mechanism to send a stream on a "well-known" multicast address to announce content to any potential listeners who may be interested. It uses the *Session Description Protocol* (SDP)[18] to describe the contents that are announced. These two protocols together have been used to create a session directory tool that is available on the Mbone. This setup creates essentially the equivalent of a "preview channel" such as is often available on cable television systems.

SDP is also used to post content on Web sites, which advertise that content to anyone who wishes to receive it.

Although these protocols were originally developed primarily to advertise multimedia streaming applications, they are also applicable for data. They provide a useful tool for "push" vendors to advertise multicast "channels" based on content that any consumer can "tune in" to.

Internet researchers describe this model as providing "loosely coupled" sessions, because the sender does not know who is listening, much like radio or TV broadcasters do not know who tunes in to their stations.

MFTP also includes a group setup protocol. The "closed group" option in MFTP provides a mechanism to create a "tightly coupled" session that is very useful to organizations that wish to deliver critical information from a central site to many remote branch offices. The closed group provides a means for the sender to define a group list centrally and direct those members so defined to join the group. This scenario is somewhat similar to e-mail, except more robust.

These instructions are sent in an "announce" message on a special multicast group address that the superset of possible candidate receivers always listens to. Hosts so directed to join the group notify their designated multicast router of their membership directed to join the group notify their designated multicast router of their membership using IGMP and "register" back to the sender of their presence. Thus, the sender knows group membership before transmission commences, and the sender can then also positively confirm delivery.

This approach has proven very desirable for organizations that have many branches where information is desired to be sent at the discretion and time determined by the and desire to send information at the discretion and time determined by the sender, and usually the information is delivered to a branch office server. Several deployments of applications that use MFTP and the closed group model with group members approaching 10,000 exist.

The MMUSIC group has also created the *Session Invitation Protocol* (SIP)[19], which is used to invite members to a conference of some sort, including possibly a data conference. This protocol is appropriate for use with whiteboard applications, for example.

Summary and Conclusions

Although multicast has often been viewed as synonymous with multimedia, there is a wide spectrum of reliable multicast applications that involve the transfer of data to multiple group members. Because this wide spectrum of applications has many different requirements, as shown in Figure 4, no one reliable multicast protocol can handle all applications and network infrastructures. The result is that numerous reliable multicast protocols are likely to become standardized, and today numerous reliable multicast protocols are either in commercial products/toolkits or due to be available soon.

The reliable multicast standardization effort now resides in the IRTF, because Internet researchers are concerned about congestion control and fairness to TCP for any protocols that might become standardized for general Internet use. This problem is difficult to solve, given the disparate requirements placed on protocols by the wide variety of applications and different network infrastructures.

Nevertheless, a significant number of reliable multicast-based product deployments have already occurred over private networks. These have been shown to save organizations much money and to help create new business opportunities for them.

Stay tuned; reliable multicast-based applications are ready to be mainstreamed. Together with multimedia multicast applications, multicast applications of all forms will become common soon, first in private intranets and extranets and then in the Internet as a whole.

C. KENNETH MILLER is the founder, Chairman, and Chief Technology Officer of StarBurst Communications. StarBurst Communications provides reliable multicast solutions for commercial applications with such corporate customers as GM, Ford, Chrysler, Toys 'R Us, Thomson Financial, and many others. Miller has been in the data communications industry since 1972. He founded Concord Data Systems in late 1980 and served as its President and CEO until 1986. Concord Data Systems produced high-speed dial modems. He was the author of the IEEE 802.4 LAN standard, which became the lower layer for the Manufacturing Automation Protocol (MAP) factory LAN standard. Miller was a regular columnist in *Data Communications Magazine* from 1992 to 1994. He has also published numerous articles and participated in many panels at trade show and other industry events. He is now writing a book entitled *Multicast Networking and Applications*, to be published in 1998 by Addison-Wesley. Miller received a BEE degree from Rensselaer Polytechnic Institute and a MSEE degree from the University of Pennsylvania, specializing in communications. Miller can be reached at **miller@starburstcom.com**

Layer 2 and Layer 3 Switch Evolution

by Thayumanavan Sridhar, Future Communications Software

Layer 2 switches are frequently installed in the enterprise for high-speed connectivity between end stations at the data link layer. Layer 3 switches are a relatively new phenomenon, made popular by (among others) the trade press. This article details some of the issues in the evolution of Layer 2 and Layer 3 switches. We hypothesize that that the technology is evolutionary and has its origins in earlier products.

Layer 2 Switches

Bridging technology has been around since the 1980s (and maybe even earlier). Bridging involves segmentation of local-area networks (LANs) at the Layer 2 level. A multiport bridge typically learns about the *Media Access Control* (MAC) addresses on each of its ports and transparently passes MAC frames destined to those ports. These bridges also ensure that frames destined for MAC addresses that lie on the same port as the originating station are not forwarded to the other ports. For the sake of this discussion, we consider only Ethernet LANs.

Layer 2 switches effectively provide the same functionality. They are similar to multiport bridges in that they learn and forward frames on each port. The major difference is the involvement of hardware that ensures that multiple switching *paths* inside the switch can be active at the same time. For example, consider Figure 1, which details a four-port switch with stations A on port 1, B on port 2, C on port 3 and D on port 4. Assume that A desires to communicate with B, and C desires to communicate with D. In a single CPU bridge, this forwarding would typically be done in software, where the CPU would pick up frames from each of the ports sequentially and forward them to appropriate output ports. This process is highly inefficient in a scenario like the one indicated previously, where the traffic between A and B has no relation to the traffic between C and D.

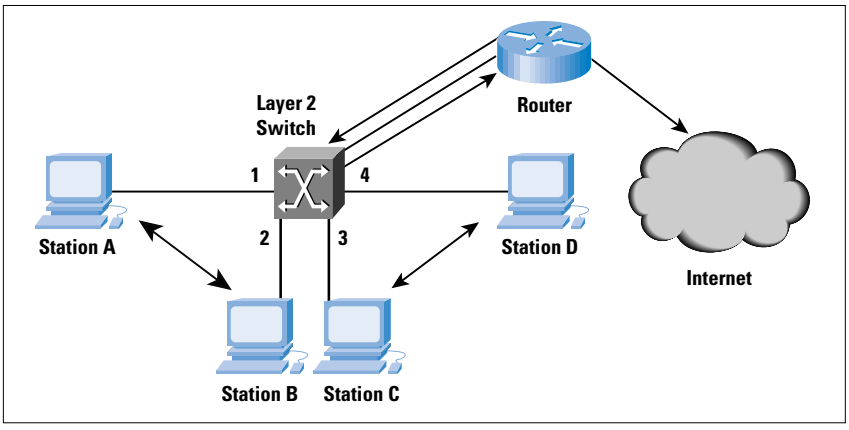

Figure 1: Layer 2 switch with External Router for Inter-VLAN traffic and connecting to the Internet

Enter hardware-based Layer 2 switching. Layer 2 switches with their hardware support are able to forward such frames in parallel so that A and B and C and D can have simultaneous conversations. The parallelism has many advantages. Assume that A and B are NetBIOS stations, while C and D are Internet Protocol (IP) stations. There may be no reason for the communication between A and C and A and D. Layer 2 switching allows this coexistence without sacrificing efficiency.

Virtual LANs

In reality, however, LANs are rarely so *clean*. Assume a situation where A,B,C, and D are all IP stations. A and B belong to the same IP subnet, while C and D belong to a different subnet. Layer 2 switching is fine, as long as only A and B or C and D communicate. If A and C, which are on two different IP subnets, need to communicate, Layer 2 switching is inadequate—the communication requires an IP router. A corollary of this is that A and B and C and D belong to different broadcast domains—that is, A and B should not "see" the MAC layer broadcasts from C and D, and vice versa. However, a Layer 2 switch cannot distinguish between these broadcasts—bridging technology involves forwarding broadcasts to all other ports, and it cannot tell when a broadcast is restricted to the same IP subnet.

Virtual LANs (VLANs) apply in this situation. In short, Layer 2 VLANs are Layer 2 broadcast domains. MAC broadcasts are restricted to the VLANs that stations are configured into. How can the Layer 2 switch make this distinction? By configuration. VLANs involve configuration of ports or MAC addresses. Port-based VLANs indicate that all frames that originate from a port belong to the same VLAN, while MAC address-based VLANs use MAC addresses to determine VLAN membership. In Figure 1, ports 1 and 2 belong to the same VLAN, while ports 3 and 4 belong to a different VLAN. Note that there is an implicit relationship between the VLANs and the IP subnets—however, configuration of Layer 2 VLANs does not involve specifying Layer 3 parameters.

We indicated earlier that stations on two different VLANs can communicate only via a router. The router is typically connected to one of the switch ports (Figure 1). This router is sometimes referred to as a *one-armed router* since it receives and forwards traffic on to the same port. In reality, of course, such routers connect to other switches or to wide-area networks (WANs). Some Layer 2 switches provide this Layer 3 routing functionality within the same box to avoid an external router and to free another switch port. This scenario is reminiscent of the large multiprotocol routers of the early '90s, which offered routing and bridging functions.

A popular classification of Layer 2 switches is "cut-through" versus "store-and-forward." Cut-through switches make the forwarding decision as the frame is being received by just looking at the header of the frame. Store-and-forward switches receive the entire Layer 2 frame

before making the forwarding decision. Hybrid adaptable switches which adapt from cut-through to store-and-forward based on the error rate in the MAC frames are very popular.

Characteristics

Layer 2 switches themselves act as IP end nodes for *Simple Network Management Protocol* (SNMP) management, Telnet, and Web based management. Such management functionality involves the presence of an IP stack on the router along with *User Datagram Protocol* (UDP), *Transmission Control Protocol* (TCP), Telnet, and SNMP functions. The switches themselves have a MAC address so that they can be addressed as a Layer 2 end node while also providing transparent switch functions. Layer 2 switching does not, in general, involve changing the MAC frame. However, there are situations when switches change the MAC frame. The IEEE 802.1Q Committee is working on a VLAN standard that involves "tagging" a MAC frame with the VLAN it belongs to; this tagging process involves changing the MAC frame. Bridging technology also involves the *Spanning-Tree Protocol*. This is required in a multibridge network to avoid loops. The same principles also apply towards Layer 2 switches, and most commercial Layer 2 switches support the Spanning-Tree Protocol.

The previous discussion provides an outline of Layer 2 switching functions. Layer 2 switching is MAC frame based, does not involve altering the MAC frame, in general, and provides transparent switching in parallel with MAC frames. Since these switches operate at Layer 2, they are protocol independent. However, Layer 2 switching does not scale well because of broadcasts. Although VLANs alleviate this problem to some extent, there is definitely a need for machines on different VLANs to communicate. One example is the situation where an organization has multiple intranet servers on separate subnets (and hence VLANs), causing a lot of intersubnet traffic. In such cases, use of a router is unavoidable; Layer 3 switches enter at this point.

Layer 3 Switches

Layer 3 switching is a relatively new term, which has been "extended" by a numerous vendors to describe their products. For example, one school uses this term to describe fast IP routing via hardware, while another school uses it to describe *Multi Protocol Over ATM* (MPOA). For the purpose of this discussion, Layer 3 switches are superfast routers that do Layer 3 forwarding in hardware. In this article, we will mainly discuss Layer 3 switching in the context of fast IP routing, with a brief discussion of the other areas of application.

Evolution

Consider the Layer 2 switching context shown in Figure 1. Layer 2 switches operate well when there is very little traffic between VLANs. Such VLAN traffic would entail a router—either "hanging off" one of the ports as a one-armed router or present internally within the switch. To augment Layer 2 functionality, we need a router—which

leads to loss of performance since routers are typically slower than switches. This scenario leads to the question: Why not implement a router in the switch itself, as discussed in the previous section, and do the forwarding in hardware?

Although this setup is possible, it has one limitation: Layer 2 switches need to operate only on the Ethernet MAC frame. This scenario in turn leads to a well-defined forwarding algorithm which can be implemented in hardware. The algorithm cannot be extended easily to Layer 3 protocols because there are multiple Layer 3 routable protocols such as IP, IPX, AppleTalk, and so on; and second, the forwarding decision in such protocols is typically more complicated than Layer 2 forwarding decisions.

What is the engineering compromise? Because IP is the most common among all Layer 3 protocols today, most of the Layer 3 switches today perform IP switching at the hardware level and forward the other protocols at Layer 2 (that is, bridge them). The second issue of complicated Layer 3 forwarding decisions is best illustrated by IP option processing, which typically causes the length of the IP header to vary, complicating the building of a hardware forwarding engine. However, a large number of IP packets do not include IP options—so, it may be overkill to design this processing into silicon. The compromise is that the most common (fast path) forwarding decision is designed into silicon, whereas the others are handled typically by a CPU on the Layer 3 switch.

To summarize, Layer 3 switches are routers with fast forwarding done via hardware. IP forwarding typically involves a route lookup, decrementing the *Time To Live* (TTL) count and recalculating the checksum, and forwarding the frame with the appropriate MAC header to the correct output port. Lookups can be done in hardware, as can the decrementing of the TTL and the recalculation of the checksum. The routers run routing protocols such as *Open Shortest Path First* (OSPF) or *Routing Information Protocol* (RIP) to communicate with other Layer 3 switches or routers and build their routing tables. These routing tables are looked up to determine the route for an incoming packet.

Combined Layer 2/Layer 3 Switches

We have implicitly assumed that Layer 3 switches also provide Layer 2 switching functionality, but this assumption does not always hold true. Layer 3 switches can act like traditional routers hanging off multiple Layer 2 switches and provide inter-VLAN connectivity. In such cases, there is no Layer 2 functionality required in these switches. This concept can be illustrated by extending the topology in Figure 1—consider placing a pure Layer 3 switch between the Layer 2 Switch and the router. The Layer 3 Switch would off-load the router from inter-VLAN processing.

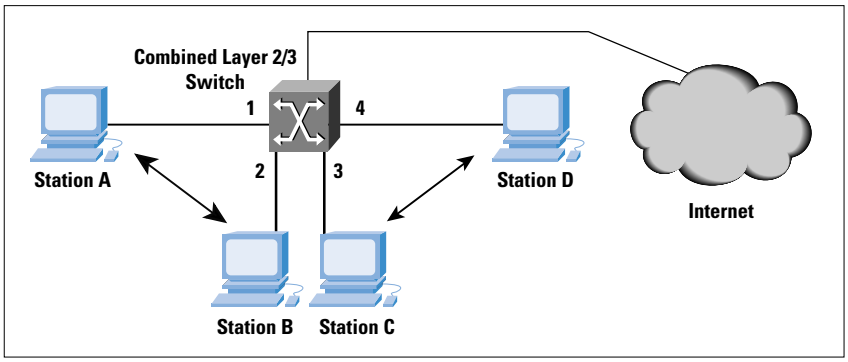

Figure 2: Combined Layer2/ Layer3 Switch connecting directly to the Internet

Figure 2 illustrates the combined Layer 2/Layer 3 switching functionality. The combined Layer 2/Layer 3 switch replaces the traditional router also. A and B belong to IP subnet 1, while C and D belong to IP subnet 2. Since the switch in consideration is a Layer 2 switch also, it switches traffic between A and B at Layer 2. Now consider the situation when A wishes to communicate with C. A sends the IP packet addressed to the MAC address of the Layer 3 switch, but with an IP destination address equal to C's IP address. The Layer 3 switch strips out the MAC header and switches the frame to C after performing the lookup, decrementing the TTL, recalculating the checksum and inserting C's MAC address in the destination MAC address field. All of these steps are done in hardware at very high speeds.

Now how does the switch know that C's IP destination address is Port 3? When it performs learning at Layer 2, it only knows C's MAC address. There are multiple ways to solve this problem. The switch can perform an *Address Resolution Protocol* (ARP) lookup on all the IP subnet 2 ports for C's MAC address and determine C's IP-to-MAC mapping and the port on which C lies. The other method is for the switch to determine C's IP-to-MAC mapping by snooping into the IP header on reception of a MAC frame.

Characteristics

Configuration of the Layer 3 switches is an important issue. When the Layer 3 switches also perform Layer 2 switching, they learn the MAC addresses on the ports—the only configuration required is the VLAN configuration. For Layer 3 switching, the switches can be configured with the ports corresponding to each of the subnets or they can perform IP address learning. This process involves snooping into the IP header of the MAC frames and determining the subnet on that port from the source IP address. When the Layer 3 switch acts like a one-armed router for a Layer 2 switch, the same port may consist of multiple IP subnets.

Management of the Layer 3 switches is typically done via SNMP. Layer 3 switches also have MAC addresses for their ports—this setup can be one per port, or all ports can use the same MAC address. The Layer 3 switches typically use this MAC address for SNMP, Telnet, and Web management communication.

Conceptually, the ATM Forum's *LAN Emulation* (LANE) specification is closer to the Layer 2 switching model, while MPOA is closer to the Layer 3 switching model. Numerous Layer 2 switches are equipped with ATM interfaces and provide a LANE client function on that ATM interface. This scenario allows the bridging of MAC frames across an ATM network from switch to switch. The MPOA is closer to combined Layer2/Layer 3 switching, though the MPOA client does not have any routing protocols running on it. (Routing is left to the MPOA server under the Virtual Router model.)

Do Layer 3 switches completely eliminate need for the traditional router ? No, routers are still needed, especially where connections to the wide area are required. Layer 3 switches may still connect to such routers to learn their tables and route packets to them when these packets need to be sent over the WAN. The switches will be very effective on the workgroup and the backbone within an enterprise, but most likely will not replace the router at the edge of the WAN (read Internet in many cases). Routers perform numerous other functions like filtering with access lists, inter-Autonomous System (AS) routing with protocols such as the *Border Gateway Protocol* (BGP), and so on. Some Layer 3 switches may completely replace the need for a router if they can provide all these functions (see Figure 2).

Book Review

Gigabit Ethernet

Gigabit Ethernet: Technology and Applications for High-Speed LANs, by Rich Seifert, ISBN 0-201-18553-9, Addison-Wesley, 1998, `http://www.awl.com/cseng/titles/0-201-18553-9`.

Gigabit Ethernet is storming its way onto the high-speed LAN scene. From a concept in 1984 to an emerging commercial reality in 1998, Gigabit Ethernet promises to give other high-speed LAN technologies, especially ATM, a serious run for their money. Capitalizing on the basic ease of use and deployment that has made other forms of Ethernet the most popular LAN technology of all, Gigabit Ethernet promises to add major bandwidth to such networks in a straightforward, completely compatible, and relatively affordable way. This book performs an excellent survey of the technologies, algorithms, and design principles that make Gigabit Ethernet possible, and also explains where the tremendous appeal of Gigabit Ethernet really lies. Much of the book is devoted to explaining Ethernet principles and operation in general, as well as exploring recent developments that have enabled gigabit technologies to emerge.

Organization

The book is divided into three parts. Part I explores the foundations that underpin Gigabit Ethernet, starting with a brief but cogent exploration of Ethernet before gigabit versions loomed on the horizon. The rest of Part I covers the trends in LAN usage in general, and Ethernet in particular, that laid the groundwork for Gigabit Ethernet. These trends include the move from shared media to dedicated media on many LANs, and likewise from shared LANs to dedicated LANs, and the concomitant deployment of full-duplex technologies to support bidirectional, high-bandwidth communications. Seifert, an original member of the DIX (Digital-Intel-Xerox) team that developed Ethernet, writes clearly and compellingly about complex issues, such as flow control, medium independence, and automatic configuration, as he explains what made Gigabit Ethernet possible, if not inevitable.

In Part II, Seifert turns his focus onto Gigabit Ethernet itself, beginning with an overview. In the rest of Part II, he explains how *Media Access Control* (MAC) works for half-duplex and full-duplex versions of Gigabit Ethernet, and makes a strong case for the essential irrelevancy of shared-media and half-duplex operation for Gigabit Ethernet. Along the way, Seifert also covers how Gigabit Ethernet networking devices, such as repeaters and switching and routing hubs, must be designed and how they work, and covers the behavior and operation of the physical layer at gigabit speeds.

He concludes this section of the book with a brief overview of the current IEEE Draft 802.3z specification that governs current Gigabit Ethernet operations, and mentions ongoing work in the 802.3ab subcommittee to define a workable implementation for Gigabit Ethernet on twisted-pair media (1000BaseT, as it will probably be known).

In Part III, Seifert tackles some of the most interesting material in this book. He begins with a discussion of how LANs and computers change roles over time in acting as the bottleneck for network use. The point here is that because of its extremely high bandwidth relative to the demands of most applications and end-user requirements, Gigabit Ethernet is likely to remain a backbone or clustering technology for the foreseeable future. He also explores the performance considerations for both networks and applications involved when extreme speeds or excessive bandwidths are available, to point out how bandwidth aggregation is presently Gigabit's most immediate and compelling contribution to networking.

Finally, he explores how Gigabit Ethernet compares to other high-speed networking technologies, including Fast Ethernet, *Fiber Distributed Data Interface* (FDDI), *High-Performance Parallel Interface* (HIPPI), *Fibre Channel*, and ATM. His discussion of why both ATM and Gigabit Ethernet are necessary, and why neither can fully supplant the other, represents a humorous and insightful analysis of why connection-oriented and connectionless communications and applications are both good, and why the two can never truly converge.

An Outstanding Contribution

A rundown of Seifert's layout and content, however, fails to do complete justice to this book. For one thing, Seifert's work includes the funniest and most ingenious footnotes I've seen in recent publications, including some truly horrendous puns and some downright howlers. For example, when discussing how repeaters work, he comments that "A jabbering station causes carrier sense to be continuously asserted and blocks all use of a shared LAN. A repeater looks for this condition and isolates the offending station." To this last sentence, he appends the following footnote: "Research is underway to determine if this mechanism can be extended for use on politicians and university lecturers." And this is just one of dozens of such gems that help to relieve the dryness that deeply technical material can sometimes manifest.

This book is also masterful simply because the author understands his material so well, and does such an outstanding job of explaining and exploring even the most abstruse networking concepts. Although I've been working with Ethernet for 15 years, I learned a great deal of new material from Part I of the book because old concepts were explained in new ways that improved my understanding. I suspect other readers will have one or two "Aha!" experiences from this tome as well.

But it's when making the case for full-duplex Gigabit Ethernet and exploring the requirements for switching and routing behaviors in Gigabit Ethernet networking devices that this material really shines.

Without a doubt, this book is among the very best of any of the literature available on high-speed networking today. I give it an A+ rating, not only because of the breadth and depth of its technical coverage and its compilation of essential concepts and information, but also because the author's deep understanding of networking protocols and communications needs enlivens all of his discussions of matters technical, business, and political. If you want to understand Gigabit Ethernet, this book is the obvious place to begin (and for many, to end) your search for enlightenment.

But even if all you want is a good read about expensive, exotic, and high-performance technology, Seifert's book offers the opportunity for outright enjoyment of the prose, and shared delight at untangling the technical dilemmas that any good design engineer must unravel on the road between a set of requirements and working implementation thereof.

Fragments

More on The Future of the Domain Name System (DNS)

Shortly after our first issue went to press, the US Government issued a so-called White Paper as a follow on to the Green Paper. The White Paper, entitled "Management of Internet Names and Addresses," can be found at:

http://www.ntia.doc.gov/ntiahome/domainname/domainhome.htm

In early July, *The International Forum on The White Paper* (IFWP) was formed. The IFWP is "an ad hoc coalition of professional, trade and educational associations representing a diversity of Internet stakeholder groups." The IFWP held a series of meetings in Reston, Brussels, Geneva, Singapore and Buenos Aires to discuss the White Paper, specifically the incorporation of the *Internet Assigned Numbers Authority* (IANA). For more information on the IFWP process, see: **http://www.ifwp.org**

The IANA has posted draft bylaws for its incorporation on the IANA web site at: **http://www.iana.org**, and asked for community input. By the time you read this, the incorporation should already have taken place. We will provide an update in our next issue.

IETF Wins Award

The *Computer Professionals for Social Responsibility* (CPSR) has chosen the *Internet Engineering Task Force* (IETF) to be honored with the Norbert Wiener award for the group's influential role in the evolution of the Internet. In its 12-year history, this is only the second time the CPSR has recognized an organization rather than an individual. The IETF will accept the award at CPSR's annual conference, on Saturday evening, October 10, 1998, in Boston. The IETF is noted for its highly open and democratic processes that have affected the development of the Internet. The CPSR believes that such open processes are both extremely important and seriously threatened, and have accordingly made Internet governance the focus of its 1998 program year. The Norbert Wiener award was established in 1987 by the CPSR in memory of the originator of the field of cybernetics, whose pioneering work was one of the pillars on which the computer technology was created. See: **http://www.cpsr.org** and **http://www.ietf.org**

From The Editor

The *Simple Network Management Protocol* (SNMP) was first standardized in 1988. It quickly became a de facto management standard, not only for Internet technologies, but for a wide range of applications. Like many early Internet protocols, the first two versions of SNMP did not include provisions for security. In 1996, two different proposals for security enhancements to SNMPv2 were put forward, with strong proponents behind each. Everyone agreed that the industry needed just *one* solution, and therefore work proceeded to incorporate the best features of the two security proposals for SNMPv2. The result is SNMPv3, and it is described in this issue by William Stallings.

As the Internet continues to grow, demand for high-speed access for residential users is increasing. Alternatives to traditional dialup service include *Digital Subscriber Line* (DSL) services, wireless solutions, and various television technologies. In this issue, we examine two aspects of Internet access using TV technologies. First, Mark Laubach gives an overview of cable modem technologies and standards, and discusses some deployment issues. In the second article, George Abe looks at the emerging digital television standards and how they could be used to provide Internet access.

The Internet lost one of its most respected pioneers when Jon Postel passed away on October 16, 1998. Jon was well-known as the Director of the *Internet Assigned Numbers Authority* (IANA) and as the editor of the *Request for Comments* (RFC) document series. Included in this issue is "I Remember IANA," a tribute to Jon Postel written by his longtime friend Vint Cerf. The remembrance has also been published as RFC 2468.

With that we have come to the end of 1998 and the end of Volume 1 of *The Internet Protocol Journal*. We wish you a pleasant holiday season and will be back with Volume 2, Number 1 in March 1999. In the meantime, please visit our Web site at **www.cisco.com/ipj**. There you will find back issues in PDF format, our Call for Papers and guidelines for authors of IPJ articles.

Security Comes to SNMP: The New SNMPv3 Proposed Internet Standards

by William Stallings

Data networks typically include bridges, routers, links into WANs, and end-user equipment from multiple vendors. Users need automated tools to help manage such configurations that are easy to install, easy to use, and don't place a great burden on the network.

This accounts for the popularity of the *Simple Network Management Protocol* (SNMP). Introduced in 1988 to provide management capability for TCP/IP-based networks, SNMP rapidly became the most widely used standardized network management tool. Virtually all vendors of network-based equipment provide SNMP.

The appeal of SNMP has indeed been its simplicity because SNMP provides a bare-bones set of functions, and it is indeed easy to implement, install, and use. And, used sensibly, it will not place undue burden on the network. Moreover, because of its simplicity, achievement of interoperability is a relatively straightforward task: SNMP modules from different vendors can be made to work together with minimal effort.

SNMP—Strengths and Weaknesses

SNMP is based on three concepts: *managers, agents,* and the *Management Information Base* (MIB). In any configuration, at least one manager node runs SNMP management software. Network devices to be managed, such as bridges, routers, servers, and workstations, are equipped with an agent software module. The agent is responsible for providing access to a local MIB of objects that reflects the resources and activity at its node. The agent also responds to manager commands to retrieve values from the MIB and to set values in the MIB. An example of an object that can be retrieved is a counter that keeps track of the number of packets sent and received over a link into the node; the manager can track this value to monitor the load at that point in the network. An example of an object that can be set is one that represents the state of a link; the manager could disable the link by setting the value of the corresponding object to the disabled state.

Such capabilities are fine for implementing a basic network-management system. To enhance this basic functionality, a new version of SNMP was introduced in 1993 and revised in 1996. SNMPv2 added bulk transfer capability and other functional extensions. However, neither SNMPv1 nor SNMPv2 offers security features. Specifically, SNMPv1/v2 can neither authenticate the source of a management message nor provide encryption. Without authentication, it is possible for nonauthorized users to exercise SNMP network management functions. It is also possible for nonauthorized users to eavesdrop on

management information as it passes from managed systems to the management system. Because of these deficiencies, many SNMPv1/v2 implementations are limited to simply a read-only capability, reducing their utility to that of a network monitor; no network control applications can be supported.

Enter SNMPv3

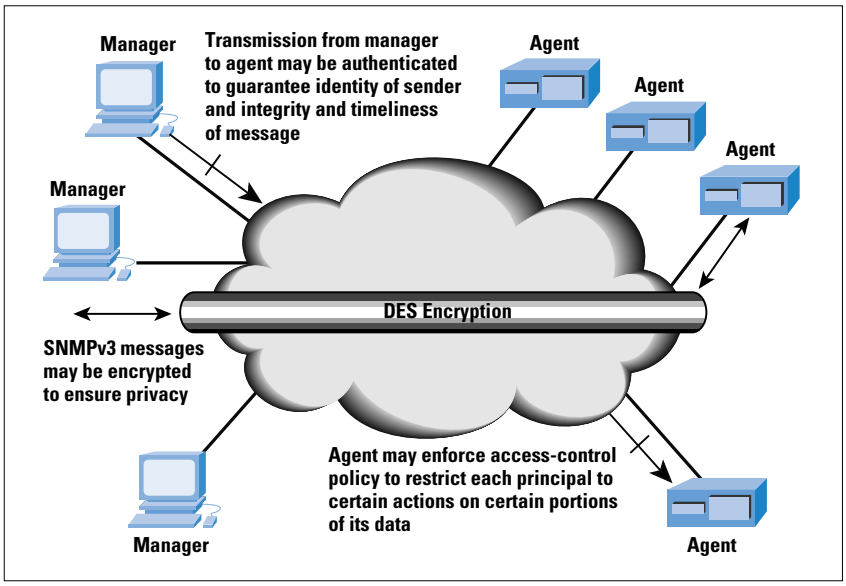
To correct the security deficiencies of SNMPv1/v2, SNMPv3 was issued as a set of Proposed Standards in January 1998 (Table 1). This set of documents does not provide a complete SNMP capability but rather defines an overall SNMP architecture and a set of security capabilities. These are intended to be used with the existing SNMPv2. As one of the SNMPv3 working documents puts it, "SNMPv3 is SNMPv2 plus administration and security."

Table 1: SNMPv3 RFCs

RFC Number	Title
2271	An Architecture for Describing SNMP Management Frameworks
2272	Message Processing and Dispatching for the Simple Network Management Protocol (SNMP)
2273	SNMPv3 Applications
2274	User-Based Security Model for SNMPv3
2275	View-Based Access Control Model (VACM) for SNMP

SNMPv3 includes three important services: *authentication, privacy,* and *access control* (Figure 1). To deliver these services in a flexible and efficient manner, SNMPv3 introduces the concept of a *principal*, which is the entity on whose behalf services are provided or processing takes place. A principal can be an individual acting in a particular role; a set of individuals, with each acting in a particular role; an application or set of applications; or combinations thereof. In essence, a principal operates from a management station and issues SNMP commands to agent systems. The identity of the principal and the target agent together determine the security features that will be invoked, including authentication, privacy, and access control. The use of principals allows security policies to be tailored to the specific principal, agent, and information exchange, and gives human security managers considerable flexibility in assigning network authorization to users.

Figure 1: SNMPv3 Security Features



SNMPv3 is defined in a modular fashion, as shown in Figure 2. Each SNMP entity includes a single SNMP *engine*. An SNMP engine implements functions for sending and receiving messages, authenticating and encrypting/decrypting messages, and controlling access to managed objects. These functions are provided as services to one or more applications that are configured with the SNMP engine to form an SNMP *entity*. This modular architecture provides several advantages. First, the role of an SNMP entity is determined by the modules that are implemented in that entity. For example, a certain set of modules is required for an SNMP agent, whereas a different (though overlapping) set of modules is required for an SNMP manager. Second, the modular structure of the specification lends itself to defining different versions of each module. This, in turn, makes it possible to (1) define alternative or enhanced capabilities for certain aspects of SNMP without needing to go to a new version of the entire standard (for example, SNMPv4), and (2) clearly specify coexistence and transition strategies.

Figure 2: SNMP Entity (RFC 2271)

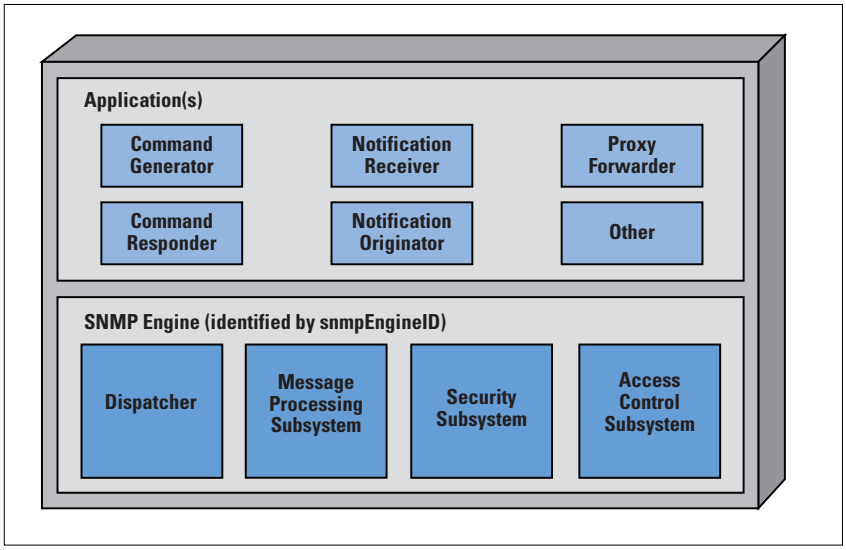


Table 2 provides a brief definition of each module.

Table 2: Components of an SNMP Entity (RFC 2271 and 2273)

Dispatcher	Allows for concurrent support of multiple versions of SNMP messages in the SNMP engine. It is responsible for (1) accepting protocol data units (PDUs) from applications for transmission over the network and delivering incoming PDUs to applications; (2) passing outgoing PDUs to the Message Processing Subsystem to prepare as messages, and passing incoming messages to the Message Processing Subsystem to extract the incoming PDUs; and (3) sending and receiving SNMP messages over the network.
Message Processing Subsystem	Responsible for preparing messages for sending and for extracting data from received messages.
Security Subsystem	Provides security services such as the authentication and privacy of messages. This subsystem potentially contains multiple Security Models.
Access Control Subsystem	Provides a set of authorization services that an application can use for checking access rights. Access control can be invoked for retrieval or modification request operations and for notification generation operations.
Command Generator	Initiates SNMP Get, GetNext, GetBulk, or Set request PDUs and processes the response to a request that it has generated.
Command Responder	Receives SNMP Get, GetNext, GetBulk, or Set request PDUs destined for the local system as indicated by the fact that the contextEngineID in the received request is equal to that of the local engine through which the request was received. The command responder application performs the appropriate protocol operation, using access control, and generates a response message to be sent to the originator of the request.
Notification Originator	Monitors a system for particular events or conditions, and generates Trap or Inform messages based on these events or conditions. A notification originator must have a mechanism for determining where to send messages, and which SNMP version and security parameters to use when sending messages.
Notification Receiver	Listens for notification messages, and generates response messages when a message containing an Inform PDU is received.
Proxy Forwarder	Forwards SNMP messages. Implementation of a proxy forwarder application is optional.

SNMPv3 Message Processing

SNMPv3 relies on the *User Datagram Protocol* (UDP) or some other transport-layer protocol to convey SNMP information. Above the UDP layer, SNMP functionality is organized into two application-level layers: a PDU processing layer and a message processing layer.

The topmost layer is the PDU processing layer. At this layer, management commands (such as Get, Set, Trap, Inform) are realized in a PDU that includes an indication of the command type and a list of variables (management objects) to which the command refers. This PDU is then passed down to the message processing layer, which adds a message header. The message header contains security-related information that may be used for authentication and privacy operations.

Figure 3 illustrates the message structure. The first five fields are generated by the message processing model on outgoing messages and processed by the message processing model on incoming messages. The next six fields show security parameters used by the security model, which is invoked by the message processing model to provide security services. Finally, the PDU, together with the contextEngineID and contextName, constitute a scoped PDU, used for PDU processing.

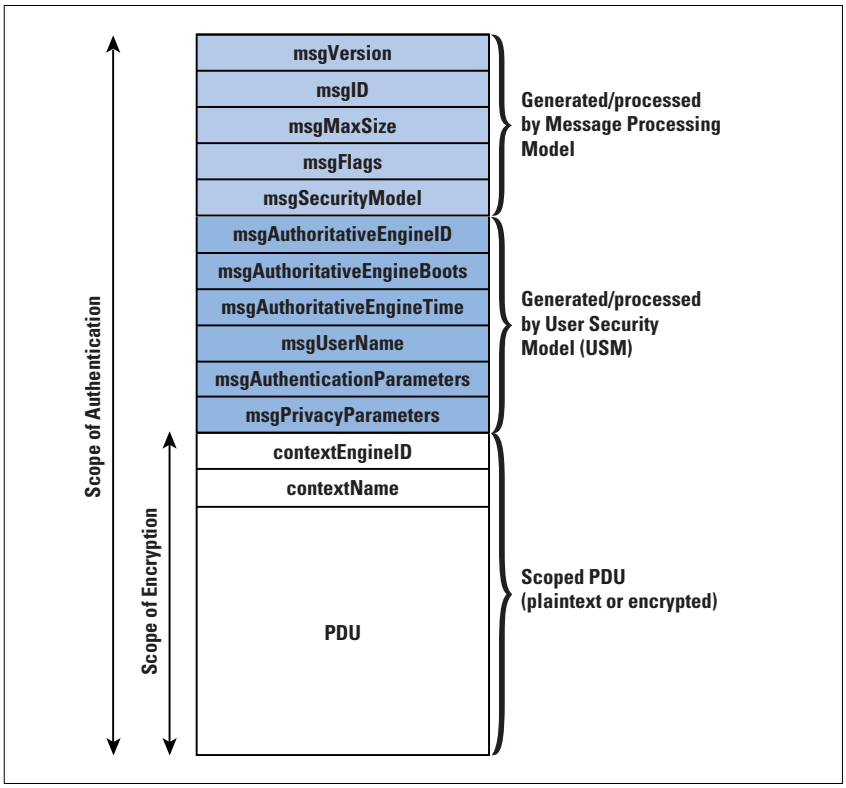

Figure 3: SNMPv3 Message Format with User-Based Security Model

The first five fields follow:

- *msgVersion:* Set to snmpv3(3).
- *msgID:* A unique identifier used between two SNMP entities to coordinate request and response messages, and by the message processor to coordinate the processing of the message by different subsystem models within the architecture. The range of this ID is 0 through 2^{31}–1.

- *msgMaxSize:* Conveys the maximum size of a message in octets supported by the sender of the message, with a range of 484 through 2^{31}–1. This is the maximum segment size that the sender can accept from another SNMP engine (whether a response or some other message type).

- *msgFlags:* An octet string containing three flags in the least significant three bits: reportableFlag, privFlag, authFlag. If reportableFlag = 1, then a Report PDU must be returned to the sender under those conditions that can cause the generation of a Report PDU; when the flag is zero, a Report PDU may not be sent. The reportableFlag is set to 1 by the sender in all messages containing a request (Get, Set) or an Inform, and set to 0 for messages containing a Response, a Trap, or a Report PDU. The reportableFlag is a secondary aid in determining when to send a Report. It is used only in cases in which the PDU portion of the message cannot be decoded (for example, when decryption fails because of incorrect key). The privFlag and authFlag are set by the sender to indicate the security level that was applied to the message. For privFlag = 1, encryption was applied and for privFlag = 0, authentication was applied. All combinations are allowed except (privFlag = 1 AND authFlag = 0); that is, encryption without authentication is not allowed.

- *msgSecurityModel:* An identifier in the range of 0 through 2^{31}–1 that indicates which security model was used by the sender to prepare this message and, therefore, which security model must be used by the receiver to process this message. Reserved values include 1 for SNMPv1, 2 for SNMPv2c, and 3 for SNMPv3.

User-Based Security Model

The *User-Based Security Model* (USM) uses the concept of an authoritative engine. In any message transmission, one of the two entities, transmitter or receiver, is designated as the authoritative SNMP engine, according to the following rules:

- When an SNMP message contains a payload that expects a response (for example, a Get, GetNext, GetBulk, Set, or Inform PDU), then the receiver of such messages is authoritative.

- When an SNMP message contains a payload that does not expect a response (for example, an SNMPv2-Trap, Response, or Report PDU), then the sender of such a message is authoritative.

Thus, for messages sent on behalf of a Command Generator and for Inform messages from a Notification Originator, the receiver is authoritative. For messages sent on behalf of a Command Responder or for Trap messages from a Notification Originator, the sender is authoritative. This designation serves two purposes:

- The timeliness of a message is determined with respect to a clock maintained by the authoritative engine. When an authoritative engine sends a message (Trap, Response, Report), it contains the current value of its clock, so that the nonauthoritative recipient can synchronize on that clock. When a nonauthoritative engine sends a message (Get, GetNext, GetBulk, Set, Inform), it includes its current estimate of the time value at the destination, allowing the destination to assess the timeliness of the message.

- A key localization process, described later, enables a single principal to own keys stored in multiple engines; these keys are localized to the authoritative engine in such a way that the principal is responsible for a single key but avoids the security risk of storing multiple copies of the same key in a distributed network.

When an outgoing message is passed to the USM by the Message Processor, the USM fills in the security-related parameters in the message header. When an incoming message is passed to the USM by the Message Processor, the USM processes the values contained in those fields. The security-related parameters include the following:

- *msgAuthoritativeEngineID:* The snmpEngineID of the authoritative SNMP engine involved in the exchange of this message. Thus, this value refers to the source for a Trap, Response, or Report, and to the destination for a Get, GetNext, GetBulk, Set, or Inform.

- *msgAuthoritativeEngineBoots:* The snmpEngineBoots value of the authoritative SNMP engine involved in the exchange of this message. The object snmpEngineBoots is an integer in the range 0 through $2^{31}-1$ that represents the number of times that this SNMP engine has initialized or reinitialized itself since its initial configuration.

- *msgAuthoritativeEngineTime:* The snmpEngineTime value of the authoritative SNMP engine involved in the exchange of this message. The object snmpEngineTime is an integer in the 0 through $2^{31}-1$ range that represents the number of seconds since this authoritative SNMP engine last incremented the snmpEngineBoots object. Each authoritative SNMP engine is responsible for incrementing its own snmpEngineTime value once per second. A non-authoritative engine is responsible for incrementing its notion of snmpEngineTime for each remote authoritative engine with which it communicates.

- *msgUserName:* The user (principal) on whose behalf the message is being exchanged.

- *msgAuthenticationParameters:* Null if authentication is not being used for this exchange; otherwise, this is an authentication parameter. For the current definition of USM, the authentication parameter is a message authentication code generated using an algorithm referred to as HMAC.

- *msgPrivacyParameters:* Null if privacy is not being used for this exchange; otherwise, this is a privacy parameter. For the current definition of USM, the privacy parameter is a parameter used in the encryption algorithm DES.

Secret-Key Authentication

The authentication mechanism in SNMPv3 assures that a received message was, in fact, transmitted by the principal whose identifier appears as the source in the message header. In addition, this mechanism assures that the message was not altered in transit and that it was not artificially delayed or replayed.

To achieve authentication, each pair of principal and remote SNMP engines that wishes to communicate must share a secret authentication key. The sending entity provides authentication by including a message authentication code with the SNMPv3 message it is sending. This code is a function of the contents of the message, the identity of the principal and engine, the time of transmission, and a secret key that should be known only to the sender and the receiver. The secret key must initially be set up outside of SNMPv3 as a configuration function. That is, the configuration manager or network manager is responsible for distributing initial secret keys to be loaded into the databases of the various SNMP managers and agents. This can be done manually or by using some form of secure data transfer outside of SNMPv3. When the receiving entity gets the message, it uses the same secret key to calculate the message authentication code again. If the receiver's version of the code matches the value appended to the incoming message, then the receiver knows that the message can only have originated from the authorized manager, and that the message was not altered in transit. The shared secret key between sending and receiving parties must be preconfigured.

Another aspect of USM authentication is timeliness verification. USM is responsible for assuring that messages arrive within a reasonable time window to protect against message delay and replay attacks. Two functions support this service: synchronization and time-window checking.

Each authoritative engine maintains two values, snmpEngineBoots and snmpEngineTime, that keep track of the number of boots since initialization and the number of seconds since the last boot. These values are placed in outgoing messages in the fields msgAuthoritativeEngineBoots and msgAuthoritativeEngineTime. A nonauthoritative engine maintains synchronization with an authoritative engine by maintaining local copies of snmpEngineBoots and snmpEngineTime for each remote authoritative engine with which it communicates. These values are updated on receipt of an authentic message from the remote authoritative engine. Between these message updates, the nonauthoritative

engine increments the value of snmpEngineTime for the remote authoritative engine to maintain loose synchronization. These values are inserted in outgoing messages intended for that authoritative engine.

When an authoritative engine receives a message, it compares the incoming boot and time values with its own boot and time values. If the boot values match and if the incoming time value is within 150 seconds of the actual time value, then the message is declared to be within the time window and, therefore, to be a timely message.

Privacy Using Conventional Encryption

The SNMPv3 USM privacy facility enables managers and agents to encrypt messages to prevent eavesdropping by third parties. Again, manager entity and agent entity must share a secret key. When privacy is invoked between a principal and a remote engine, all traffic between them is encrypted using the *Data Encryption Standard* (DES). The sending entity encrypts the entire message using the DES algorithm and its secret key, and sends the message to the receiving entity, which decrypts it using the DES algorithm and the same secret key. Again, the two parties must be configured with the shared key.

The *cipher-block-chaining* (CBC) mode of DES is used by USM. This mode requires that an initial value (IV) be used to start the encryption process. The msgPrivacyParameters field in the message header contains a value from which the IV can be derived by both sender and receiver.

View-Based Access Control Model (VACM)

The access control facility makes it possible to configure agents to provide different levels of access to the agent's MIB to different managers. An agent entity can restrict access to its MIB for a particular manager entity in two ways. First, it can restrict access to a certain portion of its MIB. For example, an agent may restrict most manager principals to viewing performance-related statistics and allow only a single designated manager principal to view and update configuration parameters. Second, the agent can limit the operations that a principal can use on that portion of the MIB. For example, a particular manager principal could be limited to read-only access to a portion of an agent's MIB. The access control policy to be used by an agent for each manager must be preconfigured; it essentially consists of a table that details the access privileges of the various authorized managers. Unlike authentication, which is done by user, access control is done by group, where a group may be a set of multiple users.

Figure 4:
VACM Flowchart

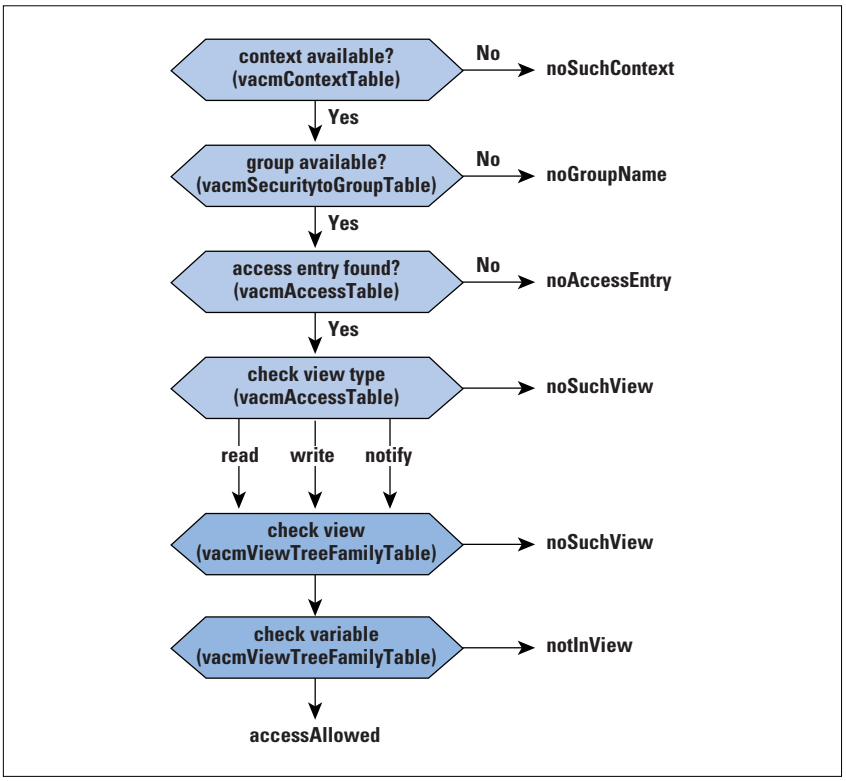

Figure 4 illustrates the overall VACM logic, which proceeds in the following steps:

1. The context name refers to a named subset of the MIB objects at an agent. VACM checks to see if there is an entry in vacmContextTable for the requested contextName. If so, then this context is known to this SNMP engine. If not, then an errorIndication of noSuchContext is returned.

2. Each principal operating under a given security model is assigned to at most one group, and access privileges are configured on a group basis. VACM checks vacmSecurityToGroupTable to determine if there is a group assigned to the requested <securityModel, securityName> pair. If so, then this principal, operating under this securityModel, is a member of a group configured at this SNMP engine. If not, then an errorIndication of noGroupName is returned.

3. VACM next consults the vacmAccessTable with groupName, contextName, securityModel, and securityLevel (indicates authentication, authentication plus privacy, or neither) as indices. If an entry is found, then an access control policy has been defined for this groupName, operating under this securityModel, at this securityLevel, for access to this contextName. If not, then an errorIndication of noAccessEntry is returned.

4. A MIB view is a structure subset of a context; it is essentially a set of managed object instances viewed as a set for access control purposes. VACM determines whether the selected vacmAccessTable entry includes reference to a MIB view of viewType (read, write, notify). If so, then this entry contains a viewName for this combination of groupName, contextName, securityModel, securityLevel, and viewType. If not, then an errorIndication of noSuchView is returned.

5. The viewName from Step 4 is used as an index into vacmViewTreeFamilyTable. If a MIB view is found, then a MIB view has been configured for this viewName. If not, then an errorIndication of noSuchView is returned.

6. VACM checks the variableName against the selected MIB view. If this variable is included in the view, then a statusInformation of accessAllowed is returned. If not, then an errorIndication of notInView is returned.

Residential Area CATV Broadband Internet Technology: Current Status

by Mark Laubach, Com21, Inc.

Cable modem technology has entered commonplace discussion and is in the early stages of widespread deployment throughout the world. The capabilities provided by cable modems promise data bandwidth speeds far in excess of those provided by traditional telephone modem services. In North America the race is on between cable operators deploying services based on standardized cable modems and telephone companies deploying *Digital Subscriber Line* (DSL) services. Internet Service Providers (ISPs) are taking position to promote any method of delivering Internet services to and from the home and are helping to fuel the race. Initially these services will only provide higher-speed Internet access and improved access to major information services (for example, AOL). Cable modem service offerings promote higher than DSL speed to the subscriber and a promise that packet voice services will be available in 1999.

As an introduction to some of the issues surrounding cable modem technology, this article summarizes two of the standardization efforts: the IEEE 802.14 Cable TV Media Access Control and Physical Protocol working group and the North American Data Over Cable Service Interface Specification. Delivering a viable Internet service to a cable TV reached subscriber community has its own set of deployment issues that are briefly reviewed and summarized.

Background

Networks based on packet technology were first presented in 1964[1]. Since then, and through numerous evolutionary steps, the Internet as we know it today was brought into existence. Today, packets are transmitted over most any media. The next economic and technical frontier is the mass deployment of moving packets over cable television (CATV) networks for serving the Internet to every home. There are several link layer approaches for delivering IP datagrams via cable modems. The always present debate of whether to use fixed or variable length packets continues in the cable modem world. This article presents overviews of two variations of cable modem protocols: first, the concept of sending small, fixed-sized packets over the CATV plant using 53-octet *Asynchronous Transfer Mode* (ATM) cells[2], as is being defined in the public standards process of the IEEE 802.14 working group; and secondly, by sending variable-length packets (IP over Ethernet) as defined by the *Multimedia Cable Network System* (MCNS) *Data Over Cable Service Interface Specification* (DOCSIS) for the North American cable industry[3]. As widely accepted standards normally motivate industrial focus and subsequent cost reduction due to vendor competitive pressures, there is an additional drive provided by North American cable operators to get the cost of the cable modem off their books and into retail channels.

The IEEE 802.14 Cable TV MAC and PHY Protocol working group is chartered with providing a single *Media Access Control* (MAC) and multiple physical sublayer (PHY) standard for cable TV networks. The efforts of 802.14 must support IEEE 802 layer services (including Ethernet) and must also be ATM compatible.

The DOCSIS specifications are managed by CableLabs on behalf of its cable television system operator members. The project was initiated by an organization called *Multimedia Cable Network System* (MCNS) Partners, L. P., which consists of Comcast Cable Communications, Cox Communications, Tele-Communications, Inc., and Time Warner Cable. In addition to MCNS, Rogers Cablesystems Limited, MediaOne, and CableLabs have all contributed to the DOCSIS documents, as have several networking and telecommunications vendors. DOCSIS documents describe the internal and external network interfaces for a system that allows bidirectional transfer of IP traffic, between the cable system head-end and customer premises, over a cable television system[4].

The customer network interface in common use today is Ethernet 10BaseT. There is a mandate for a 10 Mbps Ethernet interface in the home. Subscriber access equipment can be a personal computer, X-Terminal, or any such device that supports the TCP/IP protocol suite. Future home interfaces from the cable modem will include the *Universal Serial Bus* (USB) and IEEE 1394 (*FireWire*).

IP Over CATV System Challenges

From an IP perspective, a CATV system almost appears to be another data link layer. However, experience gained thus far has demonstrated that the marriage of IP over CATV radio frequency (RF) channels is not as straightforward as IP over any other high-speed serial point-to-point link.

In the CATV space, the downstream channels in a cable plant (cable head-end to subscribers) is a point-to-multipoint channel. This does have very similar characteristics to transmitting over an Ethernet segment where one transmitter is being listened to by many receivers. The major difference is that baseband modulation has been replaced by a more densely modulated RF carrier with very sophisticated adaptive signal processing and *forward error correction* (FEC).

In the upstream direction (subscriber cable modems transmitting towards the head-end) the environment is many transmitters and one receiver. This introduces the need for precise scheduling of packet transmissions to achieve high utilization and precise power control so as to not overdrive the receiver or other amplifier electronics in the cable system. Since the upstream direction is like a single receiver with many antennas, the channels are much much more susceptible to interfering noise products[5, 6]. In the cable industry, we generally

call this *ingress noise*. As ingress noise is an inherent part of CATV plants, the observable impact is an unfortunate rise in the average noise floor in the upstream channel. To overcome this noise jungle, upstream modulation is not as dense as in the downstream and we have to use more effective FEC as used in the downstream. There is a further complication that there are many upstream "ports" on a fully deployed *Hybrid Fiber-Coaxial* (HFC) plant that requires matching head-end equipment ports for high-speed data[7].

To further the rub on the upstream channel use, the arcane regulations of the FCC from back in the mid 1980s mandated that upstream frequency spectrum be reserved on all cable plants, regardless of whether it was actually used. This was typically the 5–42 MHz region, leaving above 50 MHz for downstream transmissions. (Note that there are other regions available for upstream, but the overwhelming majority of cable plants only use 5–42 MHz.) This leaves precious little spectral bandwidth for upstream communications.

The existing environment for high-speed data protocols therefore provides for relatively clean bandwidth in the downstream direction, allowing for higher-speed data rate channels, while in the upstream, individual channels are of lesser data rate. However, multiple upstream channels can be used per downstream channel to get effective symmetric aggregate bandwidth. Typically, we speak of cable modem systems as providing asymmetric services (higher downstream data rate than upstream). Note though that this asymmetry closely matches what we expect initially for residential high-speed data services. That is, many more subscribers at home pulling things off the Internet via web services, than pushing data back in.

Modern modulation techniques provide for a range of data carrying capability ("baud rate"). A low order modulation rate called *Quadrature Phase Shift Keying* (QPSK) provides for two data bits per symbol encoding. *Quadrature Amplitude Modulation* (QAM) provides a lower order modulation of 16 QAM (four bits per symbol) through higher order rates of 64 QAM (six bits per symbol) and 254 QAM (eight bits per symbol). Low order modulations are more robust in higher average noise environments. Higher order modulations are least robust. Therefore, high order modulations are suitable for downstream channels due to the low noise performance, while the order of upstream channel modulation is heavily effected by noise. Typically, cable modem systems will see QPSK used for upstream channels. When the plant is very clean, noise-wise, 16 QAM may be used.

One additional challenge is that the speed of RF signals in fiber and coaxial cable is much less than the speed of light. For system deployments to be effective, the cable modem protocols must support cable modems out to a wire distance of 50 miles (80 km).

At these distances the round trip propagation delay will be on the order of 800 microseconds; which is several times the length of time it takes to transmit a 64-byte packet on the upstream channel. The IEEE and DOCSIS cable modem protocols have been engineered to overcome these propagation delays in order to increase channel utilization; that is demand-based scheduling of a slotted upstream channel coupled with precise station ranging and timing.

Another challenge is in using an IP-over Ethernet approach to providing a reliable public switched packet service to an abundance of subscribers. Traditional Ethernet networking has always relied on all the Ethernet stations being within the same administrative walls with all users sharing the same common interests. Not so with metropolitan area public access networks. Data communications must now be encrypted such that the privacy of user communications is not invaded by promiscuous neighbors. In addition, users are paying for access in this cable modem world, and any abusive behavior of users must be contained so as to not affect other users. This calls for sophisticated fairness scheduling in the head-end systems and the use of comprehensive cryptological and packet filtering techniques. It is all very complicated both to create, and to manage. Each standard has its own approach for dealing with these issues.

Where IP over CATV appeared to be fundamentally similar to Ethernet when the industry first started out, in reality it is not. High-speed cable data networking, as demonstrated by the work output from various standards activities, is fundamentally a new approach to what at first appeared to be similar old problems. It's not ALOHA anymore[8], nor is it your grandfather's Ethernet[9, 10].

IEEE 802.14 Cable TV MAC and PHY Protocol Working Group

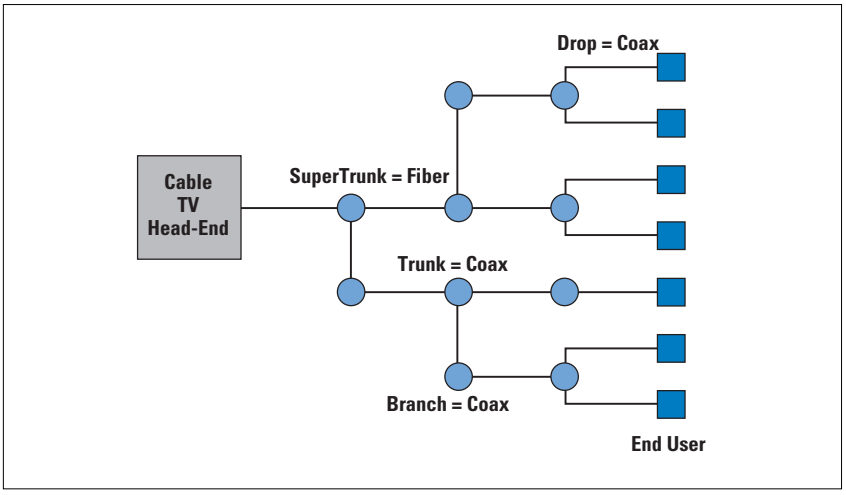
Let's briefly examine the first comprehensive standard activity created to address the current emerging world of high-speed cable data systems. In November 1994, the IEEE 802.14 CATV MAC and PHY Protocol working group met for the first time as an approved project within the 802 standards committee. Previous work had been done in 1993 through 1994 in the 802.catv study group in preparation for formal IEEE 802 project approval. The *Project Authorization Request* (PAR) charter of the group specifies that it will standardize a single MAC layer protocol and multiple PHY layer protocols for two-way HFC networks. Consistent with the IEEE LAN/MAN 802 Reference Model[11], 802.14 is producing a solution that supports the 802 protocol stack while at the same time supporting ATM in an ATM-compatible manner.

The general 802.14 requirements include:

- Communications support for all coaxial and hybrid fiber-coaxial cable TV network tree and branch topologies. (See Figure 1)

- Support of symmetrical and asymmetrical rates
- Support of *Operation, Administrations, and Maintenance* (OAM) functions
- Support of one-way delays on the order of 400 microseconds (round-trip delays to 800 microseconds)
- Support of a large number of users
- Support for moving data from an originating subnetwork to a destination subnetwork, which may be the same or a different one

Figure 1: CATV Tree and Branch Network



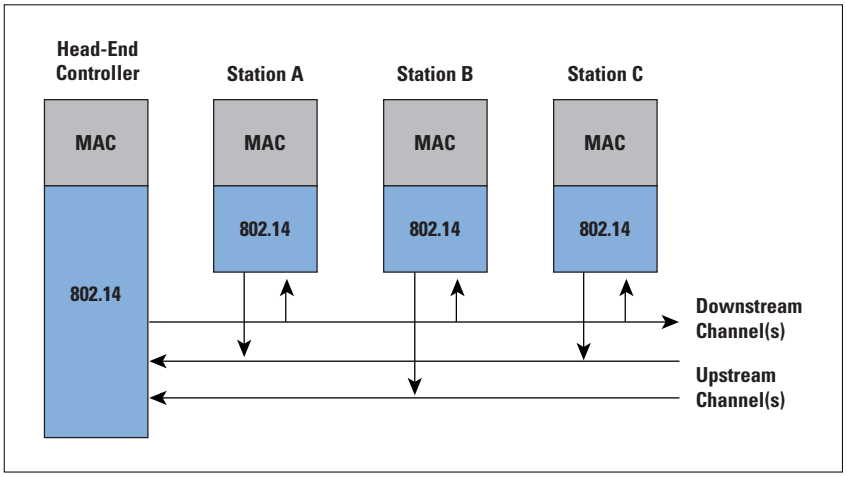
The working group completed a first-release revision of a functional requirements document back in 1995[12], which detailed the 802.14 cable topology model; defined key assumptions, constraints, and parameters; defined key performance metrics and criteria for the selection of multiple PHY protocols and a MAC protocol; and defined the support of *Quality-of-Service* (QoS) parameters. The working group's work plan called for the close of formal proposals in November 1995, with the recommended protocol defined in July 1996. Seventeen MAC protocol proposals were submitted to the working group. Needless to say, it took awhile for the working group to sort through all the issues and opinions. After much consideration, debate, and wrangling of both solutions and personalities, IEEE 802.14 stabilized on a working group draft in September 1998. This working group draft is now being submitted through the IEEE 802 standard approval process.

The 802.14 MAC and PHY specification includes:

- Definition and operational specifications for cable system Head-End Controller and cable modem Stations. (See Figure 2)
- Support of both connectionless and connection-oriented services

- Support of a formal QoS for connections; support for dynamically allocated bandwidth for different types of traffic, including *Constant Bit Rate* (CBR), *Variable Bit Rate* (VBR), and *Available Bit Rate* (ABR)
- Support for unicast, multicast, and broadcast services; interoperability with ATM
- Predictable low-average access delay without sacrificing network throughput
- Fair arbitration for shared access to the network within any level of service
- Downstream channel support for 64 QAM or 256 QAM modulation
- Compatibility for both international and North American downstream digital video standards
- Upstream channel support for QPSK or 16 QAM modulation

Figure 2: IEEE 802.14 General Model



The selection of ATM cells as the data link layer protocol data unit for IEEE 802.14 networks has the advantage that it provides a suitable integrated multiplexing platform capable of supporting a mix of guaranteed (predictive) traffic flows with best-effort (reactive) traffic flows. See Figure 3. Cable operators can deploy IEEE 802.14 based ATM systems as part of an evolutionary path to a fully integrated multimedia bearer service offering. A residential ATM bearer service easily supports Internet access to the home via the Classical IP over ATM standards of the Internet Engineering Task Force[13] or by providing an IP over Ethernet adaptation overlay service[14]. The development of QoS scheduling support in the Head-End Controller is left for vendors to implement[15, 16, 17].

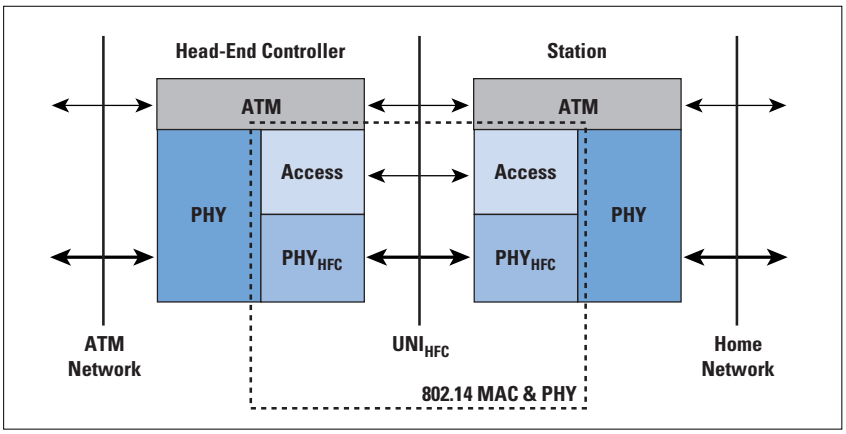
IEEE 802.14 ATM
Protocol Model



IEEE 802.14 Status

At the time of this writing, the IEEE 802.14 working group just finalized a working group draft suitable to introduction into the IEEE standards process. The entire IEEE process takes about a year from acceptance of the working group letter ballot to producing a published standard.

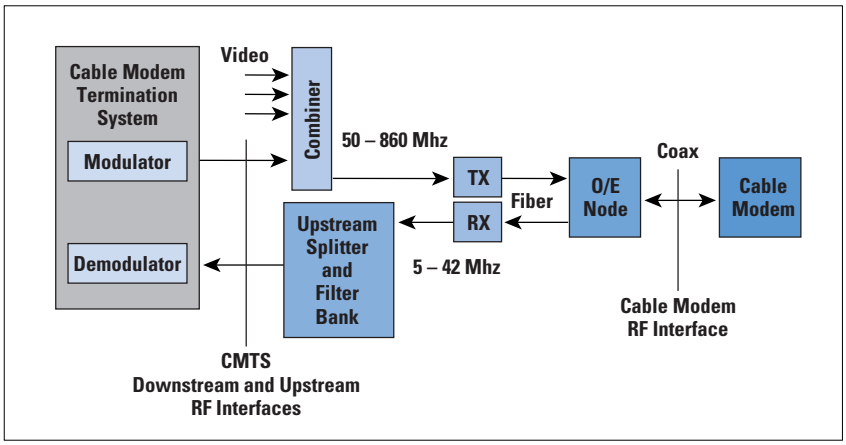
MCNS DOCSIS

The DOCSIS project is an activity of major cable companies and selected vendors to rapidly develop, on behalf of the North American cable industry, the necessary set of communications and operations support interface specifications for cable modems and associated equipment. The activity was triggered by John Malone in December 1995, in response to competition, vendor postures, and unfortunate lack of progress in the public standards process (that is, IEEE 802.14). The target for the specification was to produce a residential, "low-cost," off-the-shelf, Internet access service, with wide-scale vendor interoperability for base functions with sufficient hooks and room for vendor differentiation.

MCNS specifications are intended to be non-vendor specific, allowing cross-manufacturer compatibility for high-speed data communications services over two-way HFC cable television systems. MCNS met its specification release deadline and published versions of the *DOCSIS Radio Frequency (RF) Interface Specification* V1.0. The first draft specification was published in December 1996. The latest specification was published in July 1998[3]. The DOCSIS RFI protocol is based on the original LANCity symmetric 10 Mbps protocol, evolved to an asymmetric system, with multiple upstream and high-speed downstream (for example, 30 Mbps) channel support.

The MCNS system model is very similar to the IEEE 802.14 general model and includes many interfaces to a cable modem system, as shown in Figure 4. The goal of the DOCSIS project is to produce specifications for the CATV RF interfaces, including behavior of the *Cable Modem Termination System* (CMTS) and *Cable Modem* (CM) with respect to delivery of the residential IP over Ethernet service.

Figure 4: Data-Over-Cable RFI Reference Architecture



The DOCSIS RFI system is asymmetric, with one to several downstream channels operating asymmetrically with one to several upstream channels. Specific features of MCNS DOCSIS RFI Version 1.0 include:

- Switched Ethernet service for Internet transport via a variable length MAC packet protocol
- Best-effort service
- Downstream data channel rates from 20 Mbps (16 QAM) to 40 Mbps (256 QAM) with a typical configuration of 30 Mbps (64 QAM) in 6 MHz channels
- Compatibility for North American downstream digital video standards. (See article starting on page 27.)
- Downstream data channel rates selected from 320 Kbps (QPSK) through 10.24 Mbps (16 QAM). Channel spectral widths from 200 KHz to 3.2 MHz
- Software flexibility: ability to download new software to change/update CM behavior
- Many filters and features for controlling packet flow and classification
- Comprehensive MIB specifications for control of the cable modem and cable modem termination system
- A single large LAN segment

Due to the time-to-market push for DOCSIS RFI V1.0 interoperable modems, little to no attention was been given for QoS needs however, vendors will likely include some QoS support in their offerings. (Upstream packet fragmentation was removed from the December 1996 draft release.)

CMs and the CMTSs have basically the same protocol stack: downstream and upstream PHY, the DOCSIS RFI MAC, Ethernet and an Ethernet switching layer with substantial filtering, IP/*Address Resolution Protocol* (ARP), *User Datagram Protocol* (UDP), and *Simple Network Management Protocol/Dynamic Host Configuration Protocol/ Trivial File Transfer Protocol* (SNMP/DHCP/TFTP).

The DOCSIS RFI includes upstream and downstream optional packet encryption using the *Data Encryption Standard* (DES) to provide link privacy. RSA public key exchange is used between the CM and CMTS.

DOCSIS RFI Status

CableLabs is actively driving multiple vendor interoperability with the goal of having "silicon interoperability" as soon as possible for DOCSIS "certified" CMs and CMTSs. CableLabs runs a variety of test and certification laboratories in their facility. Numerous vendors are participating. It was the expectation to have many cable modem vendors certified by the cable industry major trade show, the Western Cable Show, in December, 1998. However, as interoperability does take time to work out, the process is taking longer than expected. There will likely be some certified vendors by December 1998, with many more in first quarter 1999. It is now expected that the first widespread deployments of DOCSIS cable modems will start in late first quarter 1999.

The DOCSIS project is currently updating the RFI Version 1.0 specification to include better support for bandwidth management and QoS support. The changes being studied include support for multiple *Service Identifiers* (SIDs), filters to perform the classification of IP packets to different SIDs for differentiated services (QoS), and the signaling support for dynamic SID creations and deletion. A scheme for packet fragmentation will be included which will give substantially better support for managing jitter for delay sensitive traffic, such as packet voice. The primary motivation for adding these extensions to DOCSIS RFI V1.0 is to provide for better support of packet voice and video over DOCSIS IP services. A major focus of the North American cable industry is to support "near toll quality" voice and video services via DOCSIS systems. The cable industry effort writing specification for packet voice and video is called *PacketCable*[18]. It is expected that the DOCSIS RFI V1.1 and initial PacketCable specifications will appear in December 1998.

DOCSIS RFI Version 1.0 was adopted by the *Society of Cable Television Engineers* (SCTE) Data Standards Subcommittee in July 1997 as the North American residential cable modem system standard.

Substantial work is in progress in the IETF *IP over Cable Data Networks* (ipcdn) working group to standardize the DOCSIS MIBs[19, 20] and to standardize IP over DOCSIS[21].

An IP over Cable Modem Example

This section presents a brief overview of a hypothetical IP over HFC system. It is meant to be an informative example to illustrate the application of the IP technology and some of the issues that surround provision of the service over a residential cable TV network. Moving IP datagrams in and out of the home over the cable plant is the important issue. The specific technology and protocols used by the cable modem vendor are important only in their ability to provide required IP service support.

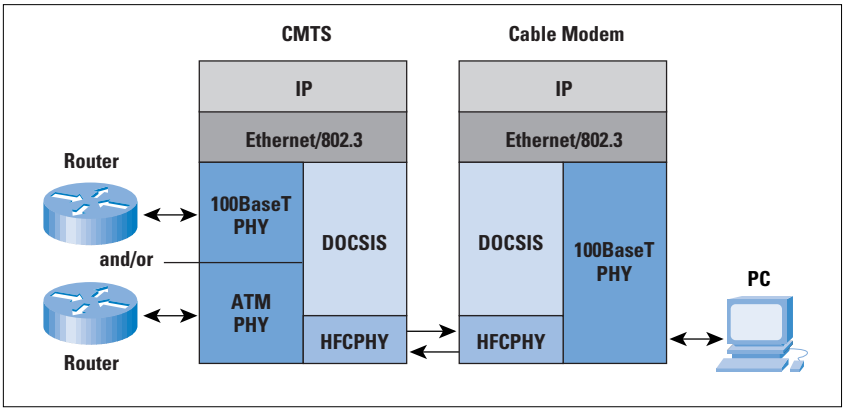
For this example, consider a system that has the following design goals and requirements:

- One-to-many service will be supported in the downstream direction; that is, many cable modems are reachable via the downstream channel
- Many-to-one service will be supported in the upstream direction; that is, the upstream channel bandwidth will be shared. There may be up to several upstream channels
- The protocol used between the Head-End Controller and the head-ends is not significant as long as it meets the needs of the IP service
- The head-end owns the upstream bandwidth and allocates resources to cable modems
- IP over Ethernet 10BaseT is the required interface in the home
- IP over Ethernet or IP over ATM is the required interface at the head-end

This example will rely on the DOCSIS RFI information presented previously in this article. The CMTS can transmit packets to any cable modem on the channel in any order or rate appropriate to the scheduling information it has and controls. The CMTS also participates in the IP multicast group membership (*Internet Group Management Protocol* [IGMP]) and IP *Resource Reservation Protocol* (RVSP) and makes changes in the cable modem resource assignments and allocations as needed. The home cable modem is permitted to use only the upstream channel under direction of the CMTS. Guaranteed and best-effort bandwidth allocations are dynamically assignable by the CMTS. It is assumed that the cable modem protocol has a bandwidth request facility that allows a CM to ask the CMTS for bandwidth. The function of the bandwidth management process is to sort these requests for service and give fair access to the requesting cable modems.

The method for implementation of an Ethernet and 802.3 bridging function over DOCSIS essentially permits the RF channels to act as a serial connection between a half-bridge function in each cable modem with a master in the CMTS. Figure 5 illustrates the protocol stack for this solution. The system presents an Ethernet-like segment to the cable operator. It is well-known how to put together such segments to construct larger internetworks.

Figure 5: Bridged Ethernet via DOCSIS Example



Cable modems provide demarcation between the Internet Service Provider's network and each home network. To help the Internet Service Provider offer fair access service to its residential customers, the cable modem will require sufficient dynamic functionality for multilayer protocol filtering and various forms of rate management (see Figure 6). The goal of this filter is to create a defense perimeter at the first point of entry to the cable network; this perimeter will protect the upstream channel from being saturated or abused by misbehaving home networks. Some examples of this filtering functionality include, but are not limited to:

- Filtering on Ethertype for permitting only certain protocols to pass upstream; for example, IP and ARP only
- Filtering on IP source or destination address to permit/deny access from the home network
- IP and Ethernet broadcast rate limiting; that is, keep any home network broadcast storms confined to the home network
- IP Multicast group address filtering; that is, explicitly permit participation of the home network in an IP multicast group

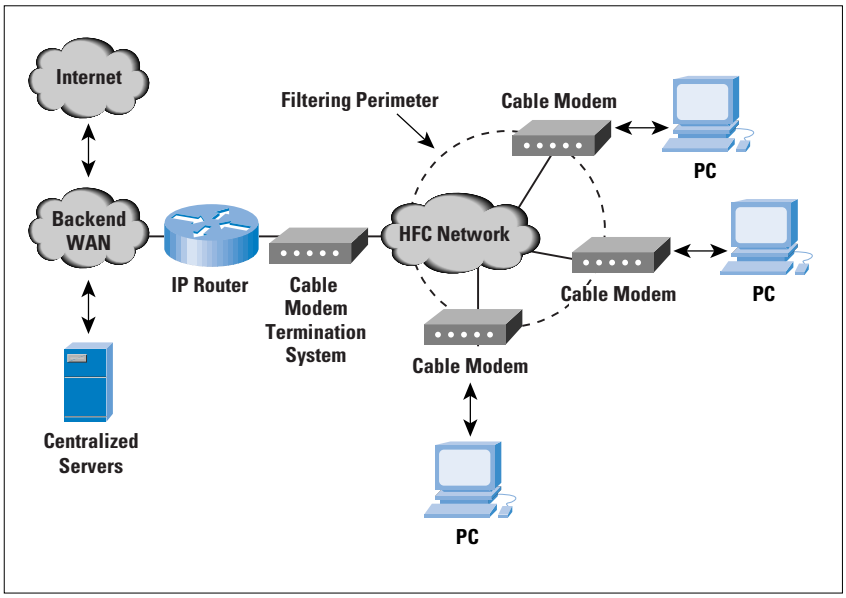


Figure 6: Internet Services via Cable Modem Deployment Model

It should be noted that these filtering functions are under consideration by numerous cable modem manufacturers, and they are being discussed in the IETF ipcdn working group.

A brief overview of IP over cable TV networks has been presented. From an engineering and deployment viewpoint, making the Internet move over cable modems is deceptively straightforward. Many issues are beyond the scope of this article: address allocation methods, back-end network design, configuration services, server placement, home customer support services, installation, firewalls, and troubleshooting.

Summary

This article has presented an overview of the work in progress of the IEEE 802.14 Cable TV MAC and PHY Protocol Standards working group and the MCNS DOCSIS effort. Initial review of these works is positive; indications are that data over HFC systems are viable. The IEEE 802.14 effort began as a study group in late 1993 and has yet to produce a standard. The MCNS DOCSIS process started in early 1996, moved rapidly, and has produced an accepted international standard specification for North American cable operators for residential cable modem service. The IEEE 802.14 standard appears to be destined for some international use and in systems where ATM over CATV is preferred by cable operators.

The cable network environment will provide a very usable and scaleable bandwidth platform for delivering Internet services to and from the home[22]. A hypothetical example was provided that illustrates a general equipment deployment model. Actual deployment of Internet to the home will occur in many areas of North America in 1998 with increasing and substantial deployment in 1999.

Digital Television: A New Venue for the Internet

by George Abe, Cisco Systems

The digitization of television is of interest to the Internet community in that it opens the possibility of a new mode of delivering IP packets to the home. IP services can be delivered over television broadcast distribution networks, whether over the air, cable, or satellite. This article introduces the basic concepts of *digital television* (DTV) and provides a point of departure for further reading.

Why Is Digital TV Happening?

The original motivation for the research into advanced TV (we avoid the term DTV for a moment) was to prop up sagging TV sales. It was mostly vendor push.

By the late 1970s, Japan and Korea had achieved domination in the production of TV sets worldwide. They were so successful that the market had become saturated, particularly in the developed world. Everyone had one or, more likely, three or four TVs at home. Further, a TV lasts over 10 years, so the replacement market is low. TV production had ceased to be a growth market. Margins were and are poor and few innovations were on the horizon.

So in the early 1980s Japan had begun research into new high-definition televisions that would stimulate new demand and enable them to keep their market leadership. Their system is called *Multiple Subnyquist* (MUSE). MUSE was an analog system, but it had better-quality pictures.

Not to be outdone, the U.S. decided it needed to try to recapture the TV market, so began its own development, under the aegis of the Federal Government. A partnership called the *Grand Alliance* was formed, and it began working in 1984. Pioneering work was done by the partnership members, particularly Zenith, MIT, and General Instruments. They created a digital specification after more than a decade of research and development. Along the way, the computer industry made contributions (or some would say interferences) of its own until the FCC announced a final specification in December 1996. The basic elements are found at **`www.atsc.org`** and referenced later in this article.

Benefits of DTV

The movement toward widespread DTV gained momentum among government officials, broadcasters, and hardware vendors when some of the benefits became clear.

First, because of improvements in technology, it is possible to transmit pictures and sound of significantly higher quality in the same 6 MHz spectrum that analog TV occupies. The 6 MHz spectrum is wasteful of bandwidth, and the government would like to recover the excess so it can be auctioned or used to support other public services (police, fire,

deep space probes, and so on), which could operate at the relatively low frequencies of VHF TV.

Second, digitally encoded TV could provide new services, such as Web access via TV or interactive TV. These have long been dreams of the consumer electronics (CE) industry, but hope springs eternal.

Third, digital TV offers greater security to the programmer and the network. There is a cottage industry in hacking analog set-top boxes. Digital techniques, such as the *Data Encryption Standard* (DES), double DES, and triple DES give operators hope that they can secure their pay-per-view content.

Finally and most interestingly, since digital TV occupies less bandwidth per program, broadcasters, satellite operators, and cable operators have the opportunity to offer more channels. Instead of a mere 10–13 channels available over the air in a single metropolitan area, it is possible to have perhaps 60 or more over the air channels. Cable operators, with their greater bandwidth underground, could have many more channels. Although technically cable could offer 500 channels, it is hard to imagine where the scripts would come from.

What Is DTV?

By our definition, digital television is the capture, production, distribution, and broadcast of programming in a digitally encoded format. Whereas today's analog TV transmits in amplitude modulation, DTV would use *Quadrature Phase Shift Keying* (QPSK), *Quadrature Amplitude Modulation* (QAM), or *Vestigal Side Band* (VSB) modulation techniques. We won't detail these techniques here except to mention that they are mutually incompatible.

When DTV standards were discussed in the 1980s, the industry could not agree on a single display. The deliberations became more protracted with the entry of the computer industry into the discussions, long after the broadcasters and consumer electronics people began their work. Would there be interlaced or progressive scanning? Would there be the existing aspect ratio or would there be a wide-screen display? Square pixels or not? How many lines of resolution would be displayed?

With the broadcasters and consumer electronics vendors arguing for interlacing, oval pixels, and wide screens and the computer people arguing for progressive scanning, square pixels, and a more square display, the disagreements could not be bridged.

Therefore, the FCC had no choice but to declare that the "market should decide" which display format would prevail. Accordingly, the FCC announced in December 1996 that 18 different display formats would be permissible for over-the-air digital TV. A broadcaster could elect to transmit in any of the approved formats. The approved formats are shown in Tables 1 and 2.

Table 1: Progressive Video Scanning Formats for Digital TV

Vertical Lines	Horizontal Pixels	Aspect Ratio	Frame Rate per Second
1080	1920	16:9	24, 30
720	1280	16:9	24, 30, 60
480	704	16:9	24, 30, 60
480	704	4:3	24, 30, 60
480	640	4:3	24, 30, 60

Table 2: Interlaced Video Scanning Formats for Digital TV

Vertical Lines	Horizontal Pixels	Aspect Ratio	Frame Rate per Second
1080	1920	16:9	30
480	704	16:9	30
480	704	4:3	30
480	640	4:3	30

The vernacular to describe the formats typically indicates the number of vertical lines and the scanning format. For example, "1080i" refers to 1080 lines, interlaced scanning; "720p" refers to 720 lines in progressive format.

In practice, only a few of the 18 approved formats are under consideration by the nation's broadcasters. NBC and CBS have declared they will support 1080i. ABC is opting for 720p, and Fox has opted for 480p.

Apart from the controversy over display, most of the other elements were quickly resolved. Modulation scheme, transport multiplexing, compression, timing, and an overall systems and testing procedure were agreed to. The apparatus for DTV was in place, almost. The time was January 1997.

High Definition or Standard Definition

Some view DTV as synonymous with high-definition television. It is not. DTV encompasses both *High-Definition TV* (HDTV) and *Standard-Definition TV* (SDTV). Hence HDTV is a proper subset of DTV. The difference between HD and SDTV is not standardized, but our definition of HD includes the display formats that have 720 or 1080 lines. Formats with fewer lines are standard definition.

The key point of difference between HD and SD is that with HD and current compression techniques (MPEG-2), only one program is accommodated in one 6-MHz channel. With SD, it is possible for the broadcaster to transmit two or more programs simultaneously, in a single 6-MHz chunk of bandwidth.

This has tremendous implications. If broadcasters can transmit multiple channels at once, it would be possible (technically) for Disney to broadcast ABC, the Disney Channel, ESPN, and A&E over the air in the same bandwidth they use to show ABC today. (Of course they won't do this for commercial and contractual reasons, but the technology makes it doable).

For Internet Service Providers, a broadcast could transmit SD programming simultaneously with datacasting, and go into the push-mode data service business. For example, Disney/ABC could download software updates for Disney Interactive, or perhaps contract with Microsoft to deliver Windows updates. Whereas most Internet folk view MPEG being transported inside IP packets on the Internet, broadcasters intend to insert IP packets into MPEG-2 transport streams. The consumer's digital set-top box would tune to the data "channel," extract the data from its MPEG capsule, and divert the data packet to an Ethernet or ATM port on the set-top.

There are nearly 1,600 broadcasters in the U.S. Each could, in theory, transmit 19.3 megabits per second. Of course, most of these bits will be used for television, but certainly 1 or 2 megabits can be accommodated by each broadcaster for data service.

Given the dearth of programming to fill multiple SD channels, broadcasters are strongly motivated to consider data services and compete for a slice of the Internet service market.

Digital TV—End to End

Whereas one easily thinks of DTV as a distribution and display technology, in fact there are major changes required to capture, edit, and distribute digital content. Thus there is the need for new cameras, post-production editors, sound mixers, and the like.

Digital TV can be transmitted over the air, through cable networks, or via *Direct Broadcast Satellite* (DBS). Today, only DBS has achieved large-scale distribution of digital TV, with over 7 million subscribers in the U.S. and 15 million worldwide.

Content is created either through a digital camera or by converting existing analog content, such as 35mm film, into digital format. Within the production environment, editing changes are made, typically using *Nonlinear Editors* (NLEs) that connect to a local-area network.

Original production is normally done in the high definition. The highest form of resolution is 1.492 Gbps. (See Table 3.) Equipment to do this is not widely available, but it will be eventually. Panasonic is shipping a digital camera capable of 1.5-Gbps output, but rumor has it they cost almost $500,000, if you can even get one. Nonetheless, 41 stations began HD programming in November, highlighted by an NFL game on CBS between the Buffalo Bills and the New York Jets on November 8.

Some compression is applied within the postproduction and editing environment. The TV industry, through the *Society of Motion Picture and TV Engineers* (**www.smpte.org**), developed a series of digital transmission standards. Chief among these is SMPTE 305M, which defines a protocol called *Serial Data Transport Interface* (SDTI), which calls for a 270- or 360-Mbps service to link various pieces of production equipment such as NLEs in a postproduction facility. SMPTE 305M is a networking scheme complete with an addressing specification.

(Interesting point about 305M: It is the first and only protocol known to this author that specifies use of IPv6 addressing.)

Another important protocol is SMPTE 259M, which is a link-layer protocol underneath 305M.

A competing protocol to SDTI is the *Digital Video Broadcasters Asynchronous Serial Interface* (DVB-ASI). Information on DVB-ASI is found at **www.dvb.org**.

From the editing environment, content is distributed via satellite or land lines to local affiliates (for local over-the-air broadcast), cable head-ends (for cable TV distribution) and satellite hubs (for direct-to-home satellite service). The distribution from national feeds to local facilities is normally at T3/E3 speeds because of the availability of T3/E3 services by telephone companies and satellite transponders for affiliate and direct-to-home distribution.

Cable providers, local broadcasters, and satellite services add their own content and make certain changes to the national feeds. Among these changes are assignment of the programming to specific frequencies or channels, insertion of local advertising, local programming, and emergency broadcasts.

After adding their own content, the local services distribute the final programming to consumers. Over-the-air broadcasters will transmit 19.3 Mbps per 6 MHz, cable will transmit 27 Mbps per 6 MHz, and satellite uses variable channelization, kept closely under wraps.

So there is the progression downward from 1492 Mbps of original encoding, to 270 Mbps for editing, to 34/45 Mbps for affiliate distribution, to 27 Mbps or less for distribution to the end user.

Table 3: Bit Rate Requirements for Various Display Formats

Format	Pixels per Line	Lines per Frame	Pixels per Frame	Frames per Second	Millions of Pixels per Second	Bits per Pixel	Mbps
SVGA	800	600	480,000	72	34.6	8	276.5
NTSC	640	480	307,200	30	9.2	24	221.2
PAL	580	575	333,500	50	16.7	24	400.2
SECAM	580	575	333,500	50	16.7	24	400.2
HDTV	1920	1080	2,073,600	30	62.2	24	1492.8
Film	2000	1700	3,400,000	24	81.6	32	2611.2

Note: Film display formats vary, depending on content and directorial prerogative.

Over the Air and Cable

All the huffing and puffing by the FCC, the consumer electronics industry, the computer industry, and the broadcasters pertains to over-the-air transmission. However, about two-thirds of the American viewing public views TV through cable. So if most Americans are to receive DTV, they must receive it through cable.

This raises important technical and regulatory questions. The technical question is: How are the digital signals produced by the broadcasters and their affiliates to be sent through wires, and what is the allocation of functions between the digital set-top and the digital receiver? This question seems simple but it is not, as we shall see.

The regulatory question pertains to whether the cable operators are to be compelled to carry DTV from broadcasters. This problem is referred to as the digital *Must Carry Problem,* now under consideration by the FCC. It certainly will be litigated, whatever the outcome of the FCC's decision.

Technical Question

Among the key provisions agreed to by the Grand Alliance is the use of a modulation technique called 8-VSB for over-the-air digital transmission. The particulars of 8-VSB are not significant here, but we will mention that this particular decision was arrived at in the mid-1980s, before the cable industry had much impact on the viewing public or on the broadcasting industry.

When the cable industry began to think about digital, in the mid-1990s, they settled on a modulation scheme called 64 QAM. 64 QAM is able to produce 27 Mbps in 6 MHz, whereas 8-VSB produces about 19.3 Mbps. The difference occurs because over-the-air broadcasting requires a more robust encoding scheme to combat the more hostile nature of over-the-air transmission, as opposed to the safer environment of coaxial cables. Thus the cable modulation technique can be more aggressive than over-the-air techniques.

(We should add that satellites use an even more robust modulation technique called QPSK, which gets fewer bits per Hertz than VSB or QAM. But robustness is needed because satellite signals must travel far greater distances than cable or local broadcast.)

Thus for cable to carry a digital over-the-air broadcast, some conversion of 8-VSB encoding to 64 QAM encoding is necessary. This necessity does not present a major technical problem, but agreement is needed on where the conversion is done and at what cost. For example, Broadcom and Sony are collaborating on the development of a chip, to be embedded in a TV, that can decode VSB and QAM. It sounds simple, but the cable industry is not interested. They want to carry QAM and QAM only on their networks.

One option is to convert the format of the digital bitstream coming out of the cable box to the IEEE 1394 *FireWire* format. Since DTVs are likely to have FireWire input, this conversion can provide a ubiquitous connection. However, this scenario raises the problem of copy protection, a sore point in Hollywood. Since digital copies are pristine, the content providers (studios and record companies) are firm in their resolve that unless there is strong copy protection, none of their content will be available over FireWire.

Another option is to build a set-top box that takes baseband signals and modulates them to look like 8-VSB broadcast signals on channel 3, similar to how VCRs work in the analog world now. This scenario is clearly rather ugly, but understood by consumers.

Finally, it could be up to the cable operators to transmodulate the 8-VSB into QAM at the cable head-end. Better yet, they can accept broadcasters' feeds in baseband, and then QAM-modulate the baseband signals for their consumers. The cable set-top box would be sending bit maps to a dumb digital monitor, like a computer monitor, which doesn't know or care that it is receiving QAM or VSB programming.

Apart from modulation, there is the issue of display format. NBC and CBS have declared they will transmit in 1080i. ABC has chosen 720p and Fox has chosen 480p, with some vague pledge for higher definition later. After all, it does not seem necessary to show *The Simpsons* in HD.

On the other hand, John Malone, Chairman of TCI, went public in May 1998 with his declaration that TCI would not voluntarily carry 1080i because it (1080i) was wasteful of bandwidth. Implied in his comment is the fact that cable operators do need to be restricted to 6-MHz channelization for digital. In fact, the entire DTV spectrum on cable could be considered a gigantic pool of bandwidth that the cable operator could allocate to individual channels, much as direct satellite does. This setup gives the cable operators incentive to downconvert the broadcasters' DTV signals. For example, when NBC sends 1080i, the cable operator may elect to transmit 720p, or less, to its customers.

Should the cable operators be required to carry the HDTV pictures from the broadcasters in the broadcasters' chosen format? Would they be allowed to downconvert the HD into standard definition? What happens when a broadcaster, say NBC, elects to transmit in SDTV and thereby has the capability of multiplexing several channels onto a single chunk of 6 MHz? What is the duty of the cable operator to carry Internet datacasting offered by the broadcasters over the cable network, in competition with services such as @Home and Roadrunner?

The complexities of multiplexing go further. Let's say ABC elects to broadcast SD. If one of the subprograms in the multiplex is a pay-per-view channel, should the authentication procedures of the cable operator be superceded? Should the electronic program guide of the cable operator be superceded?

Questions like these have technical and regulatory aspects and are being worked in industry, the FCC, and state regulatory agencies. It is possible that Congress will get involved as well. When John Malone made his statement, both sides of the aisle in Congress were not amused. They want DTV to happen so that spectrum can be freed. If the cable operators stand in the way, the conversion to digital is stopped dead in its tracks.

The Open Cable Initiative

The cable industry does not want to be a bottleneck to broadcasters. On the other hand, it needs to make quick progress into DTV to compete against satellite. Therefore, the industry has embarked on a process called *Open Cable,* which seeks to define a digital set-top box that can be available at retail. Available at retail means a nonproprietary, open design. Open Cable strives to make the DTV set-top box independent of processor platform (that is, not an Intel Pentium necessarily) and operating system independent (that is, not a Microsoft Windows CE necessarily).

The Open Cable set-top box will allow for data services through a specification written by the *Digital Audio Visual Council* (DAVIC—**www.davic.org**) and therefore, is not compatible with the current *Data-over-Cable Service Interface* (DOCSIS) specification supported by the U.S. cable industry. (See article starting on page 13.) However, it is possible for DOCSIS capabilities to be added on to an Open Cable set-top box. We mention Open Cable because it will be the key customer premises device for cable and digital TV and much hinges on its interoperability with broadcasters transmissions.

Digital TV via Satellite

In addition to over-the-air and cable, DTV can be received by satellite. As of this writing, it is the only way to receive DTV. The digital satellite industry has nearly 7 million subscribers who received DTV today. Its role in all the discussions of HD vs. SD and the provision of data services is relatively low key because it is believed that satellite will continue to be a niche provider because of its technical and legal problems in distributing locally originated TV stations.

But satellites bear watching because if they are able to deliver local channels and obtain 15–20 million homes in the U.S., then the financial consequences on cable and over the air could be crucial.

The New Digital Studio

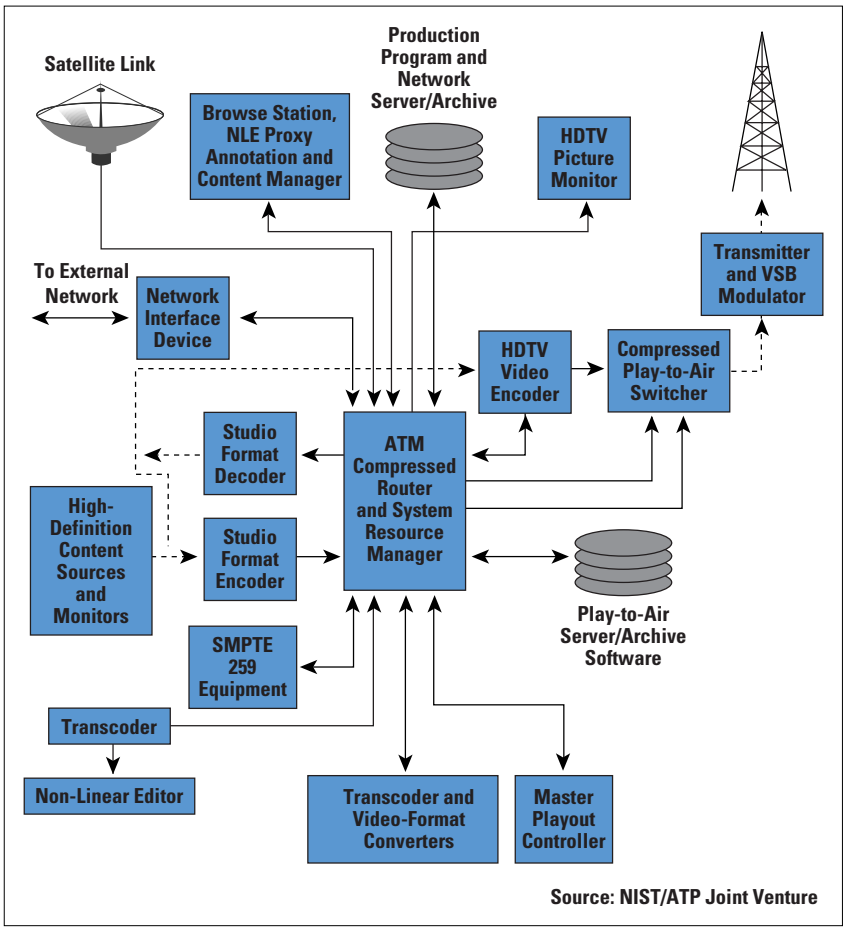
The figure shows a schematic of the elements of a DTV broadcast studio described recently by the U.S. *National Institute of Standard and Technology* (NIST). At the heart of the studio is an ATM switch with new interfaces that connect to DVB or ATSC infrastructures via DVB-ASI or SDTI interfaces.

Connection for wide-area distribution will likely be over ATM. Converters exist for DVB-ASI to ATM. For example, Cellware (**www.cellware.de**) in Germany markets such a converter, but there is no SDTI-to-ATM interface known to this author at this time.

The digital studio provides a new a marketing opportunity for the LAN industry. Broadcast digital production demands higher speeds than most other LAN applications.

Thus vendors of data communications equipment have two opportunities: to provide equipment to broadcasters who want to enter the Internet service business and to production houses that use ATM or other LANs to support editing and production applications.

Figure 1: Prototype of HDTV Broadcast Studio



Web Sites

www.atsc.org: *Advanced TV Standards Committee*. S13 and S16 are subgroups working on datacasting; S13 focuses primarily on the downstream path, whereas S16 focuses primarily on the reverse communication from the receiver. Since over-the-air is one way, this work is limited to the communications between the S13 forward channels and a telephone or Internet return path.

He currently is a Consulting Engineer at Cisco Systems, where he has dabbled in various areas of residential broadband networking since 1994. He is the author of *Residential Broadband*, Cisco Press (imprint of Macmillan Press). He expects to be a early adopter of digital TV and, when not watching TV, he can be reached at **georgea@acm.org**

I Remember IANA

by Vint Cerf, MCI WorldCom
October 17, 1998

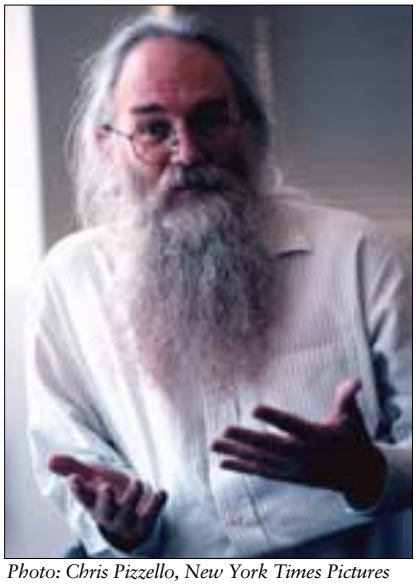

Photo: Chris Pizzello, New York Times Pictures

A long time ago, in a network, far far away, a great adventure took place! Out of the chaos of new ideas for communication, the experiments, the tentative designs, and crucible of testing, there emerged a cornucopia of networks. Beginning with the ARPANET, an endless stream of networks evolved, and ultimately were interlinked to become the Internet. Someone had to keep track of all the protocols, the identifiers, networks and addresses and ultimately the names of all the things in the networked universe. And someone had to keep track of all the information that erupted with volcanic force from the intensity of the debates and discussions and endless invention that has continued unabated for 30 years. That someone was Jonathan B. Postel, our *Internet Assigned Numbers Authority* (IANA), friend, engineer, confidant, leader, icon, and now, first of the giants to depart from our midst.

Jon, our beloved IANA, is gone. Even as I write these words I cannot quite grasp this stark fact. We had almost lost him once before in 1991. Surely we knew he was at risk as are we all. But he had been our rock, the foundation on which our every Web search and e-mail was built, always there to mediate the random dispute, to remind us when our documentation did not do justice to its subject, to make difficult decisions with apparent ease, and to consult when careful consideration was needed. We will survive our loss and we will remember. He has left a monumental legacy for all Internauts to contemplate. Steadfast service for decades, moving when others seemed paralyzed, always finding the right course in a complex minefield of technical and sometimes political obstacles.

Jon and I went to the same high school, Van Nuys High, in the San Fernando Valley north of Los Angeles. But we were in different classes and I really didn't know him then. Our real meeting came at UCLA when we became a part of a group of graduate students working for Professor Leonard Kleinrock on the ARPANET project. Steve Crocker was another of the Van Nuys crowd who was part of the team and led the development of the first host-to-host protocols for the ARPANET. When Steve invented the idea of the *Request for Comments* (RFC) series, Jon became the instant editor. When we needed to keep track of all the hosts and protocol identifiers, Jon volunteered to be the Numbers Czar and later the IANA once the Internet was in place. Jon was a founding member of the *Internet Architecture Board* (IAB) and served continuously from its founding to the present. He was the *first* individual member of the Internet Society—I know, because he and Steve Wolff raced to see who could fill out the application forms and make payment first and Jon won. He served as a trustee of the Internet Society.

He was the custodian of the .us domain, a founder of the Los Nettos Internet service, and, by the way, managed the networking research division of USC Information Sciences Institute.

Jon loved the outdoors. I know he used to enjoy backpacking in the high Sierras around Yosemite. Bearded and sandaled, Jon was our resident hippie-patriarch at UCLA. He was a private person but fully capable of engaging photon torpedoes and going to battle stations in a good engineering argument. And he could be stubborn beyond all expectation. He could have outwaited the Sphinx in a staring contest, I think.

Jon inspired loyalty and steadfast devotion among his friends and his colleagues. For me, he personified the words "selfless service." For nearly 30 years, Jon has served us all, taken little in return, indeed sometimes receiving abuse when he should have received our deepest appreciation. It was particularly gratifying at the last Internet Society meeting in Geneva to see Jon receive the Silver Medal of the International Telecommunications Union. It is an award generally reserved for Heads of State, but I can think of no one more deserving of global recognition for his contributions.

While it seems almost impossible to avoid feeling an enormous sense of loss, as if a yawning gap in our networked universe had opened up and swallowed our friend, I must tell you that I am comforted as I contemplate what Jon has wrought. He leaves a legacy of edited documents that tell our collective Internet story, including not only the technical but also the poetic and whimsical as well. He completed the incorporation of a successor to his service as IANA and leaves a lasting legacy of service to the community in that role. His memory is rich and vibrant and will not fade from our collective consciousness. "What would Jon have done?" we will think, as we wrestle in the days ahead with the problems Jon kept so well tamed for so many years.

There will almost surely be many memorials to Jon's monumental service to the Internet Community. As current chairman of the Internet Society, I pledge to establish an award in Jon's name to recognize long-standing service to the community, the *Jonathan B. Postel Service Award*, which will be awarded to Jon posthumously as its first recipient.

If Jon were here, I am sure he would urge us not to mourn his passing but to celebrate his life and his contributions. He would remind us that there is still much work to be done and that we now have the responsibility and the opportunity to do our part. I doubt that anyone could possibly duplicate his record, but it stands as a measure of one man's astonishing contribution to a community he knew and loved.

VINTON G. CERF is senior vice president of Internet Architecture and Technology for MCI WorldCom. Widely known as a "Father of the Internet," he is the co-designer of the TCP/IP protocol. Cerf served as founding president of the Internet Society from 1992–1995 and is currently chairman of the Board. Cerf holds a Bachelor of Science degree in Mathematics from Stanford University and Master of Science and Ph.D. degrees in Computer Science from UCLA. E-mail: **vcerf@mci.net**

Book Reviews

Internet Messaging

Internet Messaging: From the Desktop to the Enterprise, by Marshall T. Rose and David Strom ISBN 0-13-978610-4, Prentice-Hall PTR, 1998, **http://www.prenhall.com**

Very few Internet voices hold a status equivalent to E.F. Hutton's advertising campaign: "When they speak, we should listen." Marshall Rose and David Strom are two such voices, making any product of their combined efforts a serious matter, indeed. Rose has typically written about basic technology, Strom about the pragmatics of use, especially trials and tribulations of fitting networked pieces together. *Internet Messaging* is in the latter category, with a strong added introduction of e-mail and security technology. Anyone who has professional contact with e-mail should get a copy of this book. If commercial use of Internet mail were more advanced and stable, we probably would not need an effort like this. However, e-mail professionals must constantly deal with problems in using interesting functions and in troubleshooting interoperability. *Internet Messaging* helps with the planning, use and debugging of complex, or otherwise "interesting," e-mail services.

Updated Information

The book provides a superb survey of the relevant technology, the popular user mail software, and the rather interesting range of mail and messaging operations issues, including styles of use by organizations. The comparisons of different mail systems leave the reader with a solid understanding of functional and usage requirements for modern systems, as well as the choices available at the time of publication. Mary Houten-Kemp's Web site at **http://www.everythingemail.net** is being used to provide updated information.

E-mail includes a wide range of technical and operations issues, and *Internet Messaging* touches all of them. Its introductions cover user environment, mail transfer, mailing list services, unsolicited bulk e-mail ("spam"), encryption-based security, remote user access, virtual private networks, and directory services. Providing a single discussion, which integrates the use of these disparate technologies, is enough to justify the book.

Organization

Internet Messaging attempts very regular organization and states that the goal is to permit use as a problem/solution reference work. It primarily distinguishes between sending and receiving functions and between desktop and enterprise requirements. This creates a two-by-two matrix, defining the core four chapters. The other chapters include philosophical opening and closing discussions, a separate, very informative chapter on security, and another on general enterprise operations issues.

Most of the chapters are organized into Introduction, Problems, Standards, and Solutions. Unfortunately that regularization is all that is shown in the Table of Contents, so the reader gets little help finding specifics by reading the Table. Similarly, the organization of the chapter contents did not seem compelling for use in problem solving. The additional "How Can I" matrix (on page 10) and its associated discussion text is intended as the primary means for locating relevant discussions.

Comparisons

User software comparisons are given throughout the book, for Microsoft Outlook 4.01, Netscape Messenger 4.04, Qualcomm Eudora Pro 4.0, Lotus cc:Mail 8.1, CompuServe WinCIM 3.02, and America Online 3.0. Specific mailing lists, security, remote access, and directory software and services are also reviewed. Oddly, the discussion of remote access mentions only global, single-provider services—and their favorite is currently having financial problems—but did not mention the "association" style of service that integrates many independent providers, notably GRIC and iPass. (Full disclosure: iPass is a client.)

Most products are undergoing aggressive enhancement so that no printed text can be entirely up-to-date. Hence the Web site. For the software and services I know well, the book looked reasonable. Of course it is not entirely error free, but the errors are small and perfect detail is not required. I believe there are two major benefits to these comparisons. One is that the reader is given a very solid sense of the general capabilities and limitations of modern e-mail software. The second is to make a reasonable, first-pass filtering of candidate packages to be used in an organization. It would *not* be appropriate to attempt selecting among these packages according to subtle differences reported in the book.

Benefits

As one would expect of these authors, a very large, long-term benefit of their efforts is in their many excellent criticisms and suggestions. Unfortunately, many of them are in notes located at the end of each chapter. It's hard to imagine a less-convenient place to put them, since I found myself constantly shifting back and forth between the main text and the notes. It would not have been so irritating if the comments were less interesting; they should have been true footnotes, with easy access on each page. The stellar example of direct utility from these comments is Figure 2.1 on page 38. It shows a systems structure for user software processing of incoming mail. Every vendor should study this discussion carefully and implement it immediately. Please!

Web Security

Web Security: A Step-by-Step Reference Guide, by Lincoln D. Stein, ISBN 0-201-63489-9, Addison-Wesley, December 1997,
http://www.awl.com/cseng/titles/0-201-63489-9

Whenever the topic of the World Wide Web comes up, you can be sure that some mention of "security" will soon follow. Web users, Web creators, and even Web technology developers are all keenly aware of the security concerns. But what do we mean by "security?" The safety to use a credit card? Keeping a Web site safe from break-ins? Keeping the kids away from online erotica? And whose security are we concerned with, the user's or the Web site operator's?

This book covers most of what we might expect to find under the umbrella of security. In addition to dealing with the broad scope of Web security, the author also tries to cover the topic with sufficient simplicity for the novice and enough detail for the engineer. The good news is that this book succeeds in delivering a single volume that covers all we could possibly expect on the topic, and at levels suited for a broad audience range.

Organization

The author begins by making the distinction between security for the browser, the Web site, and the network between them. This division of the topic forms the basis for the organization of the book. Moving through each of the three parts, the author proceeds from the simple to the complex in a logical, additive order. He discusses topics introduced early in the book from a functional standpoint—how they affect the user. He may cover the same technology in later chapters, but in greater depth, detailing server and network configuration and discussing the underlying technology.

In the first part of the book, the author covers document confidentiality, including standard "text" documents as well as electronic commerce. A major theme in this section is cryptography. The author presents symmetric and public key encryption technologies from a functional standpoint. He presents various encryption standards, with a discussion of their strengths and weaknesses. In another chapter he provides a good primer on the *Secure Electronic Transaction* (SET) protocol handling, as well as other options (*Common Gateway Interface* [CGI] scripts and *Secure Sockets Layer* [SSL]) for credit card order processing.

In Part 2 we are introduced to issues of client-side security. The author devotes a full chapter to an in-depth explanation of SSL services. He also looks at issues associated with active content, and presents technologies such as Java, ActiveX, and other options, along with notes on their respective security implications. Finally, he covers issues of privacy—in this case, the personal privacy of the user. Throughout these chapters, the author emphasizes user-controllable settings such as browser configuration options.

Whereas the author focuses on user involvement in the first two parts, with an appropriate level of technical content, in part 3, targeted to Web masters and system administrators, he introduces the engineering side with an in-depth coverage of server-side security. He covers the two prominent Web-serving operating systems: UNIX and Windows NT, with good attention to various versions of each. Topics include basic system security, access control, and activity monitoring. Other chapters include an excellent discussion of encryption and certificate technology, safe CGI scripting, remote authoring of Web data, and firewalls.

Presentation and Style

The author illustrates his points with good examples. He also presents appropriate sidebar discussions and illustrations, which not only clarify the information, but also provide interest and variety in what could be a very dry volume. Each chapter ends with a listing of resources, both print and "online." Where appropriate, the author includes checklists to help the reader apply the material just covered.

As a result of the practical, well-grounded presentation of material, we are continually able to see practical applicability to our own situation. For example, the author presents us with information about dangers to our privacy, and why that might be important to us. This is immediately followed by clear instruction on changing privacy-affecting settings in various versions of both Netscape and Internet Explorer. The author uses this technique throughout the book, and it is as useful with password management, CGI scripting, or firewall configuration as it is with privacy.

Recommended

Although experts in encryption and other specific security-related technologies will find this book too simple for their personal area of expertise, the strength of the book is not in its coverage of any one area, but in its well-integrated and cohesive coverage of a broad range of interrelated topics. The ability for any reader, first-time surfer or Web guru, to find practical, easily applied information makes this book a required item on any webmaster's bookshelf, and a must-read for anyone who spends any serious time on the Web.

Internet Cryptography

Internet Cryptography, by Richard E. Smith, ISBN 0-201-92480-3, Addison-Wesley, 1998, **www.awl.com/cseng/titles/0-201-92480-3**

The 1990s might easily be known as the decade of the Internet. The Internet came into the mainstream during this decade, a global frontier with frontier problems and rules. Seemingly overnight, everyone from government agencies to Chinese restaurants had a Web presence. Young children exchanged e-mail with their grandparents and friends, a big change from just a few years ago when it was the domain of technologies and a place where everybody knew your name.

The 1990s could also be known as the decade when cryptography became mainstream. Perhaps because of the change in the Internet community, people became more aware of the need to protect the privacy of internetwork communications. Certainly, the U.S. government's attempt to push government control of cryptographic keys in the Clipper controversy helped to move cryptography and its related issues from science journals to the front pages of our newspapers. Today, while not mainstream, terms such as *Virtual Private Networks* (VPNs), *Secure Sockets Layer* (SSL), *IP Security* (IPSec), *Pretty Good Privacy* (PGP), *Secure Multipurpose Internet Mail Extensions* (S/MIME), and related technologies are known among IT professionals, and cryptography is no longer a tool used only by spies and military communication officers.

The Author

Richard E. Smith is well-known to members of various security-related forums on the Internet, as well as to security conference attendees. A security consultant with Secure Computing Corporation, Smith's background is in military-grade security. His experience on the lecture circuit, explaining issues of firewalls, cryptography, and other computer and network security topics, has directly contributed to production of a book on a lofty subject that is reachable by the nonscientist.

Organization

The chapters of this book fall into three groupings: an introduction to the basics of cryptography, its terms, methods, and mechanisms; network encryption and a discussion of VPNs, focusing on IPSec; and finally public key cryptography as it is used with message and file encryption and "Web" transactions.

The discussion in the opening chapter on basics may scare some off; Smith tends to oscillate between various levels of complexity. Consequently, some members of the intended audience of (quoting from the Preface) "people who know very little about cryptography but need to make technical decisions about cryptographic security," may, for example, zone out during the discussion of IP protocols. My suggestion would be to press on, and not worry about the random item that might go over your head. Everything there has a purpose, and the important information will fall into place by the end of each chapter.

If this book ended with Chapter 4, it would still be a useful book. The complex basics of cryptography and the issues that should be of concern to an information security officer are clearly presented and explained. The only area that is given less than adequate coverage is that of key recovery. Smith makes no mention of legitimate business reasons for the recovery of encrypted data if the originator is unavailable (the proverbial question, "What if you got hit by a truck?"), nor does he mention any mechanism other than the escrow of secret keys, although there are other, safer, methods. Of particular use are Smith's explanations of the various cryptographic algorithms and his discussions of safe key lengths and risks.

In the sections on VPNs and IPSec, Smith covers everything from mobile users and remote access, to point-to-point encryption, and the issues of key distribution, exchange, and the mechanisms used to automate encrypted communication. Everyone seems to know that IPSec will save the world and is the answer to all our security problems (and I have my tongue firmly planted in my cheek), but few know what IPSec really does, from a "features and benefits" point of view. Of particular use and interest are the sections labeled "Deployment Example." These are small case studies that show the technology in action and discuss some of the decisions and processes that came before deployment.

The section covering public key cryptography along with file and message encryption is perhaps shorter than it should be, although much of the groundwork is done earlier in the book. Missing is a "how to" on setting up a public key infrastructure (PKI) for a corporation to use. There are "Product Examples" in this section, but not "Deployment Examples." Perhaps those will have to wait for a second edition, for although this is a lack in the book, there are not many real-life examples from which to choose. Although discussed in theory for years, this is still "leading edge" in the real world. The chapter on Web servers should prove informative and useful to any organization thinking of deploying (or having already deployed) a Web server.

In the chapter entitled "Secure Electronic Mail," the fact that Smith covers *Privacy Enhanced Mail* (PEM) as a technology more than he covers S/MIME is puzzling, but the basics of PEM are useful for discussion, even if PEM as a technology seems to be dead.

Cryptography Is Necessary

The advertisement on the back of the book (not written by the author, of course) states "Here, in one comprehensive, soup-to-nuts book, is the soution for Internet security: modern-day cryptography." Obviously the claim that cryptography is *the* solution for Internet security is way overinflated; modern-day cryptography is not *the* solution, but, cryptography is an important part of a "balanced" security solution. Smith does an admirable job of making this heretofore…well, cryptic… subject, understandable, interesting, and even enjoyable.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and quality of service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ contains standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

Fragments

ICANN

The *Internet Corporation for Assigned Names and Numbers* (ICANN) was incorporated in late October. ICANN is a private, non-profit corporation, managed by an international board, formed to coordinate and administer policies and technical protocols relating to the domain name and address system that permits Internet communications to be routed to the correct person or entity. Its proposed duties include those now performed under U.S. Government contract by the *Internet Assigned Numbers Authority* (IANA), whose Director, Internet pioneer Jon Postel, died on October 16th. ICANN has elected its Initial Board and chosen Michael M. Roberts as its Interim President and Chief Executive Officer. In addition, the Board chose Esther Dyson as its Interim Chairman, and appointed an Executive Committee consisting of Dyson, Gregory L. Crew, Hans Kraaijenbrink and Roberts. The other Initial Board members include Geraldine Capdeboscq (France), George H. Conrades (United States), Gregory L. Crew (Australia), Frank Fitzsimmons (United States), Hans Kraaijenbrink (The Netherlands), Jun Murai (Japan), Eugenio Triana (Spain), and Linda S. Wilson (United States). ICANN was originally proposed by Postel on behalf of a broad coalition of Internet stakeholders in response to the request by the U. S. Government last June that the Internet community create a global consensus non-profit corporation to which the U.S. could transition the responsibility for overseeing and funding those coordination activities. APRICOT '99

The *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT) will be held in Singapore, March 1–5, 1999. APRICOT provides a forum for key Internet builders in the region to learn from their peers and other leaders in the Internet community from around the world. The week-long summit consists of seminars, workshops, tutorials, conference sessions, birds-of-a-feather sessions, and other forums—all with the goal of spreading and sharing the knowledge required to operate the Internet within the Asia Pacific region. For more information, see: **`http://www.apricot.net`**

From The Editor

Today's Internet is comprised of numerous interconnected *Internet Service Providers* (ISPs), each serving many constituent networks and end users. Just as individual regional and national telephone companies interconnect and exchange traffic and form a global telephone network, the ISPs must arrange for points of interconnection to provide global Internet service. This interconnection mechanism is generally called "peering," and it is the subject of a two-part article by Geoff Huston. In Part I, which is included in this issue, he discusses the technical aspects of peering. In Part II, which will follow in our next issue, Mr. Huston continues the examination with a look at the business arrangements (called "settlements") that exist between ISPs, and discusses the future of this rapidly evolving marketplace.

In the early 1990s, concern grew regarding the possible depletion of the IP version 4 address space because of the rapid growth of the Internet. Predictions for when we would literally run out of IP addresses were published. Several proposals for a new version of IP were put forward in the IETF, eventually resulting in IP version 6 or IPv6. At the same time, new technologies were developed that effectively slowed address depletion, most notably *Classless Inter-Domain Routing* (CIDR) and *Network Address Translators* (NATs). Today there is still debate as to if and when IPv6 will be deployed in the global Internet, but experimentation and development continues on this protocol. We asked Robert Fink to give us a status report on IPv6.

We've already discussed the historical lack of security in Internet technologies and how security enhancements are being developed for every layer of the protocol stack. This time, Marshall Rose and David Strom examine the state of electronic mail security. We clearly have a way to go before we see "seamless integration" of security systems with today's e-mail clients.

Our first Letter to the Editor is included on page 46. As always, we would love to hear your comments and questions regarding anything you read in this journal. Please contact us at ipj@cisco.com

Interconnection, Peering and Settlements—Part I

by Geoff Huston, Telstra

Technology and business models share a common evolution within the Internet. To enable deployment of the technology within a service environment, a robust and stable business model also needs to be created. This tied destiny of technology and business factors is perhaps most apparent within the area of the interconnection of *Internet Service Providers* (ISPs). Here there is an interaction at a level of technology, in terms of routing signaling and traffic flows, and also an interaction of business models, in terms of a negotiation of benefit and cost in undertaking the interconnection. This article examines this environment in some detail, looking closely at the interaction between the capabilities of the technical protocols, their translation into engineering deployment, and the consequent business imperatives that such environments create.

It is necessary to commence this examination of the public Internet with the observation that the Internet is not, and never has been, a single network. The Internet is a collection of interconnected component networks that share a common addressing structure, a common view of routing and traffic flow, and a common view of a naming system. This interconnection environment spans a highly diverse set of more than 50,000 component networks, and this number continues, inexorably, to grow and grow. One of the significant aspects of this environment is the competitive Internet service industry, where many thousands of enterprises, both small and large, compete for market share at a regional, national, and international level.

Underneath the veneer of a highly competitive Internet service market is a somewhat different environment, in which every ISP network must interoperate with neighboring Internet networks in order to produce a delivered service outcome of comprehensive connectivity and end-to-end service. No ISP can operate in complete isolation from others while still offering public Internet services, and therefore, every ISP not only must coexist with other ISPs but also must operate in cooperation with other ISPs.

This article examines both the technical and business aspects that surround this ISP interaction, commonly referred to as "interconnection, peering, and settlements." It examines the business motivation for interconnection structures, and then the technical architectures of such environments. The second part looks at the business relationships that arise between ISPs in the public Internet space, and then examines numerous broader issues that will shape the near-term future of this environment.

[This article is based in part on material in *The ISP Survival Guide*, by Geoff Huston, ISBN 201-3-45567-9, published by Wiley. Used with permission.]

Interconnection: Retailing, Reselling, and Wholesaling

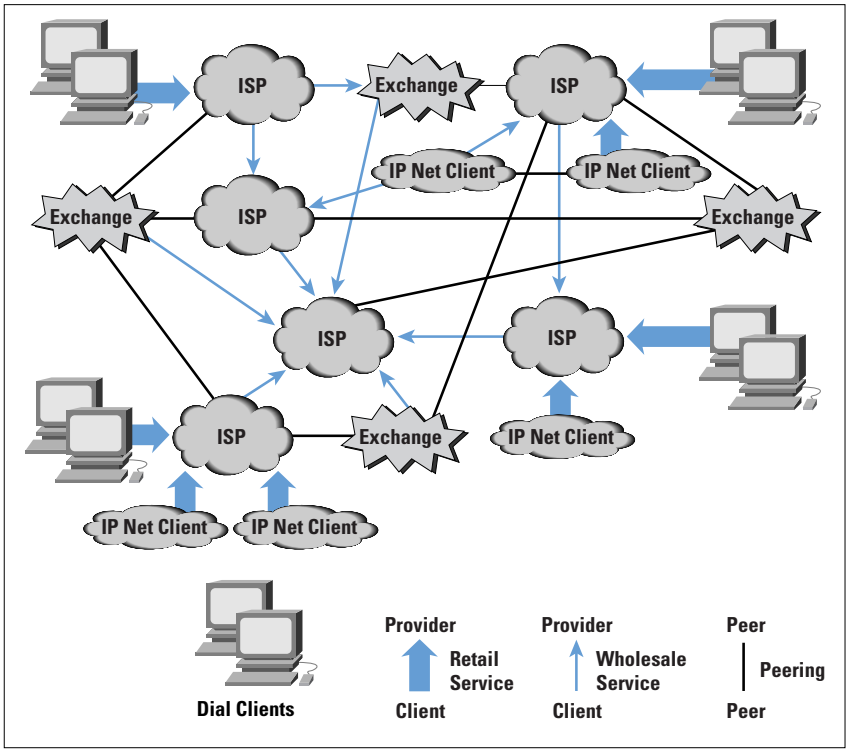
To provide some motivation for this issue of ISP interconnection, it is first appropriate to look at the nature of the environment. The regulatory framework that defined the traditional structure of other communications enterprises such as telephony or postal services was largely absent in the evolution of the Internet service industry. The resultant service industry for the Internet is most accurately characterized as an outcome of business and technology interaction, rather than a planned outcome of some regulatory process. This section examines this interaction between business and technology within the ISP environment.

A natural outcome of the Internet model is that the effective control of the retail service environment rests with a network client of an access service rather than with the access service provider. As such, a client of an ISP access service has the discretionary ability to resell the access service to third-party clients. In this environment, reselling and wholesaling are very natural developments within the ISP activity sector, with or without the explicit concurrence of the provider ISP. The provider ISP may see this reselling as an additional channel to market for its own Internet carriage services, and may adopt a positive stance by actively encouraging resellers into the market as a means of overall market stimulus, while tapping into the marketing, sales, and support resources of these reselling entities to continue to drive the volumes of the underlying Internet carriage service portfolio. The low barriers to entry to the wholesale market provide a means of increasing the scope of the operation, because to lift business cash-flow levels, the business enters into wholesale agreements that effectively resell the carriage components of the operation without the bundling of other services normally associated with the retail operation. This process allows the ISP to gain higher volumes of carriage capacity that in turn allow the ISP to gain access to lower unit costs of carriage.

Given that a retail operation can readily become a wholesale provider to third-party resellers at the effective discretion of the original retail client, is a wholesale transit ISP restricted from undertaking retail operations? Again, there is no such natural restriction from a technical or business perspective. An Internet carriage service is a commodity service that does not allow for a significant level of intrinsic product discrimination. The relatively low level of value added by a wholesale service operation implies a low unit rate of financial return for that operation. This low unit rate of financial return, together with an inability to competitively discriminate the wholesale product effectively, induces a wholesale provider into the retail sector as a means of improving the financial performance of the service operation. The overall result is that many ISPs operate both as clients and as providers. Few, if any, reasonable technical-based characterizations draw a clear and unambiguous distinction between a client and service provider when access services to networks are considered. A campus network may be a client of one or more ser-

vice providers, while the network is also a service provider to campus users. Indeed most networks in a similar situation take on the dual role of client and provider, and the ability to resell an access service can extend to almost arbitrary depths of the reselling hierarchy. From this technical perspective, very few natural divisions of the market support a stable segmentation into exclusively wholesale and exclusively retail market sectors. The overall structure of roles is indicated in Figure 1.

Figure 1: ISP Roles and Relationships



The resultant business environment is one characterized by a reasonable degree of fluidity, in which no clear delineation of relative roles or markets exists. The ISP market environment is, therefore, one of competitive market forces in which each ISP tends to create a retail market presence. However, no ISP can operate in isolation. Each client has the expectation of universal and comprehensive reachability, such that any client of any other ISP can reach the client, and the client can reach a client of any other ISP. The client of an ISP is not undertaking a service contract that limits connectivity only to other clients of the same ISP. Because no provider can claim ubiquity of access, every provider relies on every other provider to complete the user-provided picture of comprehensive connectivity. Because of this dependent relationship, an individual provider's effort to provide substantially superior service quality may have little overall impact on the totality of client-delivered service quality. In a best-effort public Internet, the service quality becomes something that can be impacted negatively by poor local engineering but cannot be uniformly improved beyond the quality provided by the network's peers, and their peers in turn. Internet wholesale carriage services in such an environment are constrained to be a com-

modity service, in which scant opportunity exists for service-based differentiation. In the absence of service quality as an effective service discriminator, the wholesale activity becomes a price-based service with low levels of added value, or in other words a commodity market.

The implication in terms of ISP positioning is that the retail operation, rather than the wholesale activity, is the major area in which the ISP can provide discriminating service quality. Within the retail operation, the ISP can offer a wide variety of services with a set of associated service levels, and base a market positioning on factors other than commodity carriage pricing.

Accordingly, the environment of interconnection between ISPs does not break down into a well-ordered model of a set of wholesale carriage providers and associated retail service providers. The environment currently is one with a wide diversity of retail-oriented providers, where each provider may operate both as a retail service operator, and a wholesale carriage provider to other retailers.

Peer or Client?

One of the significant issues that arises here is: Can an objective determination be made of whether an ISP is a peer to, or a client of, another ISP? This is a critical question, because if a completely objective determination cannot be readily made, the question then becomes one of who is responsible for making a subjective determination, and on what basis.

This question is an inevitable outcome of the reselling environment, where the reseller starts to make multiple upstream service contracts, with a growing number of downstream clients of the reselling service. At this point, the business profile of the original reseller is little distinguished from that of the original provider. The original reseller sees no unique value being offered by the original upstream provider and may conclude that it is, in fact, adding value to the original upstream provider by offering the upstream provider high-volume carriage and close access to the reseller's client base. From the perspective of the original reseller, the roles have changed, and the reseller now perceives itself as a peer ISP to the original upstream ISP provider.

This assertion of role reversal is perhaps most significant when the generic interconnection environment is one of "zero-sum" financial settlement, in which the successful assertion by a client of a change from client to peer status results in the dropping of client service revenue without any net change in the cost base of the provider's operation. The party making the successful assertion of peer interconnection sees the opposite, with an immediate drop in the cost of the ISP operation with no net revenue change.

The traditional public regulatory resolution of such matters has been through an administrative process of "licensed" communications service providers, who become peer entities through a process of

administrative fiat. In this model, an ISP becomes a licensed service provider through the payment of license fees to a communications regulatory body. The license then allows the service enterprise access to interconnection arrangements with other licensed providers. The determination of peer or client is now quite simple: A *client* is an entity that operates without such a carrier license, and a *peer* is one that has been granted such an instrument. However, such regulated environments are quite artificial in their delineation of the entities that operate within a market, and this regulatory process often acts as a strong disincentive to large-scale private investment, thereby placing the burden of underwriting the funding of service industries into the public sector. The regulatory environment is changing worldwide to shift the burden of communications infrastructure investment from the public sector, or from a uniquely positioned small segment of the private sector, to an environment that encourages widespread private investment. The Internet industry is at the leading edge of this trend, and the ISP domain typically operates within a deregulated valued-added communications service provider regulatory environment. Individual licenses are replaced with generic class licenses or similar deregulated structures in which formal applications or payments of license fees to operate in this domain are unnecessary. In such deregulated environments, no authoritative external entity makes the decision as to whether the relationship between two ISPs is that of a provider and client or that of peers.

If no public regulatory body wants to make such a determination, is there a comparable industry body that can undertake such a role? The early attempts of the *Commercial Internet eXchange* (CIX) arrangements in the United States in the early 1990s were based on a description of the infrastructure of each party, in which acknowledgments of peer capability were based on the operation of a national transit infrastructure of a minimum specified capability. This specification of peering within the CIX was subsequently modified so that CIX peer status for an ISP was simply based on payment of the CIX Association membership fee.

This CIX model was not one that intrinsically admitted bilateral peer relationships. The relationship was a multilateral one, in which each ISP executed a single agreement with the CIX Association and then effectively had the ability to peer with all other association member networks. The consequence of this multilateral arrangement is that the peering settlements can be regarded as an instance of "zero-sum" financial settlement peering, using a single-threshold pricing structure.

Other industry models use a functional peer specification. For example, if the ISP attaches to a nominated physical exchange structure, then the ISP is in a position to open bilateral negotiations with any other ISP also directly attached to the exchange structure. This model is inherently more flexible, as the bilateral exchange structure enables each represented ISP to make its own determination of whether to agree to a peer

relationship or not with any other colocated ISP. This model also enables each bilateral peer arrangement to be executed individually, admitting the possibility of a wider diversity of financial settlement arrangements.

The bottom line is that a true peer relationship is based on the supposition that either party can terminate the interconnection relationship and that the other party does not consider such an action a competitively hostile act. If one party has a high reliance on the interconnection arrangement and the other does not, then the most stable business outcome is that this reliance is expressed in terms of a service contract with the other party, and a provider/client relationship is established. If a balance of mutual requirement exists between both parties, then a stable basis for a peer interconnection relationship also exists. Such a statement has no intrinsic metrics that allow the requirements to be quantified. Peering in such an environment is best expressed as the balance of perceptions, in which each party perceives an acceptable approximation of equal benefit in the interconnection relationship in its own terms.

This conclusion leads to the various tiers of accepted peering that are evident in the Internet today. Local ISPs see a rationale to viewing local competing ISPs as peers, and they still admit the need to purchase trunk transit services from one or more upstream ISPs under terms of a client contract with the trunk provider ISP. Trunk ISPs see an acceptable rationale in peering with ISPs with a similar role profile in trunk transit but perceive an inequality of relationship with local ISPs. The conclusion drawn here is that the structure of the Internet is one in which there is a strong business pressure to create a rich mesh of interconnection at various levels, and the architecture of interconnection structures is an important feature of the overall architecture of the public Internet.

Physical Interconnection Architectures: Exchanges and NAPs

One of the physical properties of electromagnetic propagation is that the power required to transmit an electromagnetic pulse over a distance varies in accordance with this distance. The shorter the distance between the transmitter and the receiver, the lower the transmission power budget required; *closer is cheaper*.

This statement holds true not only for electrical power budgets but also for data protocol efficiency. Minimizing the delay between the sender and receiver allows the protocol to operate faster and operate more efficiently as well; *closer is faster,* and *closer is more efficient*.

These observations imply that distinct and measurable advantages are gained by localizing data traffic; that is, by ensuring that the physical path traversed by the packets passed between the sender and the receiver is kept as physically short as possible. These advantages are realizable in terms of service performance, efficiency, and service cost.

How then are such considerations of locality factored into the structure of the Internet?

The Exchange Model

A strictly hierarchical model of Internet structure is one in which a small number of global ISP transit operators is at the "top;" a second tier is of national ISP operators; and a third tier consists of local ISPs. At each tier, the ISPs are clients of the tier above, as shown in Figure 2. If this hierarchical model is strictly adhered to, traffic between two local ISPs is forced to transit a national ISP, and traffic between two national ISPs transits a global ISP—even if both national ISPs operate within the same country. In the worst case, traffic between two local ISPs needs to transit a national ISP, then a global ISP from one hierarchy, then a second global ISP, and a second national ISP from an adjacent hierarchy in order to reach the other local ISP. If the two global providers interconnect at a remote location, the transit path of the traffic between these two local ISPs could be very long indeed.

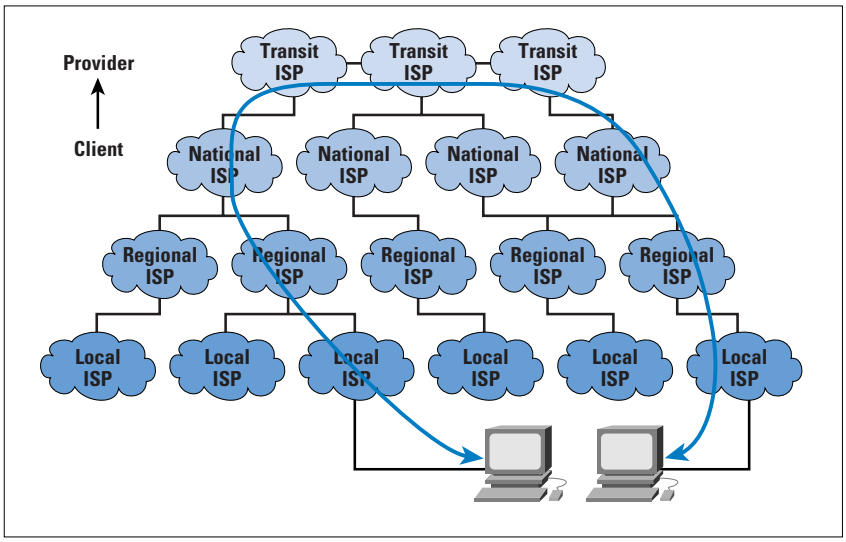


Figure 2: A Purely Hierarchical Structure for the Internet

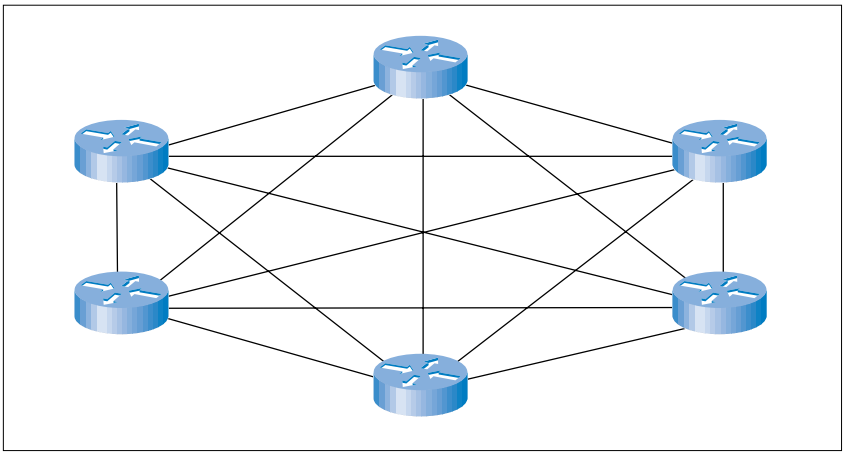
As noted above, such extended paths are inefficient and costly, and such costs are ultimately part of the cost component of the price of Internet access. In an open, competitive market, strong pressure always is applied to reduce costs. Within a hierarchical ISP environment, strong pressure is applied for the two national providers, who operate within the same market domain, to modify this strict hierarchy and directly interconnect their networks. Such a local interconnection allows the two networks to service their mutual connectivity requirements without payment of transit costs to their respective global transit ISP providers. At the local level is a similar incentive for the local ISPs to reduce their cost base, and a local interconnection with other local ISPs would allow local traffic to be exchanged without the payment of transit costs to the respective transit providers.

Although constructing a general interconnection regime based on point-to-point bilateral connections is possible, this approach does not exhibit good scaling properties. Between N providers who want to interconnect, the outcome of such a model of single interconnecting circuits is $(N^2 - N) / 2$ circuits and $(N^2 - N) / 2$ routing interconnections, as indicated in Figure 3. Given that interconnections exhibit the greatest leverage within geographical local situations, simplifying this picture within the structure of a local exchange is possible. In this scenario, each provider draws a single circuit to the local exchange and then executes interconnections at this exchange location. Between N providers who want to interconnect, the same functionality of complete interconnection can be constructed using only N point-to-point circuits.

Figure 3: Fully Meshed Peering



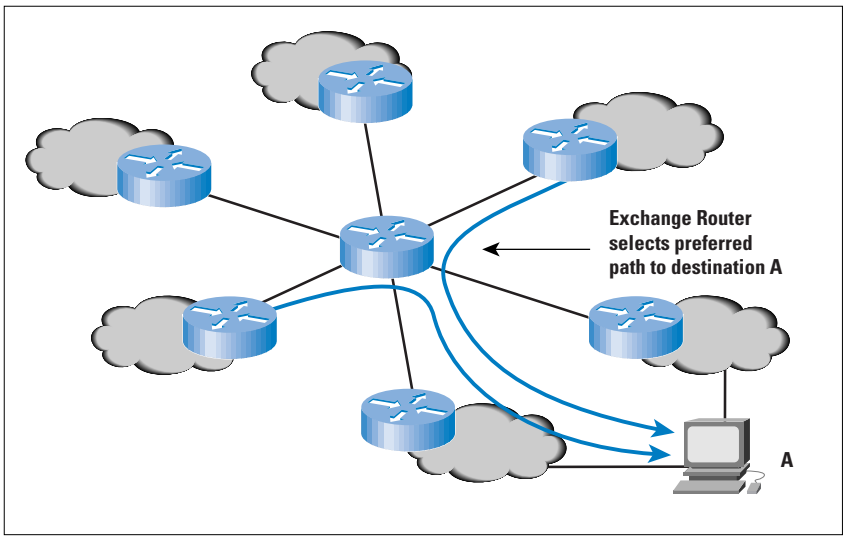
The Exchange Router

One model of an exchange is to build the exchange itself as a router, as indicated in Figure 4. Each provider's circuit terminates on the exchange router, and each provider's routing system peers with the routing process on the exchange router. This structure also simplifies the routing configuration, so that full interconnection of N providers is effected with N routing peer sessions. This simplification does allow greater levels of scaling in the interconnection architecture.

However, the exchange router model becomes an active component of the interconnect peering policy environment. In effect, each provider must execute a multilateral interconnection peering with all of the other connected providers. Selectively interconnecting with a subset of the providers present at such a router-based exchange is not easily achieved. In addition, this type of exchange must execute its own routing policy. When two or more providers are advertising a route to the same destination, the exchange router must execute a policy decision as to which provider's route is loaded in the router's forwarding table, making a policy choice of transit provider on behalf of all other exchange-connected providers.

Because the exchange is now an active policy element in the interconnection environment, the exchange is no longer completely neutral to all participants. This imposition on the providers may be seen as unacceptable, in that some of their ability to devise and execute an external transit policy is usurped by the exchange operator's policies.

Figure 4: An Exchange Router



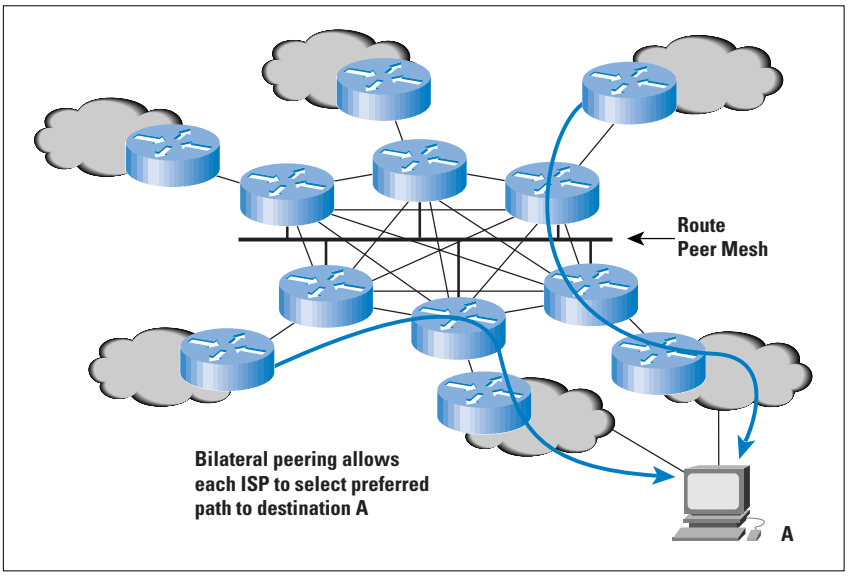
Typically, providers have a higher expectation of flexibility of policy determination from exchange structures than the base level of functionality that is provided by an exchange router. Providers want the flexibility to execute interconnections on a bilateral basis at the exchange, and to make policy decisions as to which provider to prefer when the same destination is advertised by multiple providers. They require the exchange to be neutral with respect to such individual routing policy decisions.

The Exchange Switch

The modification to the interprovider exchange structure is to use a local Layer 2 switch (or LAN) as the exchange element. In this model, a participating provider draws a circuit to the exchange and locates a dedicated router on the exchange LAN, as shown in Figure 5. Each provider executes a bilateral peering agreement with another provider by initiating a router peering session with the other party's router. When the same network destination is advertised by multiple peers, the provider can execute a policy-based preference as to which peer's route will be loaded in the local forwarding table. Such a structure preserves the cost efficiency of using N circuits to effect interconnection at the N provider exchange, while admitting the important policy flexibility provided by up to $(N^2 - N) / 2$ potential routing peer sessions.

Early interprovider exchanges were based on an Ethernet LAN as the common interconnection element. This physical structure was simple, and not all that robust under the pressures of growth as the LAN became congested.

Figure 5:
An Exchange LAN



Subsequent refinements to the model have included the use of Ethernet switches as a higher capacity LAN, and the use of *Fiber Distributed Data Interface* (FDDI) rings, switched FDDI hubs, Fast Ethernet hubs, and switched Fast Ethernet hubs. Exchanges are very-high-traffic concentration points, and the desire to manage ever-higher traffic volumes has led to the adoption of Gigabit Ethernet switches as the current evolutionary technology step within such exchanges.

The model of the exchange colocation accommodates a model of diversity of access media, in which the provider's colocated router undertakes the media translation between the access link protocol and the common exchange protocol.

The local traffic exchange hub does represent a critical point of failure within the local Internet topology. Accordingly, the exchange should be engineered in the most resilient fashion possible, using standards associated with a premium quality data center. This structure may include multiple power utility connections, uninterruptible power supplies, multiple trunk fiber connections, and excellent site security measures.

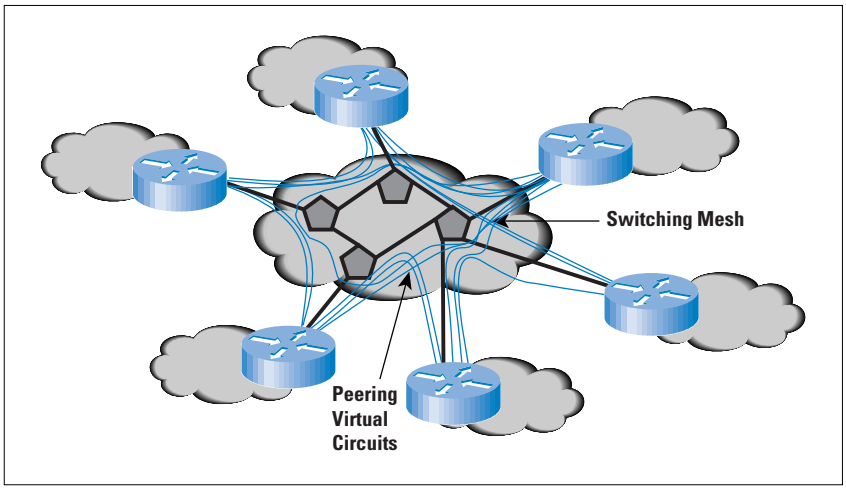
The exchange should operate neutrally with respect to every participating ISP, with the interests of all the exchange clients in mind. Thus, exchange facilities, which are operated by an entity that is not also a local or trunk ISP, enjoy higher levels of trust from the clients of the exchange.

There are also some drawbacks to an exchange, and a commonly cited example is that of imposed transit. If an exchange participant directs a default route to another exchange router, then in the absence of defensive mechanisms, the target router carries the imposed transit traffic even when there is no routing peering or business agreement between the two ISPs. Exchange-located routers do require careful configuration management to ensure that route peering and associated transit traffic matches the currently executed interconnection agreements.

Distributed Exchanges

Distributed exchange models also have been deployed in various locations. This deployment can be as simple as a metropolitan FDDI extension, in which the exchange comes to the provider's location rather than the reverse, as indicated in Figure 6. Other models that use an ATM-based switching fabric also have been deployed using *LAN Emulation* (LANE) to mimic the Layer 2 exchange switch functionality. Distributed exchange models attempt to address the significant cost of operating a single colocation environment with a high degree of resilience and security, but do so at a cost of enforcing the use of a uniform access technology between every distributed exchange participant.

Figure 6: A Distributed Exchange



However, the major challenge of such distributed models is that of switching speed. Switching requires some element of contention resolution, in which two ingress data elements that are addressed to a common egress path require the switch to detect the resource contention and then resolve it by serializing the egress. Switching, therefore, requires signaling, in which the switching element must inform the ingress element of switch contention. To increase the throughput of the switch, the latency of this signaling must be reduced. The dictates of increased switching speed have the corollary of requiring the switch to exist within the confines of a single location, if exchange performance is a paramount concern.

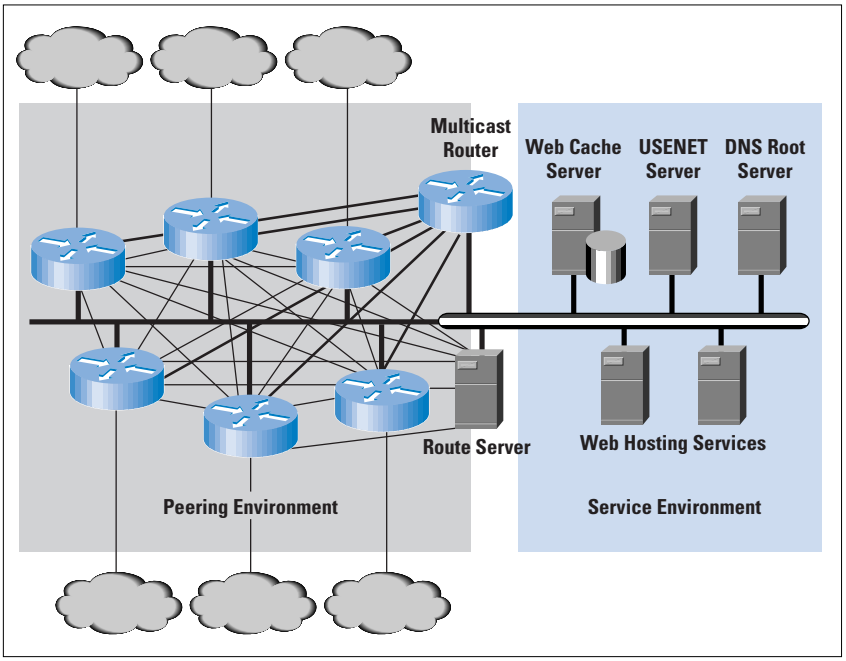
In addition to speed, the cost shift must be considered. In a distributed exchange model, the exchange operator operates the set of access circuits that form the distributed exchange. This process increases costs to providers, while it prevents the providers from using a specific access technology that matches their business requirements of cost and supportable traffic volume. Not surprisingly, to date the most prevalent form of exchange remains the third-party hosted colocation model. This model admits a high degree of diversity in access technologies, while still providing the substrate of an interconnection environment that can operate at high speed and therefore manage high traffic volumes.

Other Exchange-Located Services

The colocation environment is often broadened to include other functions, in addition to a pure routing and traffic exchange role. For a high-volume content provider, the exchange location offers minimal transit distance to a large user population distributed across multiple local service providers, as well as allowing the content provider to exercise a choice in selecting a nonlocal transit provider.

The exchange operator can also add value to the exchange environment by providing additional functions and services, as well as terminating providers' routers and large-volume content services. The exchange location within the overall network topology is an ideal location for hosting multicast services, because the location is optimal in terms of multicast carriage efficiency. Similarly, USENET trunk feed systems can exploit the local hub created by the exchange. The overall architecture of a colocation environment that permits value-added services, which can productively use the unique environment created at an exchange, is indicated in Figure 7.

Figure 7: Exchange-Located Service Platforms



Network Access Points

The role of the exchange was broadened with the introduction of the *Network Access Point* (NAP) in the architecture proposed by the National Science Foundation (NSF) in 1995 when the NSFNET backbone was being phased out.

The NAP was seen to undertake two roles: the role of an exchange provider between regional ISPs who want to execute bilateral peering arrangements and the role of a transit purchase venue, in which regional ISPs could execute purchase agreements with one or more of a set of trunk carriage ISPs also connected at the NAP. The access point concept was intended to describe access to the trunk transit service.

This mixed role of both local exchange and transit operations leads to considerable operational complexity, in terms of the transit providers being able to execute a clear business agreement. What is the bandwidth of the purchased service in terms of requirements for trunk transit, versus the access requirements for exchange traffic? If a local ISP purchases a transit service at one of the NAPs, does that imply that the trunk provider is then obligated to present all the ISP's routes at remote NAPs as a peer? How can a trunk provider distinguish between traffic presented to it on behalf of a remote client versus traffic presented to it by a local service client?

The issue that the quality of the purchased transit service is colored by the quality of the service provided by the NAP operator should also be considered. Although the quality of the transit provider's network may remain constant, and the quality of the local ISP's network and ISP's NAP access circuit may be acceptable, the quality of the transit service may be negatively impacted by the quality of the NAP transit itself.

One common solution is to use the NAP colocation facility to execute transit purchase agreements and then use so-called *backdoor* connections for the transit service provision role. This usage restricts the NAP exchange network to a theoretically simpler local exchange role. Such a configuration is illustrated in Figure 8.

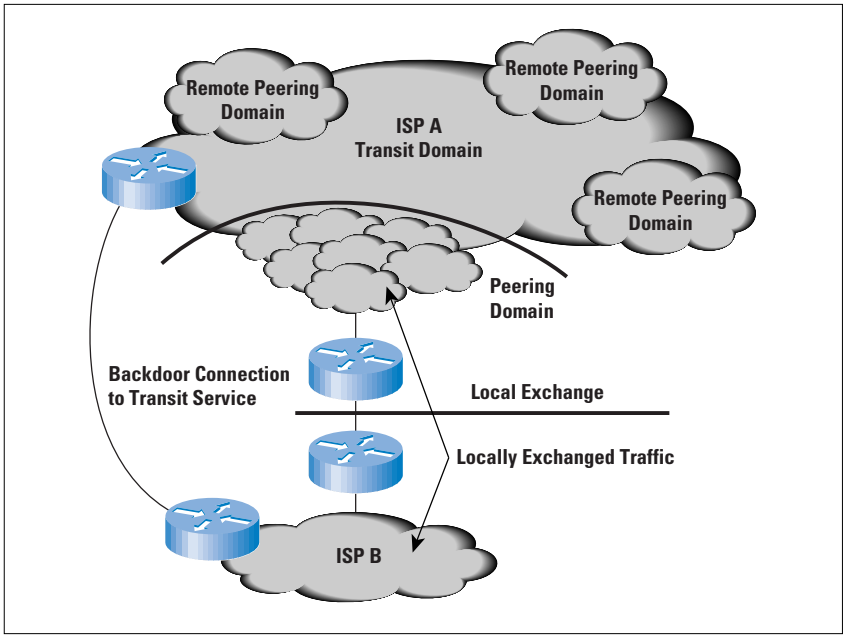


Figure 8: Peering and Transit Purchase

Exchange Business Models

For the ISP industry, many attributes are considered highly desirable for an exchange facility. The common model of an Internet exchange includes many, if not all, of the following elements:

- Operated by a neutral party who is not an ISP (to ensure fairness and neutrality in the operation of the exchange)
- Constructed in a robust and secure fashion
- Located in areas of high density of Internet market space
- Able to scale in size
- Operates in a fiscally sound and stable business fashion

A continuing concern exists about the performance of exchanges and the consequent issue of quality of services that traverse the exchange. Many of these concerns stem from an exchange business model that may not be adequately robust under pressures of growth from participating ISPs.

The exchange business models typically are based on a flat-fee structure. The most basic model uses a fee structure based on the number of rack units used by the ISP to colocate equipment at the exchange. When an exchange participant increases the amount of traffic presented over an access interface, under a flat-fee structure, this increased level of traffic is not accompanied by any increase in exchange fees. However, the greater traffic volumes do imply that the exchange itself is faced with a greater traffic load. This greater load places pressure on the exchange operator to deploy further equipment to augment the switching capacity, without any corresponding increase in revenue levels to the operator.

For an exchange operator to base tariffs on the access bandwidths is not altogether feasible, given that such access facilities are leased by the participating ISPs and the access bandwidth may not be known to the exchange operator. Nor is using a traffic-based funding model possible, because an exchange operator should refrain from monitoring individual ISP traffic across the exchange, given the unique position of the exchange operator. Accordingly, the exchange operator has to devise a fiscally prudent tariff structure at the outset that enables the exchange operator to accommodate large-scale traffic growth, while maintaining the highest possible traffic throughput levels.

Alternatively, there are business models in which the exchange is structured as a cooperative entity among numerous ISPs. In these models, the exchange is a nonprofit common asset of the cooperative body. Although widely used, these models are prone to the economic condition of the *Tragedy of the Commons*. It is in everyone's interest to maximize their exploitation of the exchange, while no single member wants to underwrite the financial responsibility for ensuring that the quality of the exchange itself is maintained.

The conclusion that can be drawn is that the exchange is an important component of Internet infrastructure, and the quality of the exchange is of paramount importance if it is to be of any relevance to ISPs. Using an independent exchange operator whose income is derived from the utility of the exchange is one way of ensuring that the exchange is managed proficiently and that the service quality is maintained for the ISP clients of the exchange.

A Structure for Connectivity

Enhancing the Internet infrastructure is quantified by the following objectives:

- Extension of reachability
- Enhancement of policy matching by ISPs
- Localization of connectivity
- Backup arrangements for reliability of operation
- Increasing capacity of connectivity
- Enhanced operational stability
- Creation of a rational structure of the connection environment to allow scalable structuring of the address and routing space in order to accommodate orderly growth

We have reached a critical point within the evolution of the Internet. The natural reaction of the various network service entities in response to the increasing number of ISPs will be to increase the complexity of the interconnection structure to preserve various direct connectivity requirements. Today, we are in the uncomfortable position of increasingly complex interprovider connectivity environments, a situation that is stressing the capability of available technologies and equipment. The inability to reach stable cost-distribution models in a transit arrangement creates an environment in which each ISP attempts to optimize its position by undertaking as many direct 1:1 connections with peer ISPs as it possibly can. Some of these connections are managed via the exchange structure. Many more are implemented as direct links between the two entities. Given the relative crudity of the inter-*Autonomous System* (AS) routing policy tools that we use today, this structure must be a source of considerable concern. The result of a combination of an increasingly complex mesh of inter-AS connections, together with very poor tools to manage the resultant routing space, is an increase in the overall instability of the Internet environment. In terms of meeting critical immediate objectives, however, such dire general predictions do not act as an effective deterrent to these actions.

The result is a situation in which the inter-AS space is the critical component of the Internet. This space can be viewed correctly as the *demilitarized zone* within the politics of today's ISP-based Internet. In the absence of any coherent policy, or even a commonly accepted set of practices, the lack of administration of this space is a source of paramount concern.

GEOFF HUSTON holds a B.Sc and a M.Sc from the Australian National University. He has been closely involved with the development of the Internet for the past decade. He was responsible for the initial build of the Internet within the Australian academic and research sector. Huston is currently the Chief Technologist in the Internet area for Telstra. He is also an active member of the IETF, and is a member of the Internet Society Board of Trustees. He is author of *The ISP Survival Guide*, and coauthor of *Quality of Service: Delivering QoS on the Internet and in Corporate Networks*, a collaboration with Paul Ferguson. Both books are published by John Wiley & Sons.

IPv6—What and Where It Is

by Robert L. Fink, Energy Sciences Network

The current Internet Protocol, known as IPv4 (for version 4), has served the Internet well for over 20 years, but is reaching the limits of its design. It is difficult to configure, it is running out of addressing space, and it provides no features for site renumbering to allow for an easy change of *Internet Service Provider* (ISP), among other limitations. Various mechanisms have been developed to alleviate these problems (for example, *Dynamic Host Configuration Protocol* [DHCP] and *Network Address Translation* [NAT]), but each has its own set of limitations.

The *Internet Engineering Task Force* (IETF) took on this problem in the early 1990s by starting an IPng (*Internet Protocol next generation*) project. After an over two-year-long process of defining goals and features, getting the best possible advice from industry and user experts, and sponsoring a protocol design competition, a new Internet Protocol was selected. Many proposed protocols were reviewed, analyzed, and evaluated. An evolved combination of several of them (*Simple Internet Protocol* [SIP], the *"P" Internet Protocol* [PIP], and *Simple Internet Protocol Plus* [SIPP]), each using fixed-length addressing, resulted in a final variation, called IPv6, which was selected over a version of the ISO OSI *Connectionless Network Protocol* (CLNP) (known as the *TCP and UDP with Bigger Addresses* (TUBA) IPng proposal).

Much work has been done since the selection of IPv6 in 1994. Over 50 implementations of IPv6 are believed to be under way or completed. A constantly growing international IPv6 testbed, called the *6bone,* now spans 260 sites in 39 countries, with over 25 different IPv6 implementations in use. Most router companies, including 3Com, Bay, Cisco Systems, Digital, Nokia, and Telebit support IPv6. IPv6 is also available for Digital, HP, IBM, Sun, WinTel, and many other end-user host systems.

IPv6 Addresses—Larger and Different

The larger 128-bit IPv6 address (versus the 32-bit IPv4 address) allows more flexibility in designing newer addressing architectures, as well as providing large enough address spaces for predicted future growth of the Internet and Internet-related technologies. A new addressing format, called the *Aggregatable Global Unicast Address Format*, has been developed to help solve route complexity scaling problems with the current IPv4 Internet. The current IPv4 provider-based addressing used in the Internet relies on separate IPv4 addresses being assigned to ISPs in contiguously numbered blocks for routing efficiency; that is, the routers need to carry fewer routes.

However, there is currently much fragmentation in the IPv4 address space. This situation, aggravated by sites not being able to easily renumber, causes many more separate routes than necessary, in turn leading to route computation complexity (too many routes, too many dynamic changes, too much computation in routers).

Public Routing Topology Prefixes

With the new aggregatable style addressing (see Figure 1), the left-most 48 bits of the address are defined as a *Public Routing Topology* (PRT) prefix. The first 3-bit field of this prefix specifies that the addressing format is aggregatable. The next 13-bit portion specifies the *Top Level Aggregator* (TLA) ID that constrains the top level of Internet routing to 8,192 major transit providers and a new concept of routing exchanges. Each TLA (top level transit ISP) is then responsible for all the remaining public routing topology assignment below it; that is, the *Next Level Aggregator* (NLA) ID. As shown in Figure 1, the NLA may have a tiered hierarchy to allow multiple levels (NLA1, NLA2, and so on) of other ISPs, each of which would then have control of the assignment of the space below it. The right-most portion of the NLA field, at whatever level it may be, would identify the end-user "leaf" site. An 8-bit reserved field has been defined to allow the growth of either the TLA or the NLA fields.

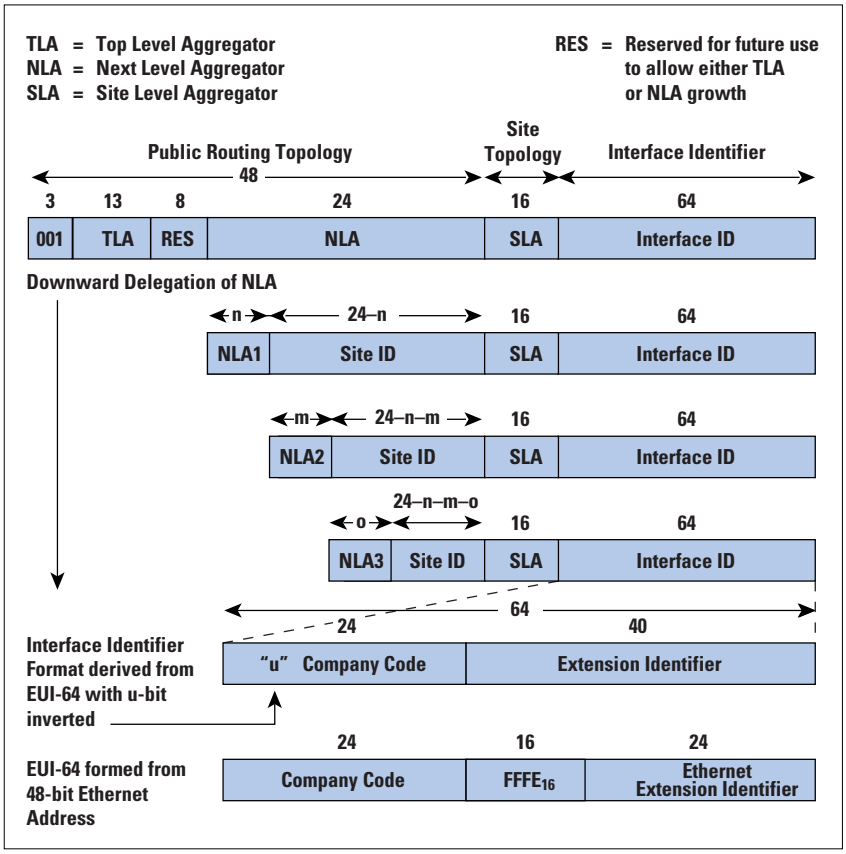

Figure 1: Aggregatable Global Unicast Address Format

The advantage of this style of addressing is that it allows automatic address clustering, or aggregation, into a constrained set of routes, which are represented through the TLA field. If the initial assignment of 13 bits (8,192 TLAs) is insufficient in the future, either the reserved field or another piece of the IPv6 128-bit address space could be utilized. Note that only one-eighth of the current IPv6 address space has been assigned to aggregatable addressing.

Even with this new concept of addressing, sites will still occasionally want to change their ISP (as in the current IPv4-based Internet) and thus will need to readdress to keep the addressing structure constrained. This is where *Site Renumbering*, which will be discussed later, comes in.

IPv6 TLA Assignment

To begin the production use of IPv6, ISPs providing IPv6 service need to be assigned TLAs so they may assign NLAs to transits and sites they are serving. Until recently, this was not possible. Recent discussions between the IETF, the IANA (*Internet Assigned Numbers Authority*), and the major address registries (APNIC, ARIN, and RIPE-NCC), have resulted in agreements that will provide a way to request and assign TLAs by early 2nd quarter 1999.

The process agreed upon is based on the above discussions that have been published as a recommendation in an Informational RFC on TLA assignments. The basic idea is to provide a slow start mechanism for TLAs by assigning one TLA ID to be used for defining a Sub-TLA field of 13 bits out of the reserved and NLA fields (see Figure 2). This will allow transits to demonstrate their need for a full TLA based on usage of the assigned Sub-TLA. These rules, based on much current practice with IPv4, are necessary to keep aggregatable addressing functional and effective for hierarchical routing as IPv6 comes into use.

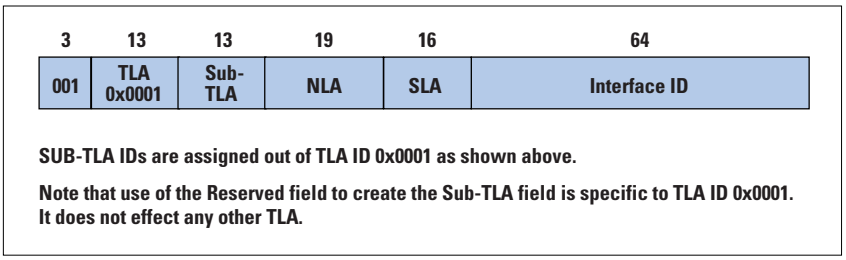

Figure 2: Sub-TLA Format for IPV6 Address Assignment

Rules for assigning these Sub-TLAs include:

- Must have a plan to offer native IPv6 service within three months from assignment; must have a verifiable track record providing Internet transit to other organizations
- Must make payment of a registration fee to the IANA and reasonable fees for services rendered by the address registry
- Must maintain registries of sites and next-level providers and make them available publicly and to the registries; must provide utilization statistics of NLA space below the assigned TLA (or Sub-TLA) and also show evidence of carrying TLA routing and transit traffic

These rules are intended to minimize route explosion and address assignment misuse to aid in the stability of the IPv6-based Internet.

Site Topology Prefixes

In addition to identifying the address of the site with the PRT prefix, aggregatable addressing provides for a site to have aggregation as well using a 16-bit *Site Level Aggregator* (SLA). The SLA might be as simple as a subnet number (more than 64,000 of them!), or a tiered hierarchy such as the NLA provides. However it is structured, the SLA is under the control of the site, and identifies the subnet that a host interface is attached to (IPv6's addressing, as IPv4's, specifies interfaces on systems, not the entire system).

It is very unlikely that an organization will ever need more than one PRT prefix, given the size and flexibility of the SLA and the *System Interface Identifier* field (described below).

System Interface Identifiers

Now that we have identified how to reach the site and the subnet a system is attached to, an interface identifier (ID) specifies the local logical address of the interface on the local subnet (or *link* as it is often called). The interface ID is formed and derived from the new IEEE EUI-64 media-level address that is an expansion of the well-known Ethernet 48-bit address format that allows for more device identifiers to be assigned by each manufacturer. The global/local bit is also inverted to make manually assigned (that is, local) addresses easy to form with only leading zeros.

If the IPv6 node is attached to an Ethernet "link," then the 48-bit address is turned into 64 bits by a filler field inserted in the middle (see Figure 1).

This enlarged Interface ID will allow newer technologies, such as *FireWire*, and newer applications, such as traffic lights and PCS/PDA telephones, to have unique interface identifiers assigned to them from a global address space.

The use of a media-level address for a network-level Interface ID allows the very important IPv6 Stateless Address Autoconfiguration Protocol to work.

Stateless Address Autoconfiguration

Automatic configuration of IPv6 end systems (hosts) is one of the most important features of IPv6. In the current IPv4 Internet, you must either manually configure IP address, network mask, and default gateway, or rely on having a DHCP server. With IPv6, this process can take place automatically, with no reliance on outside systems, using the IPv6 *Stateless Address Autoconfiguration Protocol*.

This can be done because the *Media Access Control* (MAC) address is used to form the host's interface ID. For example, if a host has an Ethernet interface that it is trying to configure for use with IPv6, the 48-bit Ethernet MAC address is formed into a 64-bit interface ID, which is the right-most 64 bits of the IPv6 address (see Figure 1). Then, using the *Neighbor Discovery* (ND) protocol, which is unique to IPv6, this formed interface ID is checked to see that it does not have a duplicate on this link (that is, subnet). If it does, a randomly generated token can be used (though a rare occurrence, it is a necessary protection against illegal Ethernet address usage and situations where the same address may be used on multiple interfaces for legitimate reasons).

At this point, an *ND Router Solicitation* multicast message is sent out to discover if there is a local IPv6 capable router, what the local site's topology ID for the host's subnet is, and what the site's public topology routing prefix is. Neighbor Discovery can also be used to control whether the site then wishes to continue with further configuration using Stateful Autoconfiguration with DHCPv6.

IPv6 Autoconfiguration thus provides for standalone operation of two or more hosts on a local LAN link with no router present, provides for operation within a site with no outside Internet connectivity present, and allows for easy changing of the site's public topology routing prefix, either when external connectivity comes on line, or when the external connectivity is changed, such as when a different ISP is chosen.

Domain Name System—Forward and Reverse

The *Domain Name System* (DNS) is an essential component of the Internet. To provide a mapping from a domain name to an IPv6 address, as well as an IPv4 address, a new DNS record type of "AAAA," or "quad A," is defined. This is a clever word play on the "A" record type that the original DNS specification defines for 32-bit IPv4 addresses, because IPv6 addresses are four times larger (128-bits), hence "AAAA"!

Most existing implementations of DNS already support AAAA records and existing IPv4 queries of DNS can access these records; that is, you don't need a DNS operating over IPv6 to retrieve these new AAAA records. This support also includes reverse lookups, similar to IPv4s, although a new reverse lookup proposal that will allow automatic partitioning of the delegation information on arbitrary bit boundaries is under consideration. This new capability should make for more reliable reverse registry than exists with IPv4, and easier maintenance when sites change their PRT prefix.

When a host with both IPv4 and IPv6 operating on it ("dual stack") queries the DNS for the address of a remote host, the A and AAAA records returned are used to indicate what protocol to use in communicating with that remote host. If no AAAA record is returned, IPv4 must be used. If only a AAAA record is returned, IPv6 must be used. If both A and AAAA are returned, either IPv4 or IPv6 may be used.

A new modification of the IPv6 DNS extensions is nearing completion that allows the automatic joining of the routing prefixes and Interface IDs when a host's IPv6 address is returned, thus making it easier to renumber a site. This new IPv6 DNS feature makes changing a site's PRT prefix (renumbering) very easy as only one entry, the PRT prefix, needs to be changed. This setup also facilitates easy support of multiple addresses for each host. These enhancements are very useful; IPv4 does not have this feature.

Renumbering Sites When ISPs Change

Because IPv6 addressing is based on the PRT prefix assigned by its ISP, it is essential that it be easy for a site to renumber itself when its choice of ISP changes. To aid in this, a new *Router Renumbering* (RR) protocol, in conjunction with Autoconfiguration, Neighbor Discovery and the new Aggregatable Unicast addressing PRT prefix are used.

RR allows a site's network administrator to set new PRT prefixes into the site's routers, as well as lower the lifetime of existing ISP PRT prefixes to specify an overlap interval, after which the old ISP's service is discontinued.

Hosts learn their new routing prefixes either when they restart, and thus are automatically configured with Autoconfiguration, or when they are informed by their local router that a new prefix is to be used during periodic router notification updates using ND.

For example, a new ISP service is readied for service while the old ISP is notified that it will provide service for just 60 more days. After the new PRT prefix is announced to the site's routers by RR, hosts will use the new prefix (that is, new ISP) for all new connections, while existing connections continue to work until the old prefix is withdrawn (that is, after 60 days in this example).

The easy renumbering of an IPv6 site will make easy a task that is currently very painful for an IPv4 site because hosts are often manually configured in many networks.

The 6bone—An IPv6 Testbed

The 6bone is an international IPv6 testbed network that is overseen and directed through the IETF *IPng Transition Working Group* (ngtrans) that provides:

- Testing of IPv6 implementations and standards
- Testing of IPv6 transition strategies
- A place to gain early applications and operations experience
- Motivation and a place for implementers, users, and ISPs to try IPv6
- An experimental first step toward transition

In the early phases of IPv6 deployment, most native IPv6 transport is restricted to site LANs with the ability to experiment with it locally. Some sites in Great Britain, The Netherlands, and Japan are using native IPv6 over WAN links.

ISPs and various other private IPv4 transit providers may not place IPv6 in their production routers in this early phase of IPv6 deployment, leaving early IPv6 testers with the need to use the existing IPv4 Internet infrastructure to deliver IPv6 packets among themselves when remotely located. Thus an IPv6 transition feature, IPv6 encapsulation (that is, *tunneling*) over IPv4, is used for parts of the 6bone where native IPv6 may not be available. In this way, the 6bone is also thoroughly testing out its own transition technology as well as providing IPv6 service.

The 6bone is a diverse community of users, ISPs, and developer organizations, many of whom provide transit on the public spirited basis of promoting and gaining early experience with IPv6. It is expected that production variations of the 6bone will also be created to more formally carry production IPv6 traffic.

Components of the 6bone

The 6bone provides this needed IPv6 transport over the public Internet infrastructure, relying on:

- Dual IPv4/IPv6 stacks in the client host
- IPv6 packets encapsulated (tunneled) in IPv4 packets
- Dual IPv4/IPv6 stack backbone routers that know IPv6 routes of 6bone participants
- DNS that supports IPv6 AAAA records
- A 6bone Routing Registry to keep track of sites and their tunnels
- A mailing list, various IPv6 tools, and a 6bone Web site at: **`www.6bone.net`**

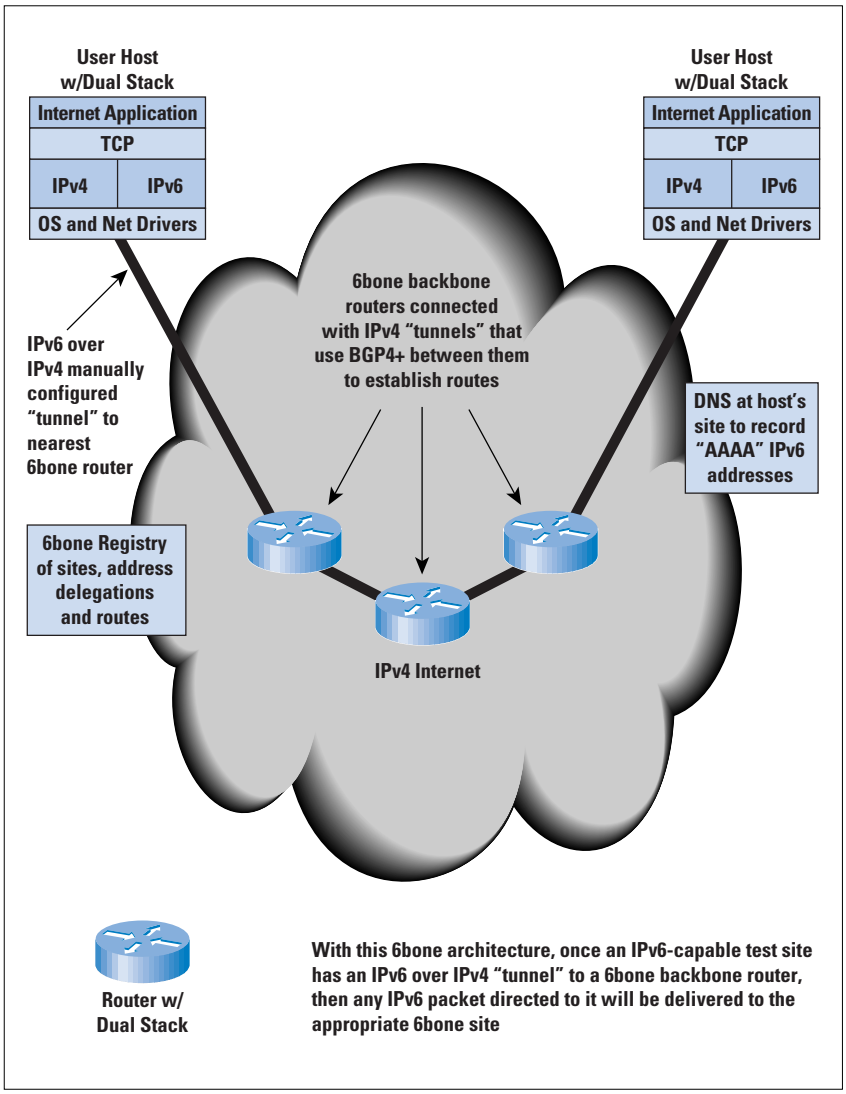
Figure 3 shows a conceptual overview of how a basic 6bone is structured and a picture of the current 6bone backbone structure can be seen at:

`http://www.cs-ipv6.lancs.ac.uk/ftp-archive/6Bone/Maps/full-backbone.gif`

…with the pseudo TLA site-to-site peering indicated by various colored links.

To date, the 6bone has spread to 260 organizations in 39 countries (see Table 1 on page 25).

Figure 3: 6bone Conc eptual Architecture



6bone History

Serious work to evolve and refine the IPv6 protocols sufficient to allow the start of various implementations of IPv6 began in 1994. By early 1996, it was obvious that a testing environment was needed, so in March 1996, several implementers and users met and agreed to start an international testbed called the 6bone.

By June 1996, two groups raced to provide the first IPv6 connectivity: the University of Lisbon (Portugal), the Naval Research Laboratory (U.S.), and Cisco Systems (U.S.); a Danish universities consortium (UNI-C), a French universities consortium (G6), and a Japanese universities consortium (WIDE).

Table 1: Countries with Sites Participating in the 6bone

AT-Austria	FI-Finland	NL-The Netherlands
AU-Australia	FR-France	NO-Norway

6bone Backbone and Addressing

By the end of 1997, the 6bone converted to the new aggregatable addressing format, a change necessitated by having originally adopted an early prototype provider-based addressing format discussed during early IPv6 design efforts.

Along with the change to a new addressing format was the need to clean up the routing used among the 6bone backbone transit sites. It was originally thought that IDRPv6 (a new Internet Domain Routing Protocol based on earlier IPv4 work) would be the prevailing *Exterior Gateway Protocol* (EGP) used for IPv6 Internet peering.

By mid 1996, various ISPs made it known that a new EGP for IPv6 was not a practical alternative, given the explosive growth of the Internet and the current evolution and widespread use of the *Border Gateway Protocol 4* (BGP4) by ISPs. There was a need to allow for multiprotocol extensions to BGP4, allowing ISPs to more easily adapt their operations to IPv6. This situation led to the rapid evolution of BGP4+, an extension of BGP4 to include IPv6 and IPv4 multiprotocol routing.

By mid 1997, the decision was made to convert the 6bone backbone to BGP4+ for its EGP. See **`http://www.cs-ipv6.lancs.ac.uk/ftp-archive/6Bone/Maps/full-backbone.gif`** for a recent picture of the 6bone backbone sites using the new aggregatable addressing format and the current status of the conversion to BGP4+.

6bone Future Plans

To date, most 6bone efforts have been to prove out basic IPv6 interoperability among the many implementations, and to create a reliable international testbed infrastructure. This has included making its backbone operationally ready with the new aggregatable addressing format and use of BGP4+ for high-reliability routing and transit.

Now that the 6bone has completed these conversions, serious work can begin on testing site renumbering, security, applications, and transition mechanisms.

Other IPv6 Trials and Testing

Other testing venues have also been very important to the evolution of IPv6: the University of New Hampshire *Inter Operability Laboratory* (IOL), various trade show demonstration networks, for example, NetWorld+Interop, and various vendor-sponsored interoperability testing.

By early 1998, the UNH IOL had hosted five IPv6 test sessions, though specific details about participating vendors are not released.

In a positive sign of industry response to evolving IPv6 specifications, the late July 1997 UNH testing resulted in the successful interoperability of all participants using the new aggregatable addressing format, no more than two months from its first Internet Draft.

Implementations

To date, over 50 different IPv6 host and router implementations are either completed or under way. More than 30 implementations have been tested and used on the 6bone.

Router implementations to date include: 3Com, Bay, Cisco Systems, Digital, Fujitsu LR550, Hitachi NR60, Inria BSD, Linux, Merit MRT, Nokia, NRL for BSD, Telebit, WIDE KAME and ZETA for BSD, and WIDE v6d.

Host implementations to date include: Apple MacOS OpenTransport demo version, Digital OpenVMS, Digital UNIX, FTP Software Windows95, Fujitsu LR450, 460, and 550, Hitachi NR60, IBM AIX, Inria BSD, Linux, HP-UX (SICS), Microsoft Research WindowsNT versions 4 and 5, Sony CSL Apertos IPv4/v6 stack, Sun Solaris, Trumpet Winsock for IPv6, UNH for BSD, NRL for BSD, WIDE KAME and ZETA for BSD, and WIDE v6d.

Several new Windows implementations that will operate under Windows95/98/NT are under way.

Transition from IPv4 to IPv6—A Seamless Approach

IPv6 is unlikely to become the Internet network-layer protocol of choice unless there is literally no choice to be made by the end user, little effort by network and system administrators, and it can operate alongside IPv4 for the indefinite future. Therefore, it must be very easy for the private network (your corporate net) and public network (your ISP) operators to equip, enable, and operate IPv6, while operating IPv4, in such a way that the user doesn't notice that IPv6 is there at all.

A system administrator, but not the user, must be conscious of IPv6 in a minimal sense. It is just another protocol stack that any Internet-based applications will operate over if the system is configured and distributed to do so by the system administrator.

At the network operator level, IPv6 is just another routing stack that can easily be turned on in the site's and ISP's routers (many sites certainly support IPX, AppleTalk, DECnet,...). IPv6 interdomain routing can be operated just like IPv4s because it uses BGP4+.

With the aid of the new *Dynamic DNS Registration Protocol* and IPv6's Stateless Autoconfiguration, users can boot up their system after it has been enabled with an IPv6 stack, in addition to its IPv4 stack, and become IPv6-ready without being aware of it at all. The system would automatically be configured with an IPv6 address, have itself registered automatically in the DNS with the host's existing name alongside its new IPv6 address (in addition to its DNS IPv4 address registration), and when finding a remote host with IPv6, start talking IPv6—all this without the user being required to consciously take action.

Early Production IPv6 Networks

In October of 1998, the *6REN* initiative, was established by the U.S. Energy Sciences Network (ESnet). The 6REN is a voluntary coordination initiative of *Research and Education Networks* (RENs) that provide production IPv6 transit service to facilitiate high quality, high performance, and operationally robust IPv6 networks.

The first participants were ESnet (the U.S. Dept. of Energy's Energy Sciences Network), Internet2 (the advanced Internetworking development collaboration comprised of many large U.S. research universities), CANARIE (the Canadian joint government and industry initiative for advanced networking), vBNS (the MCI network for NSF advanced networking) and WIDE (the Japanese research effort to establish a "Widely Integrated Distributed Environment").

Other profit and not-for-profit networks worldwide have been invited to join the 6REN. It is expected that during 1999 a sizable production environment capable of advanced demonstrations and deployment of Internet applications over IPv6 networks will be in place.

The Future for IPv6

It is too early to predict with total certainty that the Internet will adapt to the use of the IPv6 protocol. However, it should be obvious that IPv6 offers many important features for a next-generation Internet: automatic configuration, greatly expanded addressing, easy site renumbering, built-in security, and more.

One possible scenario for IPv6 is where it becomes the protocol of choice for newer applications not currently using Internet technology; for example, controlling traffic lights, reading electric meters, and so on. In these uses, IPv6 does not require coexistence with IPv4 because some form of gateway function would provide interconnection to the current Internet.

Another scenario (which doesn't exclude the previous one) is that Microsoft provides IPv6 support for a future version of Windows Networking on Windows OS, and promotes it within corporate America for its better features in supporting advanced corporate application/networking needs. In this scenario, the Internet will learn to carry IPv6 somehow, even if it is via automatically created tunnels that operate over IPv4 (somewhat similar to the 6bone's tunneling, but with dynamic creation of the tunnels as needed). It is expected that after Microsoft ships IPv6 and large corporations begin using it, ISPs will deploy IPv6 to get their business.

Yet another possibility is that the Internet telephony revolution will come to the conclusion that only IPv6 can provide cost-effective, scalable, end-to-end worldwide telephony implementations. This may be even more important as new classes of wireless networked devices, for example, PDAs and PCS phones, are integrated and built in very large volume.

Also, in parts of Asia and China, where there is little Internet connectivity at present, and very few IPv4 addresses assigned, IPv6 may become very popular because it will allow rapid growth without concerns about address space.

The probability is high that not just one of the above scenarios will happen, but that all will occur, in addition to others not yet imagined.

Whatever the implementation scenario, the probability that IPv6 will augment IPv4 as a part of the Internet of the future is very high!

Secure E-Mail: Problems, Standards, and Prospects

by Marshall T. Rose and David Strom

As we spend more and more time using e-mail, most of us eventually find that we need to be able to prove our identity to our correspondents and secure the contents of our messages so that others can't view them readily. Proving your identity is called *authentication*. In the physical world, this is accomplished by photo identification, such as a driver's license, passport, or corporate identity card. When the time comes to prove who you are (for example, before a major purchase), you show your card. Your appearance and signature match the photo and signature on your card, and the purchase is made.

On the Internet, however, the process isn't as easy. Does e-mail from **`sidney@example.com`** really originate from our friend Sidney at the Example Corporation? Maybe it's from someone else, who just happens to be using Sidney's machine when he is out to lunch. Or, worse, someone trying to impersonate Sidney illicitly. And even if the message actually is from the "real" Sidney, how can we be sure: Is there an electronic analog to a signature?

Most of us are trusting individuals; we tend to believe that people are who they say they are unless we have particular reasons to doubt their identity. But on the Internet, we have to look beyond face value. And proving that someone indeed did send a particular message is a very difficult problem.

This may be one of the main reasons why corporations employ Lotus Notes and other Internet-based messaging systems that are not 100-percent pure. They want to ensure that all messages carry the appropriate authentication with them at all times. In order for new users of Notes to start using the software, they must first obtain an electronic certificate that authenticates them to the system. The certificate is created by the Notes system administrator, who works in conjunction with that particular Notes server owned by that particular corporation.

Securing the message contents is also a challenge: all e-mail sent over the Internet, unless otherwise protected, is sent in clear ASCII text. If you have the tools, the time, and the technical expertise, you can capture this traffic and read anyone's correspondence. It isn't simple, but it is quite possible.

Besides being sent as clear text, e-mail can also be intercepted and its contents changed between the time the sender composes the message and the recipient reads it. Again, this task is neither likely nor simple, but it can be accomplished if someone is determined enough to do it. Therefore, senders can neither prove nor deny that they sent a particular message to you; it could be real or a forgery, and you have no way of knowing which.

Cryptography Standards

It would be great if we could say that the future for secure e-mail is bright, and that there will be standards in place that will help. However, the state of secure e-mail standards for the Internet is best described as a "terrible mess"! (Ed.: a less charitable phrase is used in the book from which this material is adopted.) Think that characterization is unprofessional? It is actually quite detached, considering the amount of culpability enjoyed by the principals of the Internet's secure e-mail debacle. We would love to write an article describing the high crimes and misdemeanors of these scoundrels, but that would only publicize the guilty, not punish them. So, instead we'll survey the horizon and try to make sense of what little terrain there is.[1]

In brief, no technologies for secure e-mail in the Internet meet all of the following criteria:

- Multivendor
- Interoperable
- Approved or endorsed by the Internet's standardization body

There are two competing technologies, each of which satisfies at most one of these criteria. However, for any 100-percent-pure Internet solution to succeed, we feel it must be based on technologies that satisfy all three.

Basic Concepts

In order to understand secure e-mail, you need to know only three concepts:

- Data encryption (privacy)
- Message integrity (authentication)
- Key management

Everything else is a matter of data formats.

Data Encryption

When the contents of a message are to be protected from third-party disclosure, it is necessary to agree upon an encryption algorithm. Because cryptographic algorithms are constantly being scrutinized, a secure e-mail standard must be extensible with respect to the algorithms that it allows.

Historically, *symmetric encryption algorithms* are used for this purpose. A symmetric algorithm is one in which the same key is used to both encrypt and decrypt the data. Symmetric algorithms are chosen because they are computationally less burdensome (in other words, faster to execute) than asymmetric algorithms.

As such, each time a message is to be encrypted, a new session key is generated for that purpose. Although one could send the session key via some secure path, it is easier to include the session key along with the message, but encrypted so that only the intended recipient can decipher it. Upon deciphering the session key, the recipient can apply the encryption algorithm and retrieve the original contents.

For example, Network Associates' Pretty Good Privacy (PGP), one of the two technologies we'll examine, uses an asymmetric algorithm to encrypt the session key and a symmetric algorithm to encrypt the user's data.

Message Integrity

When the contents of a message are to be verified as authored by a particular user and unaltered by any other user, it is necessary to agree upon a *signature* and *hash algorithm*. The former is used to verify the authenticity of the message, and the latter is used to verify the integrity of the message. Again, any secure e-mail standard must be extensible with respect to the algorithms that it uses for these purposes.

For signature algorithms, asymmetric algorithms are typically used. These algorithms utilize a public key and a secret key. A signature algorithm combined with a secret key allows someone to generate a digital signature for the contents of a message. A signature algorithm combined with a public key allows someone to verify the digital signature for a message. As you might expect, signature algorithms are one-way functions: You can't reconstruct the input to a signature function by looking at its output.

Hash algorithms are often called *message digest algorithms*. They simply compute a checksum on their input; no keys are involved. Hash algorithms are also one-way functions, and a good hash algorithm is one in which very similar inputs produce dramatically different outputs. Hence, if even a single bit is altered or corrupted in transit, the hash value will be different.

Key Management

All discussion now hinges on how keys are used for asymmetric algorithms. Specifically, how do you trust the identity of the secret key used to make a digital signature? To start, we have to introduce the notion of a *public key certificate*. Although the actual formats vary, at its heart a certificate contains three things:

- The identity of the "owner" of the certificate
- A public key
- Zero or more guarantees to the validity of the binding between the identity contained in the key and the owner in the "real world"

So, the next step is to ask what these identities and guarantees look like. Unfortunately, we now enter the realm of sociology rather than technology. The only theoretical limitation on an identity is that you have to be able to represent it digitally. It could be a name (for example, "Jim Bidzos") or an e-mail address (for example, **prz@pgp.com**) or a key in some database (for example, the name of an object in a directory). More interesting examples could include a series of assertions (for example, your driver's license number is this, your passport number is that, and so on).

Fortunately, the guarantees are a bit simpler to describe—they are digital signatures from other public keys that vouch for the veracity of the binding. For example, if you encountered a public key certificate in which the identity was someone's passport number, it would be natural to expect that the certificate contains a digital signature from the government entity (or its agent) that issued the passport. However, this begs another question: Why should you trust the entities that have signed someone's public key? It turns out that our two contending technologies have different answers to that question.

As you might expect, certificates have some additional properties, such as a date the certificate becomes valid, the date the certificate expires, and a "fingerprint." The fingerprint is simply a hash of the identity and public key so you can tell if it has been altered in transit.

Finally, *certificate revocation lists* identify certificates that are no longer valid. For example, if the secret key associated with a certificate is accidentally disclosed, then the corresponding certificate is revoked.

Pretty Good Privacy: The Web of Trust

Pretty Good Privacy (PGP) is encryption for the masses. Despite the fact that it required a couple of complete rewrites in order to achieve stability, it gets the job done.

An effort is under way to provide a "standards-based" version of the PGP technology, termed *OpenPGP*. The "pre-standards" version of PGP uses the RSA algorithm for signatures and the IDEA algorithm for encryption. The version being developed is more flexible with respect to the algorithms it supports.

The most remarkable thing about PGP is its trust model. Remember the earlier question: How do you know whether you should believe the identity in a public key certificate? To answer this in the context of PGP, each user assigns two attributes to the PGP certificates that they encounter: *trust* and *validity*. Trust is a measure as to how accurate the certificate's owner is with respect to signing other certificates. Validity indicates whether or not you think the identity in the certificate refers to the certificate's owner.

So, initially your local collection of certificates starts out with one—your own PGP certificate. You then sign your friend's certificate and he or she signs yours. Because you trust yourself when signing those certificates, your friend's certificates are automatically considered valid. Then, based on your judgment of your friend's abilities to sign other certificates accurately, you assign a level of trust to his or her PGP certificates. As you receive messages containing other people's certificates, if they are signed by you, or any of your trustworthy friends, they are automatically deemed valid. This organic, highly decentralized approach toward validating public key certificates is termed the *web of trust*.

Key servers are also available that are repositories of PGP certificates. If you need to send e-mail to someone, but don't have his or her certificate, you can query a server to see if a copy is there. Of course, the usual rules apply with respect to assigning trust and validity—it's up to you! Key servers also help when you receive e-mail from someone new. Although the message will contain a copy of someone's PGP certificate, you may not know about any of the signatories. So, you can go to a key server and fetch the certificates for the signatories; you might decide to trust them after seeing who signed their certificates.

We've simplified the web of trust in that validity isn't "all or nothing," as we implied previously. Rather, PGP offers a flexibility spectrum of possibilities; for example, requiring two trustworthy signatories before considering a certificate to be valid. But the one thing that should be clear is that trust and validity are *different*. You will probably have many keys in your local collection of certificates that are considered valid, but probably only a few of those will be considered authorized to vouch for others.

Secure MIME: The Hierarchy of Trust

There is an interesting concept in advertising called "ambush marketing." The basic idea is that your advertising campaign leverages off the brand and promotion of a competitor. *Secure Multipurpose Internet Mail Extensions,* or S/MIME, is an example of ambush marketing in the Internet. Although MIME is an Internet standard, which has been implemented by hundreds of vendors and provisioned in tens of thousands of networks, S/MIME is the product of a closed vendor consortium.

S/MIME has two versions: version 2 and version 3. As of this writing, products that claim to implement S/MIME implement version 2. They use the RSA algorithm for signatures and a weak algorithm for encryption (RC2 with 40-bit keys). An effort is under way to provide a "standards-based" version of the S/MIME technology—version 3. The version being developed is more flexible with respect to the algorithms it supports. S/MIME uses a hierarchical model for establishing trust. For example, if your employer assigns you an S/MIME certificate, he will act as a certification authority and sign that certificate. As a consequence, trust is established on the basis of a hierarchical relationship between the *subject* of a certificate (the identity) and the *issuer* (the signatory).

This model has some strengths: users rely on the certification authorities implicitly. However, a bootstrapping problem still exists: How do you know to trust the issuer? The answer is that your local collection of certificates also has some "top-level" certificate authorities, and it is these authorities that sign the public key certificates of the issuers. If the hierarchy of trust can be kept to one or two levels, this is manageable in practice.

The web and hierarchical models of trust share many attributes in common. For example, when you receive a message, it contains a copy of the certificate that was used to make the digital signature. If you aren't familiar with the signatories, you can look in a remote repository of keys. The only difference between the two models here is that the hierarchical model needs key servers to make its key infrastructure work. Because of this, keys are usually stored in a directory service accessed via the *Lightweight Directory Access Protocol* (LDAP).

Data Formats

The **`multipart/encrypted`** and **`multipart/signed`** contents are used to convey secure e-mail. Fortunately, they are both very simple content types.

A **`multipart/signed`** content has two subordinate body parts. The first contains the data that is being authenticated and can be any MIME content type (**`text/HTML`**, **`multipart/mixed`**, and so on). The second contains the digital signature used to authenticate the content. The **`multipart/signed`** content has two mandatory parameters. The *protocol* parameter defines the technology used to generate the digital signature, and the *micalg* (for "MIC algorithm") parameter defines the hashing algorithm used (for "MIC" read: *message integrity check*). The value of the protocol parameter is also the content type used for the second body part. The only tricky part is that the digital signature is calculated on the data before a transfer encoding, if any, is applied.

Let's make this a little more concrete. If we assume that the OpenPGP effort produces an Internet standard based on the current draft (a reasonable assumption at 50,000 feet), then the structure of a **`multipart/signed`** message created using PGP technology would look like the following:

- The protocol parameter would be **`application/pgp-signature`**
- The micalg parameter would be **`pgp-md5`**
- The first body part would be labeled as whatever you wanted to sign
- The second body part would labeled as **`application/pgp-signature`**

The second body part, a data structure defined by the OpenPGP document, contains the digital signature along with any supporting material (for example, a copy of the sender's PGP certificate).

Note that you don't encrypt the first body part in a **multipart/signed** content. In this way, if only some of your recipients have secure e-mail, but you still want to sign it for those who do, everyone can still read the first body part.

A **multipart/encrypted** content has two subordinate body parts. The first contains the information needed to decipher the encrypted data (for example, the encrypted session key along with an indication as to the certificate needed to decipher the session key). The second contains the encrypted data, labeled as **application/octet-stream**. The **multipart/encrypted** content has one mandatory parameter, protocol, which defines the technology used to encrypt the data. The value of the protocol parameter is also the content type used for the first body part.

To further define this concept, if we use OpenPGP as the basis for a hypothetical example, then the structure of a **multipart/encrypted** would look like the following:

- The protocol parameter would be **application/pgp-encrypted**
- The first body part would be labeled as **application/pgp-encrypted**
- The second body part would labeled as **application/octet-stream**. In practice, the input to the encryption algorithm would be **multipart/signed** .

Finally, one or more MIME content types might be defined for sending certificates, certificate revocation lists, and so on. These are all specific to the particular secure e-mail technology being used.

Encrypting Your Messages

If we look at popular commercial e-mail products, many of them include support for some kind of encryption. Both Microsoft's Outlook Express and Netscape Messenger include support for S/MIME, although we'll see in a moment that the two have radically different capabilities. And Qualcomm's Eudora Pro package comes with an add-on module for supporting PGP, which you may or may not have installed when you installed the software. In order to encrypt a message, you need to go through the following process:

1. Choose which of the two competing technologies (and specific e-mail software) you wish to use for your encrypted correspondence. Both methods have advantages and disadvantages.
2. Choose whether you want to just digitally sign your messages or encrypt their entire contents, or both.
3. Either choose an enterprise certificate authority and set up the appropriate server software, or obtain a certificate from a public authority. Again, both methods have advantages and disadvantages.
4. Enroll with this certificate authority and obtain an encryption certificate or key for a particular machine and a single e-mail address.

5. Exchange keys with your correspondents, and manage where these keys are stored on your machine.
6. Encrypt and decrypt messages.

If this process seems rather involved and complex, it is. The process is not nearly where it should be to enable encryption to be useful by most e-mail users, and won't be for some time. If all of this seems overwhelming to you, we certainly understand.[2] It is to us, too! But let's go through these six steps in more detail.

PGP vs. S/MIME

Our discussion in the standards section might have convinced you that encryption technology is still very much a work in progress, and after you begin to use the encryption features of your own e-mail software, you'll be further convinced. Nevertheless, unless you plan to test lots of different software products, you should first decide on which product and which encryption technology you intend to use. You definitely want to limit yourself to as small a universe as possible, because running more than one e-mail software product will only make your encryption life miserable. So which to choose?

PGP is everyman's product. It was designed for single individuals to use and still remains the easiest method to set up and get going, although it is far from simple. The version of PGP that comes with the Eudora Pro box is the individual version; a separate and more capable version is available for workgroups or businesses, called *PGP for Business Security*. This business version is the one we recommend, even if you are the only person in your corporation that will use encryption. You'll find that after you start, others will follow, and you might as well start off with the more capable version.

If you want to use PGP, you will need to run a separate piece of software to encrypt and decrypt your messages. If you already use software such as Messenger or Outlook Express, that is certainly more cumbersome than using the built-in S/MIME features of those two products.

In 1999, PGP is more capable than S/MIME when it comes to setting up an enterprise encryption policy and putting it into practice on a daily basis. For example, with PGP you could establish that all outgoing and incoming encrypted messages are first copied to a special archive, and that all outgoing messages are encrypted with a special administrator's key that can be used in an emergency to read the message if the sender forgets his key or leaves the company. S/MIME doesn't have this ability yet, although this feature is being developed for the future.

PGP is a single-vendor solution: All your software must eventually come from Network Associates to run the various certificate servers and encryption modules. With S/MIME, you'll have some degree of choice, although we found that in practice you probably want to make use of

the same e-mail product when exchanging encrypted messages if you want them to be read with a minimum of difficulty. Not all S/MIME packages can exchange encrypted messages with each other because of differences in their implementations. When Dan Backman of *Network Computing* magazine tested five different products, he found several that couldn't read messages sent by others.[3]

Part of the problem with S/MIME is the various choices of "strength" of cryptographic algorithms that are in use in today's browsers and e-mail software. This debate is more about politics than technology, because the U.S. government places restrictions on various algorithms, as mentioned earlier. Two different parameters are of interest: the length of the key itself used in any certificate and the type of encryption technology used. Netscape software supports key lengths ranging from 512 to 1024 bits, for example. In addition, several choices are available for encryption technology; they are labeled *RC2* (which can either be 40-bit encryption, the only one allowed for export by the U.S. government, or more complex encryption of 64, 128, or even 255 bits), and *Data Encryption Standard* (DES). RSA, Inc., developed RC2. On the other hand, the U.S. government developed DES. Debate abounds as to which is the better or more or less proprietary technology.

These details are outside the scope of this article, but you should know that the larger the key size and encryption algorithm, the more difficult it is for someone to decode an intercepted message.

Digital Signature Required?

Your next choice is to consider whether to just make use of a digital signature, to encrypt the entire message, or to make use of both technologies. All encryption products can do both, but in somewhat different ways.

Digital signatures guarantee that your recipients have received your message without any tampering and that they can trust that the message came from you. The actual message body, and any attachments, arrive without any encryption, meaning that someone could still capture this traffic and read your correspondence. You might want to use a digital signature without encrypting the message, if you care that your message was received intact and that your correspondents can know that you sent it.

There are two different types of signed messages: *clear* and *opaque*. With clear-signed messages, you can still read the message text, even if you don't have any encryption functions in your e-mail software. The signature is carried along with the message in a separate MIME portion of the message from the message body, which remains untouched and still readable. This feature can be handy, especially if you correspond with many people and they probably haven't adopted any particular encryption product, or if they are using older versions of e-mail software that don't support encryption. Clear signing is also useful in circum-

stances where your encryption technology isn't compatible with your correspondents' technology. PGP supports only clear signing in its products.

One problem with clear signing is e-mail gateways. They often will break the encryption of the signature, because they will either add or remove characters from the message, and that sloppiness could invalidate the signature block. After all, part of the role of the signature is to ensure that the message was delivered intact and unaltered!

Opaque signing means that your recipients will get a blank message if they aren't running any encryption software, or if their encryption software doesn't work with yours. Opaque signing wraps the entire message in a Base64 encoding, which is usually left alone by most e-mail gateways. This encoded message then gets transmitted and then decoded by the S/MIME recipient.

PGP places its signature inside the encrypted envelope when it sends messages, making it difficult to determine the signature of such a message until you first decrypt it. The PGP producers claim that this feature offers extra protection in case the message is compromised or copied en route. Newer versions of PGP offer a MIME option that places the signature outside the encrypted envelope. This is how S/MIME products work, making it easier to determine who sent it.

Choose Your Certificate Authority

Now you have another decision to face, and that is how to set up what is called the *certificate authority* (CA) for your enterprise. This software runs on a UNIX or NT server and manages the keys or certificates of everyone in your corporation. It serves as a central place of trust and signs all of your users' certificates. If you trust your CA, in theory you should be able to trust the certificates that are signed by the CA, called *inherited trust.*

The problem is that there isn't any "central" CA for the entire universe of e-mail users. Although there are several public CAs that anyone can use, either for free or for a fee, they don't necessarily trust each other, nor should they. What happens if an employee of VeriSign becomes disgruntled and starts issuing bad certificates? There should be checks and audits to ensure that these types of problems can't undermine the entire CA system, just as there are checks and audits to prevent rogue banking employees from crediting their own accounts.

Setting up a CA is the beginning of setting up a very complex security infrastructure for your enterprise. Your CA needs to establish a link of trust from all your users to the administrator or operator of the CA itself, and from your CA to other CAs with which you communicate.

There are two different kinds of CAs: One uses software that you install on your own server inside your enterprise and you maintain; the other is

public servers. Having your own server places the burden on creating and revoking certificates on your security administrator, or whoever is going to operate the CA server. In many cases, these products can be administered from a Web browser after they are installed, and the servers can handle certificates from a wide variety of S/MIME products, one of the few shining spots on the interoperability scene at the moment.

PGP for Business comes with its own version of a certificate server. It runs on a Windows desktop machine and typically is used by the administrator of the entire security apparatus to handle certificates. It can handle only PGP certificates.

Some popular software products that function as certificate servers are listed below.

Vendor	URL	Product
Enterprise CAs:		
Netscape	`www.netscape.com`	Certificate Server
Xcert	`www.xcert.com`	Sentry CA
Public CAs:		
VeriSign	`www.verisign.com`	Secure Server ID
Thawte	`www.thawte.com`	Public CA

Enroll and Acquire Your Certificate

When you have your certificate authority either in mind or installed, you next have to set up how you want to acquire your own certificate.

You have two broad methods: by Web or by e-mail. Actually, you don't have any choice: If you have picked your e-mail product and CA at this point in the process, you have to use whatever method comes with that choice. Netscape Messenger and Microsoft's Outlook Express, among others, make use of their related Web browsers to enroll certificates, as you might suspect. And other products make use of e-mail to send and enroll certificates. For example, Xcert's Sentry CA sends you a message telling you that your certificate has been granted, but in the e-mail it has URLs for both Communicator and Internet Explorer where you can download the certificate and place it inside the appropriate software. Why two different links? Because each product supports a different way of acquiring certificates, of course. So much for standards.

Exchange and Manage Certificates

Now comes the hard part—dealing with the certificates of your correspondents, and managing both theirs as well as other certificates around your corporation.

As we mentioned in our standards section, you need to exchange certificates with your correspondents before you can begin to exchange encrypted e-mail. And that means sending your public key to them, and getting their public keys from them, before you can exchange actual encrypted messages. If you are corresponding with someone who doesn't have the same CA in common, you'll first need to establish a trust relationship and exchange root CA certificates before you can exchange the individual certificates. This is somewhat painful, but when you get the hang of it, it isn't that difficult.

After you begin to exchange more than a few of these certificates, you might think that this is a job for a directory server, and, thankfully, the vendors are already there. The CA server can set up entries in an LDAP directory to keep track of who is issued a certificate, and you can query this LDAP server to find who has them. That is the good news, and indeed the PGP product makes use of its own LDAP server to keep track of its certificates. However, the LDAP server is only used by PGP; if you want a general-purpose LDAP server to keep track of your users, you'll have to install something else.

As a challenge for open systems and interoperability, we installed the Xcert Sentry CA and Netscape's Directory Server on a test network. The Xcert was used to create and manage our certificates for our test corporation, and the entries were placed in the Netscape LDAP directory. We created the certificates using the Netscape browser and stored the information in our Messenger e-mail software. After going through the process described previously, we had a valid certificate and could see it in the Security|Messenger settings. Although the Sentry CA couldn't automatically deposit a certificate in the Netscape LDAP server, we (operating as the security administrator) could do so with a few simple Web forms and keystrokes. So far, so good.

The challenge was trying to pry these certificates loose using other products, such as Outlook Express. There we ran into trouble, mainly because the Netscape software creates the certificate in a nonstandard place in the LDAP directory. According to the standards documents, the certificate should be placed in a particular spot in the LDAP directory schema, called *usercertificate*. Netscape, for whatever reason, places them at a location called *usersmimecertificate*. This meant that non-Netscape products couldn't view the certificates in our directory, because they were looking in the wrong place.

This brings up a very good point: The connection between a user and his or her certificate is tenuous at best. Just because you know that `david@strom.com` is the e-mail address of David Strom and you have his certificate, it doesn't mean that any of your expensive software tools can make this connection. This situation will create all sorts of headaches for your security administrators, and it means that you need to maintain at least two directories on your own machine—one for users and one for certificates.

It would be nice if the address books of our e-mail software could handle this automatically, but they don't.

That's not the only issue with managing certificates. What if someone leaves the company? Or changes his or her e-mail address? Or if you want to use the same certificate, but on several different machines? Most certificates are tied to a particular machine and a particular e-mail address, meaning that any new address will require a new certificate. Again, we find this situation unacceptable.

Encrypt and Decrypt Messages

Now you can finally go and encrypt your messages. Various options are available in your e-mail software to do this, and you can choose to sign a message as well as to encrypt it.

That is the encryption portion. What about the decryption side? If you have done your homework and exchanged certificates as we discussed earlier, then when you receive your encrypted message, it should automatically decrypt and display in plain text. You shouldn't have to do anything else—unless the encryption system is broken by a gateway or product incompatibility.

Futures

The obvious question is whether the Internet needs two standards for secure e-mail.

Proponents for both sides can make superficially compelling arguments. PGP proponents point to a grassroots constituency and a huge installed base of legacy systems. PGP emphasizes privacy for individuals. S/MIME proponents, on the other hand, point to some major vendors and an emphasis on nonrepudiation.

If history is any judge, the PGP side will win because less infrastructure is required to make it work. S/MIME has to solve all the problems that PGP has to solve, plus a few more. However, these things aren't decided overnight. So, our prediction is rather straightforward: The two sides will compete in the Internet marketplace for a couple of years, but ultimately the game is PGP's to lose. It requires less infrastructure and fewer broad agreements to achieve ubiquity.

Endnotes

Book Review

IP Multicasting

IP Multicasting: The Complete Guide to Interactive Corporate Networks, by Dave Kosiur, ISBN 0-471-24359-0 Wiley Computer Publishing, 1998, **http://www.wiley.com/compbooks/kosiur**

There is nothing remarkable about the statement: As technology becomes more affordable, applications once limited to power users find their way to the mainstream desktop. Video streaming, audio streaming, collaborative applications, and videoconferencing are all examples of applications once found exclusively on high-end workstations but now making their way to the mainstream desktop. If widespread deployment of these applications is to occur, we must be prepared to supply a supporting infrastructure.

The use of IP multicasting is gaining popularity, but many of the fundamentals that drive this and other network technologies, such as routing protocols and transport protocols, are still being debated. This book supplies a comprehensive view of the state-of-the-art as well as practical procedures one can follow in order to incorporate mulitcasting into existing network topologies.

Organization

Chapter 2 presents an introduction to TCP/IP basics and routing. Chapter 3, The Basics of Multicasting, addresses three sender-based multicasting protocols (ST-II, XTP, and MTP) and concentrates on IP multicast (a receiver-based multicasting protocol). The book would be much easier to follow if this chapter had been combined with Chapter 6.

Chapter 4, Multicast Routing Concepts, Chapter 5, Multicast Routing Protocols, and Chapter 6, Transport Protocols, constitute the heart of this book.

Beginning with basic concepts of unicast routing and routing algorithms, the author extends the models to deal with the problems of routing multicast data. Tree maintenance techniques form the bulk of Chapter 4.

Chapter 5 covers four multicast routing protocols: *Distance Vector Multicast Routing Protocol* (DVMRP); *Multicast Open Shortest Path First* (MOSPF); *Protocol Independent Multicast* (PIM); and *Core-Based Trees* (CBT). Placing the emphasis on PIM, Kosiur covers both PIM-SM (*sparse mode*) and PIM-DM (*dense mode*). He does a nice job of describing each of the protocols and summarizes each by reviewing its advantages and disadvantages. Finally, the author concludes by examining ways of achieving interdomain routing and protocol interoperability.

In Chapter 6, Kosiur provides an overview of the *Real-Time Transport Protocol* (RTP)/*Real-Time Transport Control Protocol* (RTCP) and the *Real-Time Streaming Protocol* (RTSP).

In addition, he discusses a dozen or more multicast protocols, all trying to answer the question: "How is retransmission of lost packets handled?" He classifies the protocol approaches into *receiver-based* or *sender-based*. In my opinion, this is the most interesting problem of multicasting. Answer this question wrong, and you find yourself with a nonscalable network cluttered with acknowledgments (ACKs).

Chapters 4 through 7 all consider delivering Quality of Service and so I was a little surprised to see Chapter 7 devoted to the subject.

Kosiur provides a good introduction to RSVP (*Resource ReserVation Protocol*), but until we see RSVP in wide deployment I would look at the previous three chapters for practical knowledge on the topic. In Chapter 7, and then in Chapter 11 he covers a lot of practical issues concerning Quality of Service, as well as ways to support multicasting over various networks, such as ATM, Frame Relay, and ISDN/dialup networks.

Chapter 9 is a compilation of some free and commercial software packages that use multicasting. Chapter 10 covers *Mbone* (the Multicast backbone), a popular experimental multicasting network. It is arguable that the state of multicasting wouldn't be where it is today without the Mbone.

A C+

This book rates a C+. Kosiur certainly has an understanding of the material, but his descriptions are neither clear nor concise. Reading this book is difficult, and learning from it even more so, but better organization could turn it into a gem.

Letter to the Editor

I just read the September 1998 issue of *The Internet Protocol Journal* and thoroughly enjoyed it. It was well written with excellent technical detail but more importantly, the contributors wrote in an understandable and organized method. This is not always the norm for good technical resources; so many times it is simply the reprint of a vendor's documentation.

"What is a VPN—Part II," written by Paul Ferguson and Geoff Huston, was a great article which described the various components and methodologies of VPNs. The information and explanation of the Virtual Private Dial Networking implementations, voluntary versus compulsory tunneling, subscriber's perspectives and real world applications clarified my understanding and knowledge on this subject. I also appreciate an article that ends with a conclusion. I have already located Part I of this article and will be reading it soon. There is one comment; it would be interesting to know which vendor when an example is used, regarding specifically the Frame Relay service provider.

The "Reliable Multicast Protocols and Applications" article was useful and informative, including the scaling issues and the information regarding the new reliable multicast protocols. The details of the *Pretty Good Multicast* (PGM) protocol and how it may improve scaling for multicast was very interesting.

The *Gigabit Ethernet* book review written by Ed Tittel was one of the most informative and well structured book reviews that I have read, especially in a smaller publication. Thanks for providing three pages for book reviews in a forty-seven page publication. This review provided all the information that would assist with the determination of purchasing the book or not.

I hope you continue to publish IPJ in hard copy. I do read and gather information from the Web like everyone else, but I prefer a physical copy to carry with me if I am traveling or at my home. Thanks again for a great publication and I can hardly wait for the next issue.

—Joe Brannan
joe.brannan@pepsi.com

Ed.: We appreciate your comments about our publication. Regarding your question about the Frame Relay example, it is our policy to avoid as much as possible any discussion of products, but we encourage readers to contact the authors directly for that kind of information.

We certainly plan to continue the print edition of IPJ. We are also developing a companion Web site (at **www.cisco.com/ipj***) that will contain additional information such as glossaries, links to other documents, updates, corrections, and so on. Thanks for writing.*

Fragments

ICANN Update

Back in the summer of 1997, the Clinton Administration decided that it was time to privatize the remaining Internet functions that were being managed within the federal research establishment, mostly dealing with Internet names and addresses. These functions had been handled very successfully over many years by the *Internet Assigned Numbers Authority* (IANA) under the direction Dr. Jon Postel and his staff at the Information Sciences Institute of the University of Southern California under contract to DARPA. But it was clear from the rapid expansion of the Internet, the emergence of important players on the industry side, and rising controversy over issues such as Network Solutions' monopoly in issuing domain names for **.com**, that change was necessary.

After two major policy papers and months of argumentative debate, the government recognized the *Internet Corporation for Assigned Names and Numbers* (ICANN) as the new body to assume responsibility for these largely technical management functions. Working from plans drawn up by Dr. Postel, his advisors and the Jones Day law firm, ICANN is endeavoring to satisfy the many constituencies that seek a voice in future decisions on Internet naming and addressing. Sadly, Jon died last fall just as his plan was approaching endorsement by the federal government.

The young organization, incorporated at the end of September, 1998, began operation in early November, has an initial Board of nine appointed Directors headed by Chairman Esther Dyson, and an interim President/CEO Mike Roberts. They are responsible for completing organizational details, devising a representation structure for electing their successors, and beginning to deal with a backlog of undone policy work, such as a determination on if, how and when new top level domains (TLDs) will be created. The new Board has Directors from six countries and plans to hold meetings quarterly in locations throughout the world, beginning with Singapore in March, 1999 and Berlin in May, 1999.

Being neither a Congressionally chartered corporation nor an industry trade association, but something in between, ICANN is an international organization that faces a tough political future with many skeptics challenging the notion that the Internet community can successfully govern itself in the important naming and addressing area. But with a startup fund from corporate contributions, Chairman Dyson and President Roberts, both short timers by design, are determined to get ICANN off the ground and into operation in coming months. More information is available at: **www.icann.org**

June 1999 Volume 2, Number 2

A Quarterly Technical Publication for Internet and Intranet Professionals

In This Issue

You can download IPJ back issues and find subscription information at: **www.cisco.com/ipj**

From The Editor

In this issue, Geoff Huston concludes his two-part article on Interconnection, Peering, and Settlements. Last time Geoff discussed the technical aspects for Internet Service Provider (ISP) interconnection. This time he examines the associated business relationships that arise out of ISP peering arrangements. He also looks at some future directions for the ISP interconnection environment, particularly with respect to Quality-of-Service considerations.

A recurring theme in this journal has been the traditional lack of security in Internet technologies and systems. We have examined several ways in which security has been added at all levels of the protocol stack. This time we look at *firewalls*, a popular way to segregate internal corporate intranet traffic from Internet traffic while still maintaining Internet connectivity. Fred Avolio gives the history of firewalls, their current state, and future directions.

Computer viruses have probably existed for as long as we have had computers. However, the ease with which viruses can be distributed as Internet e-mail attachments has made the problem more prevalent. Recently, the *Melissa* virus achieved some notoriety because of its "self-replication" properties. Barbara Fraser, Lawrence Rogers, and Linda Pesante of the Software Engineering Institute at Carnegie Mellon University examines some of the issues raised by this kind of virus.

This issue is the first anniversary issue of *The Internet Protocol Journal* (IPJ). You can find all of our back issues in PDF format at the IPJ Web site: **www.cisco.com/ipj**. Please let us know if you have suggestions for articles, books you want to review, or general feedback for this journal. Our contact address is: **ipj@cisco.com**.

Interconnection, Peering and Settlements—Part II

by Geoff Huston, Telstra

In Part I we examined the business drivers behind the adoption of the exchange model as the common basis of interconnection, and also examined the advantages and pitfalls associated with the operation of such exchanges within the public Internet. (See *The Internet Protocol Journal,* Volume 2, No. 1, March 1999.) In continuing our examination of the technology and business considerations that are significant within the subject of Internet Service Provider (ISP) interconnection, in this part we focus on the topic from a predominately business perspective.

Interaction Financials: Peering and Settlements

Any large multiprovider distributed service sector has to address the issue of cost distribution at some stage in its evolution. Cost distribution is the means by which various providers can participate in the delivery of a service to a customer who purchases a service from a single provider, and providers can each be compensated for their costs in an equitable structure of interprovider financial settlement.

As an example, when an airline ticket is purchased from one air service provider, various other providers and service enterprises may play a role in the delivery of the service. The customer does not separately pay the service fee of each airport baggage handler, caterer, or other form of service. The customer's original fare, paid to the airline, is distributed to other providers who incurred cost in providing components of the total service. These costs are incurred through sets of service contracts, and are the subject of various forms of interprovider financial settlements, all of which are invisible to the customer.

The Internet is in a very similar situation. Some 50,000 constituent networks must interconnect in one fashion or another to provide comprehensive end-to-end service to each client. In supporting a data transaction between two clients, the two parties often are not clients of the same network. Indeed, the two-client service networks often do not directly interconnect, and one or more additional networks must act in a transit provider role to service the transaction. Within the Internet environment, how do all the service parties to a transaction who incur cost in supporting the transaction receive compensation for their cost? What is the cost distribution model of the Internet?

Here, we examine the basis for Internet interprovider cost distribution models and then look at the business models currently used in the interprovider Internet environment. This area commonly is termed *financial settlement,* a term the Internet has borrowed from the telephony industry.

The Currency of Interconnection

What exactly is being exchanged between two ISPs who want to interconnect? In the sense of the meaning of currency as the circulating medium, the question is: What precisely is being circulated at the exchange and within the realm of interconnection? The technical answer to the question is: *routing entries*. When two parties exchange routing entries, the outcome is that traffic flows in response to the flow of routing entries. The route advertisement and traffic flows move in opposite directions, as indicated in Figure 1, and a bilateral routing-mediated flow occurs only when routes are passed in both directions.

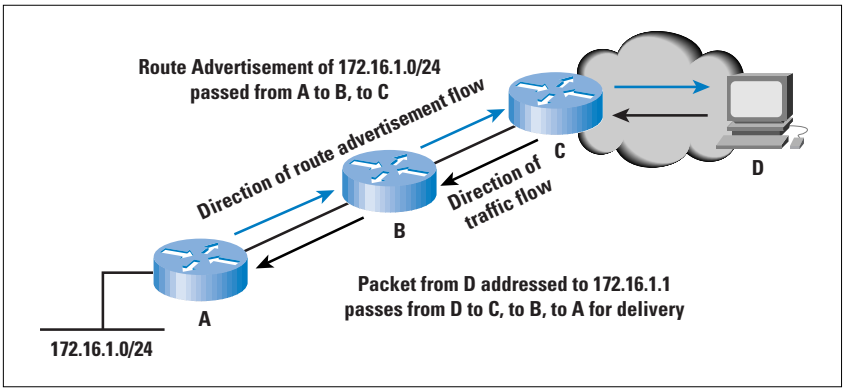

Figure 1: Routing and Traffic Flows

Within the routing environment of an ISP there are many different classes of routes, with the classification based predominately on the way in which the route has been acquired by the ISP:

- *Client routes* are passed into the ISP's routing domain by virtue of a service contract with the client. The routes may be statically configured at the edge of the ISP's network, learned by a *Border Gateway Protocol* (BGP) session with the client, or they may constitute part of an ISP pool of addresses that are dynamically assigned to the client as part of the dialup session.
- *Internal ISP routes* fall into numerous additional categories. Some routes correspond to client services operated by the ISP, solely for access to the clients of the ISP, such as Web caches, *Post Office Protocol* (POP) mail servers, and game servers. Some routes correspond to ISP-operated client services that require Internet-wide access, such as *Domain Name System* (DNS) forwarders and *Simple Mail Transfer Protocol* (SMTP) relay hosts. Lastly are internal services with no visibility outside the ISP network, such as *Simple Network Management Protocol* (SNMP) network management platforms.
- *Upstream routes* are learned from upstream ISPs as part of a transit service contract the ISP has executed with the upstream provider.
- *Peer routes* are learned from exchanges or private interconnections, corresponding to routers exported from the interconnected ISP.

How then should the ISP export routes so that the inbound traffic flow matches the outbound flows implied by this route structure? The route export policy is generally structured along the following lines:

- *Clients:* All available routes in the preceding four categories, with the exception of internal ISP service functions, should be passed to clients, either in the form of a *default route* or as *explicit route entries* passed via a BGP session.
- *Upstream providers:* All client routes and all internal ISP routes corresponding to Internet-wide services should be passed to upstream providers. Some clients may want further restrictions placed on their routes being advertised in such a fashion. The ability for a client to specify such caveats on the routing structure, and the mechanism used by the ISP to allow this to happen, should be clearly indicated in the service contract.
- *Peer ISPs:* All client routes and all ISP routes corresponding to Internet-wide service should be passed to peer ISPs. Again the clients may want to place a restriction on such an advertisement of their routes as a qualification to the ISP's own route export policy.

This structure is shown in Figure 2.

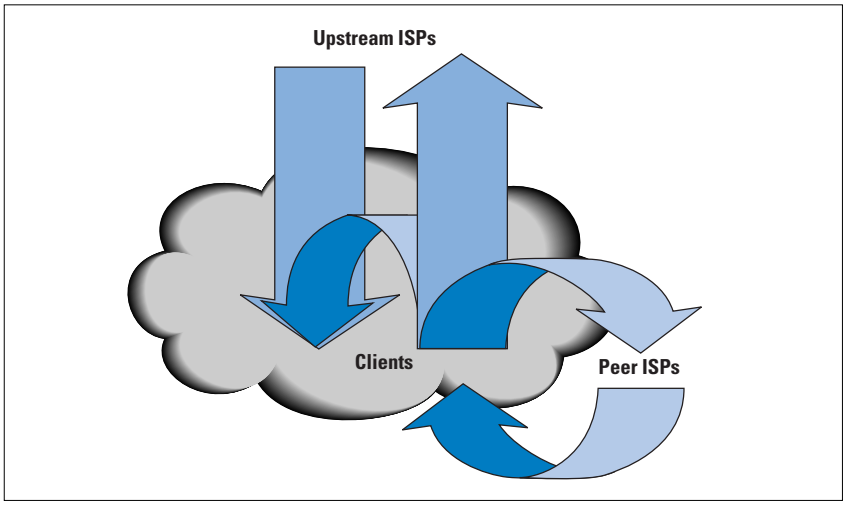

Figure 2: External Routing Interaction

The implicit outcome of this routing policy structure is that the ISP does not act in a transit role to peer ISPs and permits neither peer-to-peer transit nor peer-to-upstream transit. Peer ISPs have visibility only to clients of the ISP. From the service visibility perspective, client-only services are not visible to peer ISPs or upstream ISPs, and, therefore, value-added client services are implicitly visible only to clients and only when they access the service through a client channel.

Settlement Options

Financial settlements have been a continual topic of discussion within the domain of Internet interconnection. To look at the Internet settlement environment, let's first look at the use of interprovider financial settlements within the international telephony service industry. Then, we will look at the application of these generic principles to the Internet environment.

Within the traditional telephony model, interprovider peering takes place within one of three general models:

Bilateral Settlements

The first, and highly prevalent, international peering model is that of bilateral settlements. A *call-minute* is the unit of settlement accounting. A call is originated by a local client, and the local client's service provider charges the client for the duration of the entire end-to-end call. The call may pass through, or transit, many providers, and then terminate within the network of the remote client's local provider. The cost distribution mechanism of settlements is handled bilaterally. In the most general case of this settlement model, the originating provider pays the next hop provider to cover the costs of termination of the call. The next hop provider then either terminates the call within the local network, or undertakes a settlement with the next hop provider to terminate the call. The general telephony trunk model does not admit many multiparty transit arrangements. Most telephony settlements are associated with trunk calls that involve only two providers: the originating and terminating providers.

Within this technology model, the bilateral settlement becomes easier, because the model simplifies to the case where the terminating provider charges the originating provider a per-call-minute cost within an accounting rate that has been bilaterally agreed upon between the two parties. Because both parties can charge each other using the same accounting currency, the ultimate financial settlement is based on the net outcome of the two sets of call-minute transactions with the two call-minute termination accounting rates applied to these calls. (There is no requirement for the termination rates for the two parties to be set at the same level.) Each provider invoices the originating end user for the entire call duration, and the financial settlements provide the accounting balance intended to ensure equity of cost distribution in supporting the costs of the calls made between the two providers. Where there is equity of call accounting rates between the two providers, the bilateral interprovider financial settlements are used in accordance with originating call-minute imbalance, in which the provider hosting the greater number of originating call-minutes pays the other party according to a bilaterally negotiated rate as the mechanism of cost distribution between the two providers.

As a side note, the *Federal Communications Commission* of the United States (FCC) asserts that U.S. telephone operators paid out some $5.6 billion in settlement rates in 1996, and the FCC is voicing the view that accounting rates have now shifted into areas of non-cost-based settings, rather than working as a simple cost distribution mechanism.

This accounting settlement issue is one of the drivers behind the increasing interest in voice-over-IP solutions, because typically no accounting rate settlement component exists in such solutions, and the call termination charges are cost-based, without bilateral price setting. In those cases

where accounting rates have come to dominate the provider's call costs, voice-over-IP is perceived as an effective lever to bypass the accounting rate structure and introduce a new price point for call termination in the market concerned.

Sender Keeps All

The second model, rarely used in telephony interconnection, is that of *Sender Keeps All* (SKA), in which each service provider invoices its originating client's user for the end-to-end services, but no financial settlement is made across the bilateral interconnection structure. Within the bilateral settlement model, SKA can be regarded as a boundary case of bilateral settlements, where both parties simply deem the outcome of the call accounting process to be absolutely equal, and consequently no financial settlement is payable by either party as an outcome of the interconnection.

Transit Fees

The third model is that of transit fees, in which one party invoices the other party for services provided. For example, this arrangement is commonly used as the basis of the long-distance/local access provider interconnection arrangements. Again, this case can be viewed as a boundary case of a general bilateral settlement model, where in this case the parties agree to apply call accounting in only one direction, rather than bilaterally.

Telephony Settlement Trends

The international telephony settlement model is by no means stable, and currently, significant pressure is being placed on the international accounting arrangements to move away from bilaterally negotiated uniform call accounting rates to rates separately negotiated for calls in each direction of a bilateral interconnection. Simultaneously, communications deregulation within many national environments is changing the transit fee model, as local providers extend their network into the long-distance area and commence interconnection arrangements with similar entities. Criticism also has been directed at the bilaterally negotiated settlement rates, because of the observation that in many cases the accounting rates are not cost-based rates but are based on a desire to create a revenue stream from accounting settlements.

Internet Considerations

Numerous critical differences exist between the telephony models of interconnection and the Internet environment; these differences have confounded all attempts to cleanly map telephony interconnection models into the Internet environment.

Internet Settlement Accounting by the Packet

Internet interconnection accounting is a packet-based accounting issue, because there is no "call-minute" in the Internet architecture. Therefore, the most visible difference between the two environments is the replacement of the *call* with the *packet* as the currency unit of interconnection.

Although we can argue that a TCP session has much in common with a call, this concept of an originating TCP call-minute is not always readily identified within the packet forwarding fabric, and accordingly it is not readily apparent that this is a workable settlement unit. Unlike a telephony call, no concept of state initiation exists to pass a call request through a network and lock down a network transit path in response to a call response. The network undergoes no state change in response to a TCP session, and therefore, no means is readily available to the operator to identify that a call has been initiated, and by which party. Of course the use of *User Datagram Protocol* (UDP), and various forms of tunnelling traffic, also confound any such TCP call-minute accounting mechanism.

Packets may be dropped

When a packet is passed across an interconnection from one provider to another, no firm guarantee is given by the second provider that the packet will definitely be delivered to the destination. The second provider, or subsequent providers in the transit path, may drop the packet for quite legitimate reasons, and will remain within the protocol specification in so doing. Indeed, the TCP protocol uses packet drop as a rate-control signal. For the efficient operation of the TCP protocol, some level of packet drop is a useful and anticipated event. However, if a packet is used as the accounting unit in a general cost distribution environment, should the provider who receives and subsequently drops the packet be able to claim an accounting credit within the interconnection? The logical response is that such accounting credits should apply only to successfully delivered packets, but such an accounting structure is highly challenging to implement accurately within the Internet environment.

Packet paths are not predetermined

Packet transit paths can be within the explicit control of the end user, not the provider. Users can exercise some significant level of control of the path a packet takes to transit the Internet if source routing is honored, so that the relative packet flows between two providers can be arbitrarily manipulated by any client, if so desired.

Routing and traffic flow are not paired

Packet forwarding is not a verified operation. A provider may choose to forward a packet to a second provider without reference to the particular routes the second provider is advertising to the first party. A packet may also be forwarded to the second provider with a source address that is not being advertised to the second provider. Given that the generic Internet architecture strives for robustness under extreme conditions, attempts to forward a packet to its addressed destination are undertaken irrespective of how the packet may have arrived at this location in the first place, and irrespective of how a packet with reverse header IP addresses will transit the network.

Comprehensive routing information is not uniformly available

Complete information is not available to the Internet regarding the status and reachability of every possible Internet address. Only as a packet is forwarded closer to the addressed destination does more complete information regarding the status of the destination address become apparent to the provider. Accordingly, a packet may have incurred some cost of delivery before its ultimate undeliverability becomes evident. An intermediate transit provider can never be completely assured that a packet is deliverable.

Settlement Models for the Internet

Where a wholesale or retail service agreement is in place, one ISP is, in effect, a customer of the other ISP. In this relationship, the customer ISP (downstream ISP) is purchasing transit and connectivity services from the supplier ISP (upstream ISP). The downstream ISP resells this service to its clients. The upstream ISP must announce the downstream ISP's routes to all other customers and other egress points of the ISP's networks to honor the service contract to the downstream ISP customer.

However, given two ISPs who interconnect, the decision as to which party should assume the upstream provider role and which party should assume the downstream customer role is not always immediately obvious to either party, or even to an outside observer. Greater geographic coverage may be the discriminator here that allows the customer/provider determination. However, this factor is not the only possible one within the scope of the discussion. One ISP may host significant content and may observe that access to this content adds value to the other party's network, which may be used as an offset against a more uniform customer relationship. In a similar vein, an ISP with a very large client population within a limited geographic locality may see this large client base as an offset against a more uniform customer relationship with the other provider. In many ways, the outcome of these discussions can be likened to two animals meeting in the jungle at night. Each animal sees only the eyes of the other, and from this limited input, they must determine which animal should attempt to eat the other!

An objective and stable determination of which ISP should be the provider and which should be the client is not always possible. In many contexts, the question is inappropriate, given that for some traffic classes the respective roles of provider and client may swap over. The question often is rephrased along the lines of, "Can two providers interconnect without the implicit requirement to cast one as the provider and the other as the client?" Exploration of some concepts of how the question could possibly be answered is illustrative of the problem space here.

Packet Cost Accounting

One potential accounting model is based on the observation that a packet incurs cost as it is passes through the network. For a small interval of time, the packet occupies the entire transmission capacity of each circuit over which it passes.

Similarly, for a brief interval of time, the packet is exclusively occupying the switching fabric of the router. The more routers the packet passes through, and the greater the number and distance of transmission hops the packet traverses, the greater the incurred cost in carrying the packet.

A potential settlement model could be constructed from this observation. The strawman model is that whenever a packet is passed across a network boundary, the packet is effectively sold to the next provider. The sale price increases as the packet transits through the network, accumulating value in direct proportion to the distance the packet traverses within the network. Each boundary packet sale price reflects the previous sale price, plus the value added in transiting the ISP's infrastructure. Ultimately, the packet is sold to the destination client. This model is indicated in Figure 3.

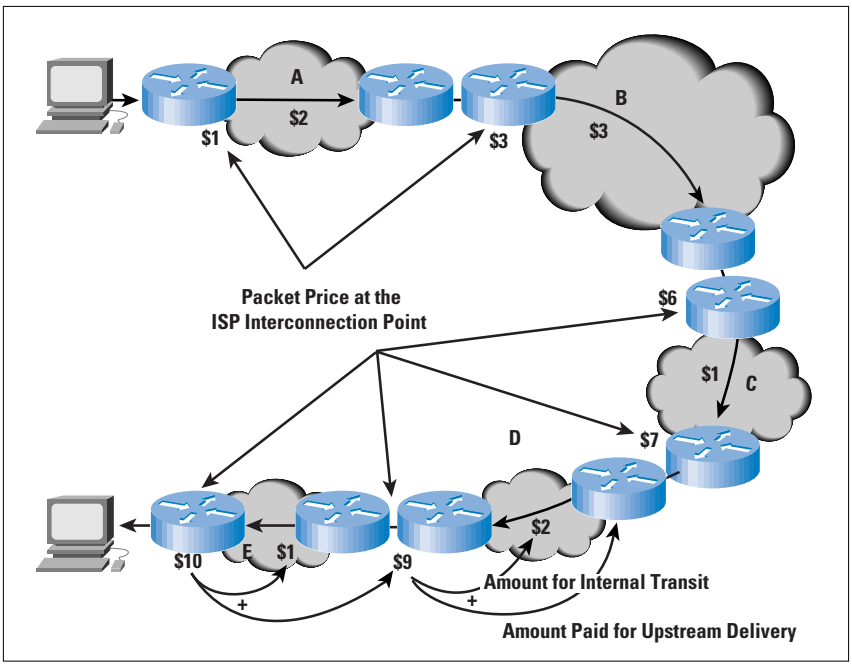

Figure 3: Financial Interprovider Settlement via Packet Cost Accounting

As with all strawman models, this one has numerous critical weaknesses, but let's look at the strengths first. An ISP gains revenue from a packet only when delivered on egress from the network, rather than in network ingress. Accordingly, a strong economic incentive exists to accept packets that will not be dropped in transit within the ISP, given that the transmission of the packet generates revenue to the ISP only on successful delivery of the packet to the next hop ISP or to the destination client. This factor places strong pressure on the ISP to maintain quality in the network, because dropped packets imply foregone revenue on local transmission. Because the packet was already purchased from the previous provider in the path, packet loss also implies financial loss. Strong pressure also is exerted to price the local transit function at a commodity price level, rather than attempt to undertake opportunistic pricing. If the chosen transit price is too great, the downstream provider has the opportunity to extend its network to reach the next upstream

provider in the path, resulting in bypassing the original upstream ISP and purchasing the packets directly from the next hop upstream source. Accordingly, this model of per-packet pricing, using a settlement model of egress packet accounting, and locally applied value increments to a cumulative per-packet price, based on incremental per-hop transmission costs, does allow for some level of reasonable stability and cost distribution in the interprovider settlement environment.

However, weaknesses of this potential model cannot be ignored. First, some level of packet drop is inevitable, irrespective of traffic load. Generally, the more remote the sender from the destination, the less able the sender is to ascertain that the destination address is a valid IP address, and the destination host is available. To minimize the liability from such potential packet loss, the ISP should maintain a relatively complete routing table and accept only packets in which a specific route is maintained for the network. More critical is the issue that the mechanism is open to abuse. Packets that are generated by the upstream ISP can be transmitted across the interface, which in turn results in revenue being generated for the ISP. Of course, per-packet accounting within the core of the network is a significant refinement of existing technology. Within a strict implementation of this model, packets require the concept of an attached value that ISPs augment on an ingress-to-egress basis, which could be simplified to a hop-by-hop value increment. Implementations feasibly can use a level of averaging to simplify this process by using a tariff for domestic transit and a second for international transit.

TCP Session Accounting

These traffic-based metrics do exhibit some weaknesses because of their inability to resist abuse and the likelihood of exacting an interprovider payment even when the traffic is not delivered to an ultimate destination. Of more concern is that this settlement regime has a strong implication in the retail pricing domain, where the method of payment on delivered volume and distance is then one of the more robust ways that a retail provider can ensure that there is an effective match between the interprovider payments and the retail revenue. Given that there is no intrinsic match of distance, and therefore cost, to any particular end-to-end network transaction, such a retail tariff mechanism would meet with strong consumer resistance.

Does an alternative settlement structure that can address these weaknesses exist? One approach is to perform significantly greater levels of analysis of the traffic as it transits a boundary between a client and the provider, or between two providers, and to adopt financial settlement measures that match the type of traffic being observed. As an example, the network boundary could detect the initial TCP SYN handshake, and all subsequent packets within the TCP session could be accounted against the session initiator, while UDP traffic could be accounted against the UDP source. Such detailed accounting of traffic passed across a provider boundary could allow for a potential settlement structure based on duration (*call-minutes*), or volume (*call-volumes*).

Although such settlement schemes are perhaps limited more by imagination in the abstract, very real technical considerations must be borne to bear on this speculation. For a client-facing access router to detect a TCP flow and correctly identify the TCP session initiator requires the router to correctly identify the initial SYN handshake, the opening packet, and then record all in-sequence subsequent packets within this TCP flow against this accounting element. This identification process may be completely impossible within the network at an interprovider boundary. The outcome of the routing configuration may be an asymmetric traffic path, so that a single interprovider boundary may see only traffic passing in a single direction.

However, the greatest problem with this, or any other traffic accounting settlement model, is the diversity of retail pricing structures that exist within the Internet today. Some ISPs use pricing based on received volume, some on sent volume, some on a mix of sent and received volume, and some use pricing based on the access capacity, irrespective of volume. This discussion leads to the critical question when considering financial settlements: Given that the end client is paying the local ISP for comprehensive Internet connectivity, when a client's packet is passed from one ISP to another at an interconnection point, where is the revenue for the packet? Is the revenue model one in which the packet sender pays or one in which the packet receiver pays? The packet egress model described here assumes a uniform retail model in which the receiver pays for Internet packets. The TCP session model assumes the session initiator pays for the entire traffic flow. This uniformity of retail pricing is simply not mirrored within the retail environment of the Internet today.

Although this session-based settlement model does attempt to promote a quality environment with fair carriage pricing, it cannot address the fundamental issue of financial settlements.

Internet Settlement Structures

For a financial settlement structure to be viable and stable, the settlement structure must be a uniform abstraction of a relatively uniform retail tariff structure. This conclusion is critically important to the entire Internet financial settlement debate.

The financial structure of interconnection must be an abstraction of the retail models used by the two ISPs. If the uniform retail model is used, the party originating the packet pays the first ISP a tariff to deliver the packet to its destination within the second ISP; then the first ISP is in a position to fund the second ISP to complete the delivery through an interconnection mechanism. If, on the other hand, the uniform retail model is used in which the receiver of the packet funds its carriage from the sender, then the second ISP funds the upstream ISP. If no uniform retail model is used, when a packet is passed from one provider to the other, no understanding exists about which party receives the revenue for the carriage of the packet and accordingly, which party settles with

the other party for the cost incurred in transmission of the packet. The answer to these issues within the Internet environment has been to commonly adopt just two models of interaction. These models sit at the extreme ends of the business spectrum, where one is a customer/provider relationship, and the other is a peering relationship without any form of financial settlement, or SKA. These models approximately correspond to the second and third models described previously from traditional models of interconnection within the communications industry. However, an increasing trend has moved toward models of financial settlement in a bilaterally negotiated basis within the Internet, using non-cost-based financial accounting rates within the settlement structure. Observing the ISP industry repeat the same well-trodden path, complete with its byways into various unproductive areas and sometimes mistakes of the international telephony world, is somewhat interesting to say the least. Experiential learning is often observed to be a rare commodity in this area of Internet activity.

No Settlement and No Interconnection

Examining the option of complete autonomy of operation, without any form of interaction with other local or regional ISPs, is instructive within this examination of settlement options.

One scenario for a group of ISPs is that a mutually acceptable peering relationship cannot be negotiated, and all ISPs operate disconnected network domains with dedicated upstream connections and no interconnection. The outcome of such a situation is that third-party connectivity would take place, with transit traffic flowing between the local ISPs being exchanged within the domain of a mutually connected third-party ISP (or via transit across a set of third-party ISPs). For example, for an Asian country, this situation would result in traffic between two local entities, both located within the same country, being passed across the Pacific, routed across numerous network domains within the United States, and then passed back across the Pacific. Not only is this scenario inefficient in terms of resource utilization, but this structure also adds a significant cost to the operation of the ISPs, a cost that ultimately is passed to the consumer in higher prices for Internet traffic.

Note that this situation is not entirely novel; the Internet has seen such arrangements appear in the past; and these situations are still apparent in today's Internet. Such arrangements have arisen, in general, as the outcome of an inability to negotiate a stable local peering structure.

However, such positions of no interconnection have proved to be relatively short-lived because of the high cost of operating international transit environments, the instability of the significantly lengthened interconnection paths, and the unwillingness of foreign third-party ISPs to act (often unwittingly) as agents for domestic interconnection in the longer term. As a result of these factors, such off-shore connectivity structures generally have been augmented with domestic peering structures.

The resultant general operating environment of the Internet is that effective isolation is not in the best interests of the ISP, nor is isolation in the interests of other ISPs or the consumers of the ISPs' services. In the interests of a common desire to undertake rational and cost-effective use of communications resources, each national (or regional) collection of ISPs acts to ensure local interconnectivity between such ISPs. A consequent priority is to reach acceptable ISP peering arrangements.

Sender Keeps All

Sender Keeps All (SKA) peering arrangements are those in which traffic is exchanged between two or more ISPs without mutual charge (an interconnection arrangement with no financial settlement). Within a national structure, typically the marginal cost of international traffic transfer to and from the rest of the Internet is significantly higher than domestic traffic transfer. In these cases, any SKA peering is likely to relate to only domestic traffic, and international transit would be provided either by a separate agreement or independently by each party.

This SKA peering model is most stable where the parties involved perceive equal benefit from the interconnection. This interconnection model generally is used in the context of interconnection or with providers with approximate equal dimension, as in peering regional providers with other regional providers, national providers with other national providers, and so on. Oddly enough, the parties themselves do not have to agree on what that value or dimension may be in absolute terms. Each party makes an independent assessment of the value of the interconnection, in terms of the perceived size and value of the ISP and the value of the other ISP. If both parties reach the conclusion that in their terms a net balance of value is achieved, then the interconnection is on a stable basis. If one party believes that it is larger than the other and SKA interconnection would result in leverage of its investment by the smaller party, then an SKA interconnection is unstable.

The essential criterion for a stable SKA peering structure is perceived equality in the peering relationship. This criterion can be achieved in many ways, including the use of entry threshold pricing into the peering environment or the use of peering criteria, such as the specification of ISP network infrastructure or network level of service and coverage areas as eligibility for peering.

A typical feature of the SKA peering environment is to define an SKA peering in terms of traffic peering at the client level only. This definition forces each peering ISP to be self-sufficient in the provision of transit services and ISP infrastructure services that would not be provided across a peering point. This process may not result in the most efficient or effective Internet infrastructure, but it does create a level of approximate parity and reduces the risks of leverage within the interconnection. In this model, each ISP presents at each interconnection or exchange only those routes associated with the ISP's customers and accepts only traffic

from peering ISPs at the interconnection or exchange directed to such customers. The ISP does not accept transit traffic destined to other remote exchange locations, nor to upstream ISPs, nor traffic directed to the ISP's infrastructure services. Equally, the ISP does not accept traffic that is destined to peering ISPs, from upstream transit providers. The business model here is that clients of an ISP are contracting the ISP to present their routes to all other customers of the ISP, to the upstream providers of the ISP, and to all exchange points where the ISP has a presence. The particular tariff model chosen by the ISP in servicing the customers is not material to this interconnection model. Traffic passed to a peer ISP at the exchange becomes the responsibility of the peer ISP to pass to its customers at its cost.

Another means of generating equity within an SKA peering is to peer only within the terms of a defined locality. In this model, an ISP would present routes to an SKA peer in which the routes correspond to customers located at a particular access POP, or a regional cluster of access POPs. The SKA peer's ability to leverage advantage from the greater level of investment (assuming that the other party is the smaller party) is now no longer a factor, because the smaller ISP sees only those parts of the larger ISP that sit within a well-defined local or regional zone. This form of peering is indicated in Figure 4.

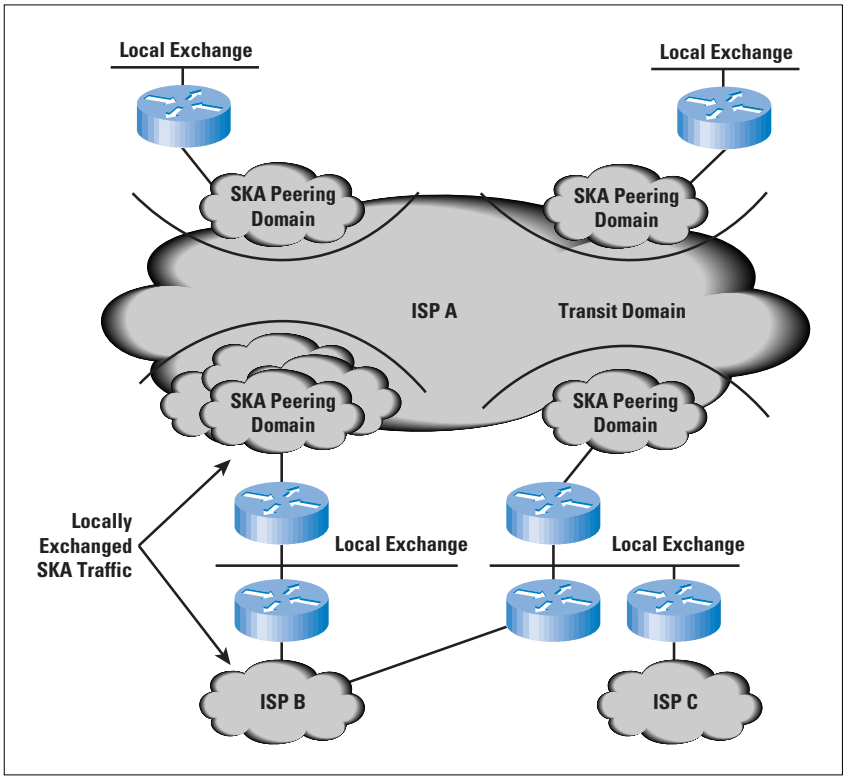

Figure 4: SKA Peering Using Local Cells

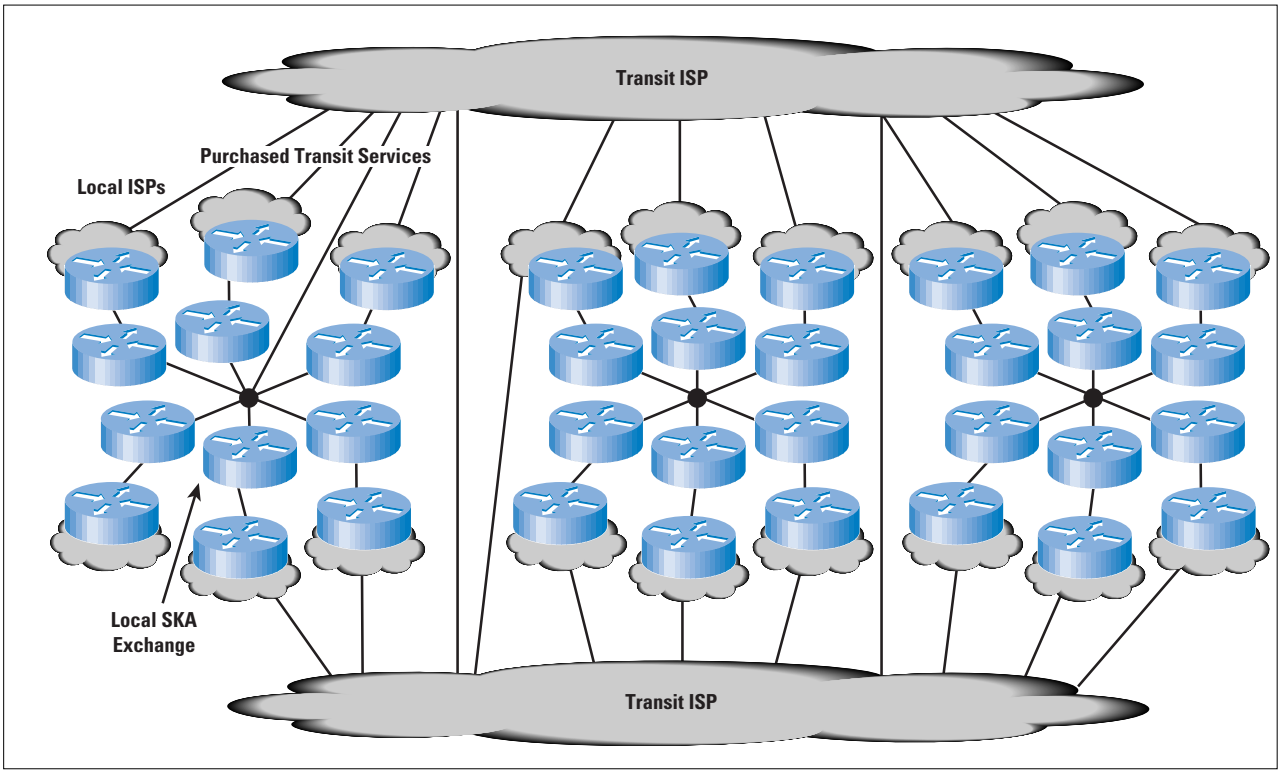
The probable outcome of widespread use of SKA interconnections is a generalized ISP domain along the lines of Figure 5. Here, the topology is segregated into two domains consisting of a set of transit ISPs, whose predominate investment direction is in terms of high-capacity carriage infrastructure and high-capacity switching systems, and a collection of local ISPs, whose predominate investment direction is in service infrastructure supporting a string retail focus. Local ISPs participate at exchanges and announce local routes at the exchange on an SKA basis of interconnection with peer ISPs. Such ISPs are strongly motivated to prefer to use all routes presented at the exchange within such peering sessions, because the ISP is not charged any transit cost for the traffic under an SKA settlement structure. The exchange does not provide comprehensive connectivity to the ISP, and this connectivity needs to be complemented with a separate purchase of transit services. In this role, the local ISP becomes a client of one or more transit ISPs explicitly for the purpose of access to transit connectivity services.

Figure 5: ISP Structure of Local and Transit Operations



In this model, the transit ISP must have established a position of broad-ranging connectivity, with a well-established and significant market share of the wholesale transit business. A transit ISP also must be able to present customer routes at a carefully selected set of major exchange locations and have some ability to exchange traffic with all other transit ISPs. This latter requirement has typically been implemented using private interconnection structures, and the associated settlements often are negotiated bilaterally. These settlements possibly may include some element of financial settlement.

Negotiated Financial Settlement

The alternative to SKA and provider/client role selection is the adoption of a financial settlement structure. The settlement structure is based on both parties effectively selling services to each other across the interconnection point, with the financial settlement undertaking the task of balancing the relative sales amounts.

The simplest form of undertaking this settlement is to measure the volume of traffic being passed in each direction across the interconnection and to use a single accounting rate for all traffic. At the end of each accounting period, the two ISPs would financially settle based on the agreed accounting rate applied to the net traffic flow.

Which way the money should flow in relationship to traffic flow is not immediately obvious. One model assumes that the originating provider should be funding the terminating provider to deliver the traffic, and therefore, money should flow in the same direction as traffic. The reverse model assumes that the overall majority of traffic, is traffic generated in response to an action of the receiver, such as web page retrieval or the downloading of software. Therefore, the total network cost should be imposed on the discretionary user, so that the terminating provider should fund the originating provider. This latter model has some degree of supportive evidence, in that a larger provider often provides more traffic to a smaller attached provider than it receives from that provider. Observation of bilateral traffic flow statistics tends to support this, indicating that traffic-received volumes typically coincide with the relative interconnection benefit to the two providers.

The accounting rate can be negotiated to be any amount. There is a caveat on this ability to set an arbitrary accounting rate, because where an accounting rate is not cost-based, business instability issues arise. For greater stability, the agreed settlement traffic unit accounting rate would have to match the average marginal cost of transit traffic in both ISP networks for the settlement to be attractive to both parties. Refinements to this approach can be introduced, although they are accompanied by significant expenditure on traffic monitoring and accounting systems. The refinements are intended to address the somewhat arbitrary determination of financial settlement based on the receiver or the sender. One way is to undertake flow-based accounting, in which the cost accounting for the volume of all packets associated with a TCP flow is directed to the initiator of the TCP session. Here, the cost accounting for all packets of a UDP flow is directed to the UDP receiver. The session-based accounting is significantly more complex than simple volume accounting, and such operational complexity would be reflected in the cost of undertaking such a form of accounting. However, asymmetric paths are a common feature of the inter-AS environment, so that it may not always be possible to see both sides of a TCP conversation and perform an accurate determination of the session initiator.

Another refinement is to use a different rate for each provider, where the base rate is adjusted by some agreed size factor to ensure that the larger provider is not unduly financially exposed by the arrangement. The adjustment factor can be the number of Points of Presence, the range of the network, the volume carried on the network, the number of routes advertised to the peer, or any other metric related to the ISP's investment and market share profile. Alternatively, a relative adjustment factor can simply be a number, without any basis in a network metric, to which both parties agree.

Of course, such a relative traffic volume balance is not very robust either, and the metric is one that is vulnerable to abuse. The capability to adjust the relative traffic balance comes from the direct relationship between the routes advertised and the volume of traffic received. To reduce the amount of traffic received, the ISP reduces the number of routes advertised to the corresponding peer. Increasing the number of routes, and at the same time increasing the number of specific routes, increases the amount of received traffic. When there is a rich mesh of connectivity, the primary objective of routing policy is no longer that of supporting basic connectivity, but instead the primary objective is to maximize the financial return to the operator. If the ISP is paying for an "upstream" ISP service, the motivation is to minimize the cost of this contract, either by maximizing the amount of traffic covered under a fixed cost, or minimizing the cost by minimizing the traffic exchanged with the upstream ISP. Where there is a financially settled interconnection, the ISP will be motivated to configure its routing policies to maximize its revenue from such an arrangement. And of course an ISP will always prefer to use customer routes wherever possible, as a basic means of maximizing revenue into the operation.

Of greater concern is the ability to abuse the interconnection arrangements. One party can generate and then direct large volumes of traffic to the other party. Although overt abuse of the arrangements is often easy to detect, greed is a wonderful stimulant to ingenuity, and more subtle forms of abuse of this arrangement are always possible. To address this, both parties would typically indicate in an interconnection agreement their undertaking not to indulge in such forms of deliberate abuse.

Notwithstanding such undertakings by the two providers, third parties can still abuse the interconnection in various ways. Loose source routing can generate traffic flows that pass across the interconnection in either direction. The ability to remotely trigger traffic flows through source address spoofing is possible, even where loose source routing is disabled. This window of financial vulnerability is far wider than many ISPs are comfortable with, because it opens the provider to a significant liability over which it has a limited ability to detect and control. Consequently, financial settlement structures based on traffic flow metrics are not a commonly deployed mechanism, because they introduce significant financial risks to the ISP interconnection environment.

The Settlement Debate

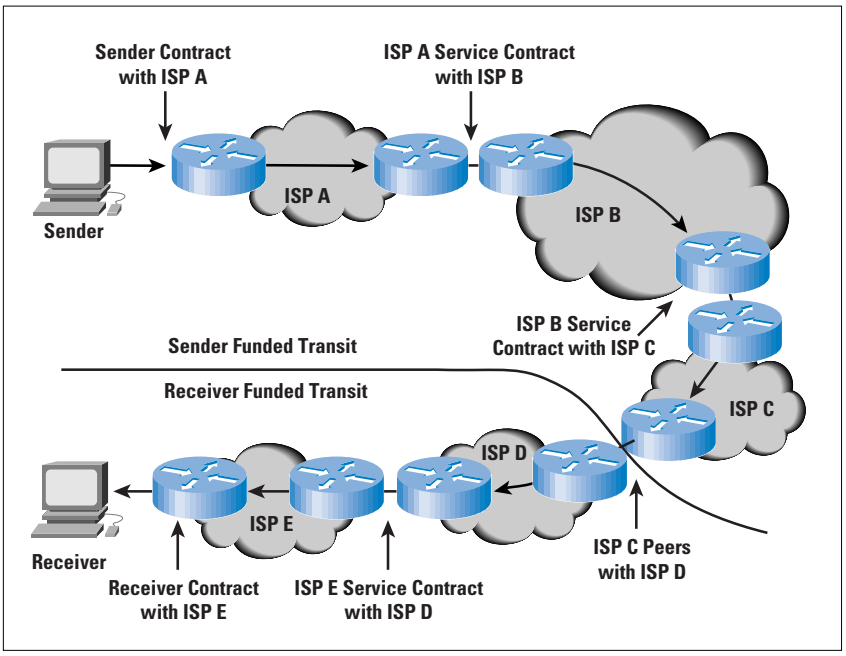
The issue of Internet settlements, and associated financial models of settlement, has occupied the attention of a large number of ISPs, traditional communications carriers, public regulators, and many other interested bodies for many years now. Despite these concentrated levels of attention and analysis, the Internet interconnection environment remains one where there are no soundly based models of financial settlement in widespread use today.

It is useful to look further into this matter, and pose the question: "Why has the Internet managed to pose such a seemingly intractable challenge to the ISP industry?" The prime reason is likely to be found within the commonly adopted retail model of ISP services. The tariff for an ISP retail service does not implicitly cover the provision of an Internet transmission service from the client to all other Internet-connected hosts. In other words, the Internet service, as retailed to the client, is not a comprehensive end-to-end service.

In a simple model of the operation of the Internet, each ISP owns and operates some local network infrastructure, and may choose to purchase services from one or more upstream service providers. The service domain offered to the clients of this network specifically encompasses an Internet subdomain limited to the periphery of the ISP network together with the periphery of the contracted upstream provider's service domain. This is a recursive domain definition, in that the upstream provider in turn may have purchased services from an upstream provider at the next tier, and so on. After the client's traffic leaves this service domain, the ISP ceases to directly, or indirectly, fund the carriage of the client's traffic, and the funding burden passes over to a funding chain linked to the receiver's retail service.

For example, when traffic is passed from an ISP client to a client of another provider, the ISP funds the traffic as it transits through the ISP and indirectly funds the cost of carriage through any upstream provider's network. When the traffic leaves the provider's network, to be passed to either a different client, another ISP, or to a peer provider, the sender's ISP ceases to fund the further carriage of the traffic. This scenario is indicated in Figure 6. In other words, these scenarios illustrate the common theme that the retail base of the Internet is not an end-to-end tariff base. The sender of the traffic does not fund the first hop ISP for the total costs of carriage through the Internet to the traffic's destination, nor does the ultimate receiver pay the last hop ISP for these costs. The ISP retail pricing structure reflects an implicit division of cost between the two parties, and there is no consequent structural requirement for inter-provider financial balancing between the originating ISP and the terminating ISP.

Figure 6: Partial-Path Paired Services



An initial reaction to this partial service model would be to wonder why the Internet works at all, given that no single party funds the carriage of traffic on the complete path from sender to receiver. Surely this would imply that once the traffic had passed beyond the sending ISP's service funded domain the traffic should be discarded as unfunded traffic? The reason why this is not the case is that the receiver implicitly assumes funding responsibility for the traffic at this handover point, and the second part of the complete carriage path is funded by the receiver. In an abstract sense, the entire set of connectivity paths within the Internet can be viewed as a collection of bilaterally funded path pairs, where the sender funds the initial path component and the receiver funds the second terminating path component. This underscores the original observation that the generally adopted retail model of Internet services is not one of end-to-end service delivery, but instead one of partial path service, with no residual retail price component covering any form of complete path service.

Financial settlement models typically are derived from a different set of initial premises than those described here. The typical starting point is that the retail offering is a comprehensive end-to-end service, and that the originating service provider utilizes the services of other providers to complete the delivery of all components of the retailed service. The originating service provider then undertakes some form of financial settlement with those providers who have undertaken some form of an operational role in providing these service elements. This cost-distributed business structure allows both small and large providers to operate with some degree of financial stability, which in turn allows a competitive open service market to thrive. Through the operation of open competition, the consumer gains the ultimate price and service benefit of cost-efficient retail services.

The characteristics of the Internet environment tend to create a different business environment to that of a balanced cost distribution structure. Here there is a clear delineation between a customer/provider relationship and a peer relationship, with no stable middle ground of a financially settled inter-ISP bilateral relationship. An ISP customer is one that assumes the role of a customer of one or a number of upstream providers, with an associated flow of funding from the customer to the upstream provider, whereas an ISP upstream service provider views the downstream provider as a customer. An ISP peer relationship is where the two ISPs execute a peering arrangement, where traffic is exchanged between the two providers without any consequent financial settlement, and such peering interactions are only stable while both providers perceive some degree of parity in the arrangement; for example, when the two providers present to the peering point Internet domains of approximate equality in market coverage and market share. An ISP may have multiple simultaneous relationships, being a customer in some cases, an upstream provider in others, and a peer in others. In general, the relationships are unique within an ISP pairing, and efforts to support a paired relationship which encompasses elements of both peering and customer/provider pose significant technical and business challenges.

The most natural business outcome of any business environment is for each provider to attempt to optimize its business position. For an ISP, this optimization is not simply a case of a competitive impetus to achieve cost efficiency in the ISP's internal service operation, because the realization of cost efficiencies within the service provider's network does not result in any substantial change in the provider's financial position with respect to upstream costs or peering positioning. The ISP's path toward business optimization includes a strong component of increasing the size and scope of the service provider operation, so that the benefits of providing funded upstream services to customers can be maximized, and non-financially settled peering can be negotiated with other larger providers.

The conclusion drawn is that the most natural business outcome of today's Internet settlement environment is one of aggregation of providers, a factor quite evident in the Internet provider environment at present.

Quality of Service and Financial Settlements

Within today's ISP service model, strong pressure to change the technology base to accommodate more sophisticated settlement structures is not evident. The fundamental observation is that any financial settlement structure is robust only where a retail model exists that is relatively uniform in both its nature and deployment, and encompasses the provision of services on an end-to-end basis. Where a broad diversity of partial-service retail mechanisms exists within a multiprovider environment, the stability of any form of interprovider financial settlement structure will always be dubious at best.

If paired partial path service models and SKA peering interconnection comfortably match the requirements of the ISP industry today, is this entire financial settlement issue one of simple academic interest?

Perhaps the strongest factor driving change here is the shift towards an end-to-end service model associated with the current technology impetus toward support of distinguished *Quality of Service* (QoS) mechanisms. Where a client signals the requirement for some level of preemption or reservation of resources to support an Internet transaction or flow, the signal must be implemented on an end-to-end basis in order for the service request to have any meaning or value. The public Internet business model to support practical use of such QoS technologies will shift to that of the QoS signal initiator undertaking to bear the cost of the entire end-to-end traffic flow associated with the QoS signal. This is a retail model where the application initiator undertakes to fund the entire cost of data transit associated with the application. This model is analogous to the end-to-end retail models of the telephony, postal, and freight industries. In such a model, the participating agents are compensated for the use of their services through a financial distribution of the original end-to-end revenue, and a logical base for inter-agent financial settlements is the outcome. It is, therefore, the case that meaningful inter-provider financial settlements within the Internet industry are highly dependent on the introduction of end-to-end service retail models. There financial settlements are, in turn, dependent on a shift from universal deployment of a best effort service regime with partial path funding to the introduction of layered end-to-end service regimes that feature both end-to-end service-level undertakings and end-to-end tariffs applied to the initiating party.

The number of conditionals in this argument is not insignificant. If QoS technologies are developed that scale to the size of the public Internet, that provide sufficiently robust service models to allow the imposition of service level agreements with service clients, and are standardized such that the QoS service models are consistent across all vendor platforms, then this area of inter-provider settlements will need to change as a consequence. The pressure to change will be emerging market opportunities to introduce interprovider QoS interconnection mechanisms and the associated requirement to introduce end-to-end retail QoS services. The consequence is that there will be pressure to support this with inter-provider financial settlements where the originating provider will apportion the revenue gathered from the QoS signal initiator with all other providers that are along the associated end-to-end QoS flow path.

Such an end-to-end QoS settlement model assumes significant proportions that may in themselves impact on the QoS signaling technologies. It is conceivable that each provider along a potential QoS path may need to signal not only their capability of supporting the QoS profile of the potential flow, but also the unit settlement cost that will apply to the flow. The end user may then use this cost feedback to determine

whether to proceed with the flow given the indication of total transit costs, or request alternate viable paths in order to choose between alternative provider paths so as to optimize both the cost and the resultant QoS service profile. The technology and business challenges posed by such an end-to-end QoS deployment model are certainly an impressive quantum change from today's best effort Internet.

With this in mind, one potential future is that the public Internet environment will adopt a QoS mediated service model that is capable of supporting a diverse competitive industry through interprovider financial settlements. The alternative is the current uniform best effort environment with no logical role for interprovider settlements, with the associated strong pressures for provider aggregation. The reliance on Internet QoS technologies to achieve not only Internet service outcomes, but also to achieve desired public policy outcomes in terms of competitive pressures, is evident within this perspective. It is unclear whether the current state of emerging QoS technologies and QoS interconnection agreements will be able to mature and be deployed in time to forge a new chapter in the story of the Internet interconnection environment. The prognosis for this is, however, not good.

Futures

Without the adoption of a settlement regime that supports some form of cost distribution among Internet providers, there are serious structural problems in supporting a diverse and well populated provider industry sector. These problems are exacerbated by the additional observation that the Internet transmission and retail markets both admit significant economies of scale of operation. The combination of these two factors leads to the economic conclusion that the Internet market is not a sustainable open competitive market. Under such circumstances, there is no natural market outcome other than aggregation of providers, leading to the establishment of monopoly positions in the Internet provider space. This aggregation is already well underway, and direction of the Internet market will be forged through the tension between this aggregation pressure and various national and international public policy objectives that relate to the Internet industry.

The problem stated here is not in the installation of transmission infrastructure, nor is it in the retailing of Internet services. The problem faced by the Internet industry is in ensuring that each provider of infrastructure is fairly paid when the infrastructure is used. In essence, the problem is how to distribute the revenue gained from the retail sale of Internet access and services to the providers of carriage infrastructure. While explosive growth has effectively masked these problems for the past decade, after market saturation occurs and growth tapers off, these issues of financial settlement between the various Internet industry players will then shape the future of the entire global ISP industry.

Firewalls and Internet Security, the Second Hundred (Internet) Years

by Frederic Avolio,
Avolio Consulting

Interest and knowledge about computer and network security is growing along with the need for it. This interest is, no doubt, due to the continued expansion of the Internet and the increase in the number of businesses that are migrating their sales and information channels to the Internet. The growth in the use of networked computers in business, especially for e-mail, has also fueled this interest. Many people are also presented with the post-mortems of security breaches in high-profile companies in the nightly news and are given the impression that some bastion of defense had failed to prevent some intrusion. One result of these influences is that that many people feel that Internet security and Internet firewalls are synonymous. Although we should know that no single mechanism or method will provide for the entire computer and network security needs of an enterprise, many still put all their network security eggs in one firewall basket.

Computer networks may be vulnerable to many threats along many avenues of attack, including:

- *Social engineering*, wherein someone tries to gain access through social means (pretending to be a legitimate system user or administrator, tricking people into revealing secrets, etc.)
- *War dialing,* wherein someone uses computer software and a modem to search for desktop computers equipped with modems that answer, providing a potential path into a corporate network
- *Denial-of-service attacks,* including all types of attacks intended to overwhelm a computer or a network in such a way that legitimate users of the computer or network cannot use it
- *Protocol-based attacks,* which take advantage of known (or unknown) weaknesses in network services
- *Host attacks,* which attack vulnerabilities in particular computer operating systems or in how the system is set up and administered
- *Password guessing*
- *Eavesdropping* of all sorts, including stealing e-mail messages, files, passwords, and other information over a network connection by listening in on the connection.

Internet firewalls have been around for a hundred years—in Internet time. Firewalls can help protect against some of these attacks, but certainly not all. Firewalls can be very effective at what they do. The people who set up and use them must have the knowledge of how they work, and also be aware of what they can and cannot protect. In this article, we examine the Internet firewall, touch on its history, see how firewalls are used today, and discuss changes that are in place for the next hundred years.

Internet History

In the beginning, there was no Internet. There were no networks. There was no e-mail, and people relied on postal mail or the telephone to communicate. The very busy sent telegrams. Few people used ugly names to refer to others whom they had never met. Of course, the Internet has changed all this. The Internet, which started as the *Advanced Research Projects Agency Network* (ARPANET), was a small, almost closed, community. It was a place, to borrow a line from the theme to *Cheers,* "where everybody knows your name, and they're always glad you came."

On November 2, 1988, something happened that changed the Internet forever. Reporting this incident, Peter Yee at the NASA Ames Research Center sent a note out to the TCP/IP Internet mailing list that reported, "We are currently under attack from an Internet VIRUS! It has hit Berkeley, UC San Diego, Lawrence Livermore, Stanford, and NASA Ames." Of course, this report was the first documentation of what was to be later called *The Morris Worm*. The researchers and contributors that had built the Internet, as well as the organizations that were starting to use it, realized at that moment that the Internet was no longer a closed community of trusted colleagues. In fact, it hadn't been for years. To their credit, the Internet community did not overreact to this situation. Rather, they started sharing information on their practices to prevent future disruptions.

(One of the results of this problem was a growth in the number of Internet mailing lists dedicated to security and bug tracking. The *firewalls* list—subscribe with e-mail to **`Majordomo@lists.gnac.net`**—and the *bugtraqs* list—**`LISTSERV@netspace.org`**—are two examples, as well as the *CERT Coordination Center*—**`http://www.cert.org/`**.)

Other famous, and general, attacks followed:

- Bill Cheswick's "evening with Berferd"[4]
- Clifford Stoll's run-in with German spies[7]
- The massive password capture of the winter of 1994
- The IP spoofing attack that Kevin Mitnick used against Tsutomu Shimomura[6]
- The rash of denial-of-service attacks in January 1996, and the "Web site break-in of the week."

All these viruses have made it into the popular press, and all have raised awareness of the need for good computer and network security. As these, and other, events were unfolding, the firewall was starting its rapid evolution. Although the development of firewall technology and products may be seen as very fast, it sometimes seems that firewalls are just barely keeping up with the new applications and services that spring up and immediately become a "requirement" for many Internet users.

Firewall History

We are used to firewalls in other disciplines, and, in fact, the term did not originate with the Internet. We have firewalls in housing, separating, for example, a garage from a house, or one apartment from another. Firewalls are barriers to fire, meant to slow down its spread until the fire department can put it out. The same is true for firewalls in automobiles, segregating the passenger and engine compartments.

Cheswick and Bellovin, in the definitive text on Internet firewalls[4], said an Internet firewall has the following properties: it is a single point between two or more networks where all traffic must pass (choke point); traffic can be controlled by and may be authenticated through the device, and all traffic is logged. In a talk, Bellovin later stated, "Firewalls are barriers between 'us' and 'them' for arbitrary values of 'them.'"

The first network firewalls appeared in the late 1980s and were routers used to separate a network into smaller LANs. In these scenarios—and using Bellovin's definition, above—"us" might be—well, "us." And "them" might be the English Department. Firewalls like this were put in place to limit problems from one LAN spilling over and affecting the whole network. All this was done so that the English Department could add any applications to its own network, and manage its network in any way that the department wanted. The department was put behind a router so that problems due to errors in network management, or noisy applications, did not spill over to trouble the whole campus network. The first security firewalls were used in the early 1990s. They were IP routers with filtering rules. The first security policy was something like the following: allow anyone "in here" to access "out there." Also, keep anyone (or anything I don't like) "out there" from getting "in here." These firewalls were effective, but limited. It was often very difficult to get the filtering rules right, for example. In some cases, it was difficult to identify all the parts of an application that needed to be restricted. In other cases, people would move around and the rules would have to be changed.

The next security firewalls were more elaborate and more tunable. There were firewalls built on so-called *bastion hosts*. Probably the first commercial firewall of this type, using filters and application gateways (proxies), was from Digital Equipment Corporation, and was based on the DEC corporate firewall. Brian Reid and the engineering team at DEC's Network Systems Lab in Palo Alto originally invented the DEC firewall. The first commercial firewall was configured for and delivered to the first customer, a large East Coast-based chemical company, on June 13, 1991. During the next few months, Marcus Ranum at Digital invented security proxies and rewrote much of the rest of the firewall code. The firewall product was produced and dubbed DEC SEAL (for *Secure External Access Link*). The DEC SEAL was made up of an external system, called *Gatekeeper,* the only system the Internet could talk to, a filtering gateway, called *Gate,* and an internal *Mailhub* (see Figure 1).

In this same time frame, Cheswick and Bellovin at Bell Labs were experimenting with circuit relay-based firewalls. Raptor Eagle came out about six months after DEC SEAL was first delivered, followed by the ANS InterLock.

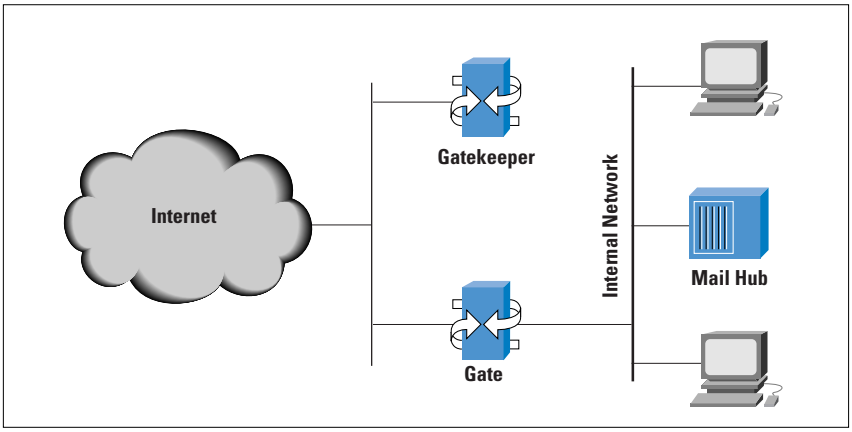

Figure 1: DEC SEAL—First Commercial Firewall

On October 1, 1993, the Trusted Information Systems (TIS) *Firewall Toolkit* (FWTK) was released in source code form to the Internet community. It provided the basis for TIS' commercial firewall product, later named *Gauntlet*. At this writing, the FWTK is still in use by experimenters, as well as government and industry, as a basis for their Internet security. In 1994, Check Point followed with the *Firewall-1* product, introducing "user friendliness" to the world of Internet security. The firewalls before Firewall-1 required editing of ASCII files with ASCII editors. Check Point introduced icons, colors, and a mouse-driven, X11-based configuration and management interface, greatly simplifying firewall installation and administration.

Early firewall requirements were easy to support because they were limited to the Internet services available at that time. The typical organization or business connecting to the Internet needed secure access to remote terminal services (Telnet), file transfer (*File Transfer Protocol* [FTP]), electronic mail (*Simple Mail Transfer Protocol* [SMTP]), and USENET News (the *Network News Transfer Protocol*—NNTP). Today, we add to this list of "requirements" access to the World Wide Web, live news broadcasts, weather information, stock quotes, music on demand, audio and videoconferencing, telephony, database access, file sharing, and the list goes on.

What new vulnerabilities are there in these new "required" services that are daily added to some sites? What are the risks? Too often, the answer is "we don't know."

Types of Firewalls

There are four types of Internet firewalls, or, to be more accurate, three types plus a hybrid. The details of these different types are not discussed here because they are very well covered in the literature.[1, 3, 4, 5]

Packet Filtering

One kind of firewall is a packet filtering firewall. Filtering firewalls screen packets based on addresses and packet options. They operate at the IP packet level and make security decisions (really, "to forward, or not to forward this packet, that is the question") based on the headers of the packets.

The filtering firewall has three subtypes:

- *Static Filtering,* the kind of filtering most routers implement—filter rules that must be manually changed
- *Dynamic Filtering,* in which an outside process changes the filtering rules dynamically, based on router-observed events (for example, one might allow FTP packets in from the outside, if someone on the inside requested an FTP session)
- *Stateful Inspection,* a technology that is similar to dynamic filtering, with the addition of more granular examination of data contained in the IP packet

Dynamic and stateful filtering firewalls keep a dynamic state table to make changes to the filtering rules based on events.

Circuit Gateways

Circuit gateways operate at the network transport layer. Again, connections are authorized based on addresses. Like filtering gateways, they (usually) cannot look at data traffic flowing between one network and another, but they do prevent direct connections between one network and another.

Application Gateways

Application gateways or proxy-based firewalls operate at the application level and can examine information at the application data level. (We can think of this as the *contents* of the packets, though strictly speaking proxies do not operate with packets.) They can make their decisions based on application data, such as commands passed to FTP, or a URL passed to HTTP. It has been said that application gateways "break the client/server model."

Hybrid firewalls, as the name implies, use elements of more than one type of firewall. Hybrid firewalls are not new. The first commercial firewall, DEC SEAL, was a hybrid, using proxies on a bastion host (a fortified machine, labeled "Gatekeeper" in Figure 1), and packet filtering on the gateway machine ("Gate"). Hybrid systems are often created to quickly add new services to an existing firewall. One might add a circuit gateway or packet filtering to an application gateway firewall, because it requires new proxy code to be written for each new service provided. Or one might add strong user authentication to a stateful packet filter by adding proxies for the service or services.

No matter what the base technology, a firewall still basically acts as a controlled gateway between two or more networks through which all traffic must pass. A firewall enforces a security policy and it keeps an audit trail.

What a Firewall Can Do

A firewall intercepts and controls traffic between networks with differing levels of trust. It is part of the network perimeter defense of an organization and should enforce a network security policy. By Cheswick's and Bellovin's definition, it provides an audit trail. A firewall is a good place to support strong user authentication as well as private or confidential communications between firewalls. As pointed out by Chapman and Zwicky[2], firewalls are an excellent place to focus security decisions and to enforce a network security policy. They are able to efficiently log internetwork activity, and limit the exposure of an organization.

The exposure to attack is called the "zone of risk." If an organization is connected to the Internet without a firewall (Figure 2), every host on the private network can directly access any resource on the Internet. Or to put it as a security officer might, every host on the Internet can attack every host on the private network. Reducing the zone of risk is better. An internetwork firewall allows us to limit the zone of risk. As we see in Figure 3, the zone of risk becomes the firewall system itself. Now every host on the Internet can attack the firewall. With this situation, we take Mark Twain's advice to "Put all your eggs in one basket—and watch that basket."

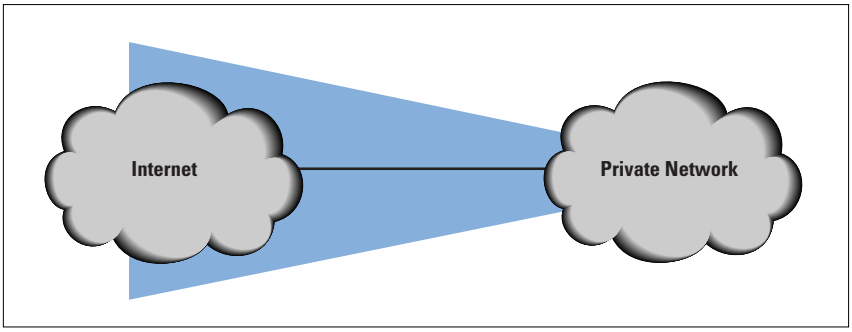

Figure 2: Zone of Risk for an Unprotected Private Network

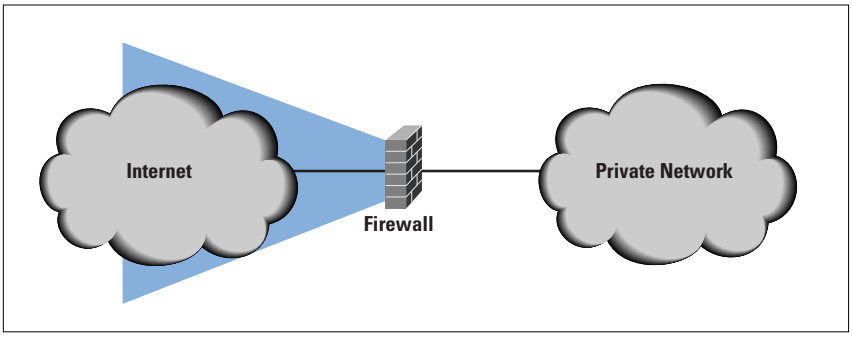

Figure 3: Zone of Risk with a Firewall

What a Firewall Cannot Do

Firewalls are terrible at reading people's minds or detecting packets of data with "bad intent." They often cannot protect against an insider attack (though might log network activity, if an insider uses the Internet gateway in his crime). Firewalls also cannot protect connections that do not go through the firewall. In other words, if someone connects to the Internet through a desktop modem and telephone, all bets are off. Firewalls provide little protection from previously unknown attacks, and typically provide poor protection against computer viruses.

Firewalls Today: Additions

The first add-on to Internet firewalls was strong user authentication. If your security policy allows access to the private network from an outside network, such as the Internet, some kind of user authentication mechanism is required. User authentication simply means "to establish the validity of a claimed identity." A username and password provides user authentication, but not *strong* user authentication. On a nonprivate connection, such as an unencrypted connection over the Internet, a username and password can be copied and replayed. Strong user authentication uses cryptographic means, such as certificates, or uniquely keyed cryptographic calculators. These certificates prevent "replay attacks"—where, for example, a username and password are captured and "replayed" to gain access. Because of where it sits—on both the "trusted" and "untrusted" networks—and because of its function as a controlled gateway, a firewall is a logical place to put this service.

The next add-on to Internet firewalls was firewall-to-firewall encryption, first introduced on the ANS InterLock Firewall. Today, such an encrypted connection is known as a Virtual Private Network, or VPN. It is "private" through the use of cryptography. It is "virtually" private because the private communication flows over a public network—the Internet, for example. Although VPNs were available before firewalls via encrypting modems and routers, they came into common use running on firewalls. Today, most people expect a firewall vendor to offer a VPN option. Firewalls act as the endpoint for VPNs between the enterprise and mobile users or telecommuters, keeping communication confidential from notebook PC, home desktop, or remote office.

In the past two years, it has become popular for firewalls to also act as content screening devices. Some additions to firewalls in this area include virus scanning, URL screening, and key word scanners (also known in U.S. government circles as "guards"). If the security policy of your organization mandates screening for computer viruses—and it should—it makes sense to put such screening at a controlled entry point for computer files, such as the firewall. In fact, standards exist for plugging antivirus software into the data flow of the firewall, to intercept and analyze data files. Likewise, URL screening—firewall controlled access to the World Wide Web—and content screening of files and messages seem like logical additions to a firewall. After all, the data is

flowing through the fingers of the firewall system, so why not examine it and allow the firewall to enforce the security policies of the organization? The downside to this scenario is performance. Also virus scanning must ultimately be performed on each desktop because data may come in to the desktops from paths other than through the firewall—for instance, the floppy.

Recently, some firewall and router vendors have been making the case for a relatively new firewall add-on called "flow control" to deliver Quality of Service (QoS). QoS, for example, can limit the amount of network bandwidth any one user can take up, or limit how much of the network capacity can be used for specific services (such as FTP or the Web). Once again, because the firewall is the gateway, it is the logical place to put a QoS arbitrating mechanism.

Firewalls Tomorrow

In 1997, The Meta Group, and others, predicted that firewalls would be the center of network and internetwork security[7]. After all, firewalls were the first big security item, the first successful Internet security product, and the most visible security device. They quickly became a "must have"—this is good—and a "good enough"—this is not good because firewalls alone are not sufficient. Firewalls became synonymous with security, as mentioned above. The firewall console becoming the network security console seemed natural at that time. But this scenario has not happened, nor will it happen. The reason? The firewall is just another mechanism used to enforce a security policy. This specific enforcement device will not be the policy management device.

As organizations broaden the base of measures and countermeasures used to implement a comprehensive network and computer security policy, firewalls will need to communicate with and interact with other devices. Intrusion detection devices—running on or separate from the firewall—must be able to reconfigure the firewall to meet a new perceived threat (just as dynamic filtering firewalls today "reconfigure" themselves to meet the needs of a user).

Firewalls will have to be able to communicate with network security control systems, reporting conditions and events, allowing the control system to reconfigure sensors and response systems. A firewall could signal an intrusion detection system to adjust its sensitivity, as the firewall is about to allow an authenticated connection from outside the security perimeter. A central monitoring station could watch all this, make changes, react to alarms and other notifications, and make sure that all antivirus software and other content screening devices were functioning and "up to rev." Some products have started down this path already. The *Intrusion Detection System* (IDS) and firewall reconfiguration of network routers based on perceived threat is a reality today. Also, firewall-resident IDS and help-desk software enable another vendor's system to expand from a prevention mechanism into detecting and re-

sponding. The evolution continues and firewalls are changing rapidly to address the next 100 (Internet) years.

In June 1994, the author wrote[5], "Firewalls are a stopgap measure—needed because many services are developed that operate either with poor security or no security at all." This statement is erroneous. Firewalls are *not* a stopgap measure. Firewalls play an important part in a multilevel, multilayer security strategy. Internet security firewalls will not go away, because the problem firewalls address—access control and arbitration of connections in light of a network security policy—will not go away.

As use of the Internet and internetworked computers continues to grow, the use of Internet firewalls will grow. They will no longer be the only security mechanism, but will cooperate with others on the network. Firewalls will morph—as they have—from what we recognize today, just as walls of brick and mortar were eventually replaced by barbed wire, motion sensors, and video cameras—and brick and mortar. But Internet firewalls will continue to be a required part of the methods and mechanisms used to enforce a corporate security policy.

Was the Melissa Virus So Different?

by Barbara Y. Fraser, Lawrence R. Rogers, and Linda H. Pesante,
Software Engineering Institute, Carnegie Mellon University

Was the recent electronic mail-based *Melissa* virus so different from similar events in our noncyberspace lives that it merits special behavior? We don't think so. But recent events raise some interesting questions about where to draw the line in our concern about the safety of our mailbox contents.

We regularly receive samples in the mail and don't give them much thought. They run the gamut from laundry detergents to shampoos to cereals to pain relievers. How often do we rip open that sample box of sugar-coated cereal and chomp down a few handfuls as a snack? Do we question whether the labeling accurately reflects the contents of the package? And what about the shampoo samples in those convenient little bottles, just the right size for tossing into our travel bag for the next trip. We use the shampoo with no thought that it might really be hair dye that would turn our hair purple or green. Then there are the sample medications and herbal remedies. Do we use the sample, assuming that it is exactly what it seems to be, without verifying it in some way?

For many of us, these examples represent common behavior today. When we open the samples we find in our mailbox, we don't question whether someone intent on harming us has sent a product that appears to be something we would use and that seems to come from a trusted source. Rarely, if ever, would we call manufacturers and ask whether they had really sent the sample.

How different is this from our approach to the contents of our electronic mailbox? We urge people *never* to click on an attachment before verifying its contents—or at least not until they've verified that it came from the stated sender. Surely we must make these recommendations because of malicious code in electronic mail messages. But we may be asking people to behave differently in cyberspace than they typically do in their noncyberspace life.

What are we to do then? Responsible cyberspace behavior says to trust nothing and verify everything as completely as possible. This scenario would mean that attachments added to an electronic mail messages must be analyzed before being used. To be the most effective, analyzers must be kept up-to-date with the latest information. Even then, rapidly spreading viruses like Melissa can slip under our "radar" for a while. Tools that support authentication and integrity are another building block we should use to gain trust in information that we should otherwise consider untrustworthy.

In our noncomputer lives, how do we know that the medication sample that came in the mail actually came from the attributed vendor? How do we know that the sample was not changed after it left the manufacturing point? The best we can to is to call the manufacturer and exchange some information about the sample: product numbers, packaging color, descriptions of the sample, and so on. Still, we cannot be completely sure that the product is what the packing says it is. Similarly, how do we know that the electronic mail attachment actually came from the stated sender or that it was not changed in transit?

Here cyberspace has the edge over noncyberspace. Technologies are available that help us to verify the mail sender (authentication) and the validity of the message (integrity). Alas, none of the available technologies are multivendor, interoperable, or approved or endorsed by the Internet's standardization body. These technologies are an improvement over their noncyberspace counterparts, but they are not yet mature enough or widespread enough to be as effective as they ultimately will become. Unfortunately, we need that maturity now.

Returning to our original question: Was the Melissa virus so different? Our answer is *no,* it was not so different from the comparable free samples we receive in our noncyberspace lives. Unfortunately, those lives are fraught with the same kind of problems, yet we accept those risks with little concern for our well-being. The real answer is that both our cyberspace and noncyberspace lives need to change to reflect the challenges of our modern world.

About Melissa

The CERT CC began receiving reports of a new virus on Friday, March 26, 1999. The macro virus is activated when a user opens an infected document in Microsoft Word 97 or Word 2000 with macros enabled. The virus is then quickly spread by sending an infected document to the first 50 addresses in the victim's Microsoft Outlook address book. It also infects the **`Normal.dot`** template file, a situation which in turn causes other Word documents created using this template to be infected with the virus. If these newly infected documents are opened by a second user, the document, including the virus, will propogate, sending the docuemnt to 50 addresses in the second user's address book. The CERT CC handled over 300 reported incidents involving Melissa, affecting over 100,000 computers. This estimate is very convervative because it counts only those who contaced the CERT CC. It is believed that millions of host computers were infected.

BARBARA FRASER is a senior member of the technical staff at the Software Engineering Institute (SEI) located at Carnegie Mellon University. She is currently working in the Networked Systems Survivability Program of the SEI and the CERT® Coordination Center. Barbara leads the team that is currently developing an adaptive security management model for networked systems that will allow organizations to adapt to technology and organization changes while maintaining an appropriate level of security in their networked systems. Her professional interests are in developing tools and techniques for improving the survivability of technologies currently deployed in the Internet. Barbara has been involved with the CERT Coordination Center since 1990. She has developed and delivered many talks and courses on Internet security and security incident response, and has worked with many organizations to help them understand and address security issues as they relate to the Internet. Barbara is currently coteaching a graduate course, "The Economics of Information Security," for the Heinz School of Public Policy at Carnegie Mellon University. Barbara is active in the security area of the Internet Engineering Task Force (IETF) and was one of the authors of RFC 1281, "Guidelines for the Secure Operation of the Internet," and RFC 2196, "Site Security Handbook." She is currently a member of the Security Area Directorate and chairs two IETF working groups (GRIP and SSH). Prior to joining the SEI, Barbara was a senior engineer at Martin Marietta Corporation (now Lockheed Martin), where she led a team of software engineers in the development of aircraft simulator software. Barbara holds a bachelor's degree in biology and an M.S. degree in computer science. E-mail: **byf@cert.org**

LAWRENCE R. ROGERS is a senior member of the technical staff in the Networked Systems Survivability Program at the Software Engineering Institute (SEI). The CERT Coordination Center is also a part of this program. Larry's primary focus in this group is analyzing system and network vulnerabilities and helping to transition security technology into production use. His professional interests are in the areas of the administering systems in a secure fashion and software tools and techniques for creating new systems being deployed in the Internet. Before joining the SEI, Larry worked for ten years at Princeton University, first in the Department of Computer Science on the Massive Memory Machine project, and later at the Department of Computing and Information Technology (CIT). While at CIT, Larry directed and managed the UNIX Systems Group that was charged with administering the UNIX computing facilities used for undergraduate education and campus-wide services. Larry coauthored the book Advanced Programmer's Guide to UNIX Systems V with Rebecca Thomas and Jean Yates. Larry received a B.S. degree in Systems Analysis from Miami University in 1976 and an M.A. degree in Computer Engineering in 1978 from Case Western Reserve University. E-mail: **lrr@cert.org**

LINDA HUTZ PESANTE has been a member of the technical staff of the Software Engineering Institute (SEI) since 1987. She is currently the leader of the Information Services Team for the CERT Coordination Center and SEI Networked Systems Survivability Program. She also teaches communication skills in the Master of Software Engineering Program at Carnegie Mellon University. At the University, she is a member of the Institutional Review Board for the Protection of Human Subjects in Research. She holds a B.A. in English and M.A. in professional writing from Carnegie Mellon, and an M. Ed. from the University of Pittsburgh. She has published on the topics of technical communication, network security, and teaching writing in computer science and software engineering programs. E-mail: **lhp@cert.org**

Book Review

OPSF *OSPF: Anatomy of an Internet Routing Protocol,* John T. Moy, Addison Wesley Longman, ISBN 0-201-63472-4, 1998.
http://www.awl.com/cseng/titles/0-201-63472-4

Audience

John Moy takes the somewhat difficult topic of Internet routing and presents an understandable and engaging tour of specific parts of routing and how this one instance interrelates with other parts of Internet routing. This book is not for the routing novice, although the first couple of chapters provide a quick overview and history of routing and one viewpoint on the distinctions between two architectural choices in routing protocol design, *Distance Vector* and *Link State*. This book is really targeted for people that have a basic understanding of what routing is and would like to gain an understanding of this particular tool in the Internet routing "toolbox."

Organization

The second section goes into great detail on one implementation of the Link State architecture, *Open Shortest Path First Protocol* (OSPF). There is a companion volume which contains OSPF specific details and includes source code for building an OSPF service on FreeBSD systems. He covers some background in the design phases of OPSF, delineating why certain choices were made in the evolution of OSPF as we know it today and then starts into what I think of as the heart of the book, an understandable, brief discussion of OSPF design with packet formats. In this section of the book, the author takes a textbook approach and closes each chapter with a series of exercises which test understanding of the principles covered in each chapter. At the end of the section, the FAQ answers a number of questions which operators that are considering OSPF will ask.

The book then changes focus and examines the basics of routing in the context of multicast aware infrastructure. This is an area that is still very dynamic and several of the presumptions that John makes in this section may not be as relevant in today's networking environment. However, he does demonstrate the ability of OSPF to support new features, in this case the variant called *Multicast OSPF* or MOSPF. A discussion of the integration of MOSPF into OSPF networks as well as MOSPF in *Distance Vector Multicast Routing Protocol* (DVMRP) networks points out how different routing protocols can work together. DVMRP forms the central core of the Multicast Backbone or *Mbone*. Both DVMRP and MOSPF lack policy features that many operators demand and so this section remains more of academic interest in understanding how multicast can work.

The fourth section covers configuration and management of OSPF in real networks. Of specific interest to me is the discussion on how OSPF can take advantage of authentication features to ensure the integrity of the routing protocol and the data it sends. Others may find that a discussion of tools for troubleshooting more interesting. A fair amount of the discussion in this section deals with the use of *Simple Network Management Protocol* (SNMP) as the tool for managing and configuring OSPF. Its not clear to me that operators of parts of the Internet are comfortable with this approach since SNMP has known vulnerabilities. Such techniques are useful for monitoring OPSF activities and may be used in private networks with a higher comfort level.

Protocol Review

The book closes with a review of popular routing protocols, both current and historic for unicast and multicast environments. John covers some basic ideas on protocol interactions when systems run more than one but does not cover the interactions between multicast and unicast protocols.

—Bill Manning, USC-ISI
manning@isi.edu

Would You Like to Review a Book for IPJ?

We receive numerous books on computer networking from all the major publishers. If you've got a specific book you are interested in reviewing, please contact us and we will make sure a copy is mailed to you. The book is yours to keep if you send us a review. We accept reviews of new titles, as well as some of the "networking classics." Contact us at **ipj@cisco.com** for more information.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

Fragments

ICANN Update

As mentioned in previous issues of IPJ, the *Internet Corporation for Assigned Names and Numbers* (ICANN) began operation in early November 1998. Recently, ICANN announced that five companies have been selected to participate in the initial testbed phase of the new competitive *Shared Registry System.* These five participants will be the first to implement the new system for competition in the market for **.com**, **.net**, and **.org** domain name registration services. Currently, registration services for these domains are provided by Network Solutions, Inc. (NSI), which has enjoyed an exclusive right to handle registrations under a 1993 Cooperative Agreement with the U.S. Government. The five registrars participating in the testbed are, in alphabetical order: America Online, CORE (*Internet Council of Registrars*), France Telecom/Oléane, Melbourne IT, and register.com.

Under the Cooperative Agreement between NSI and the U.S. Government, the competitive registrar testbed program began on April 26 and will last until June 24, 1999 (Phase I). Following the conclusion of Phase I, the Shared Registry System for the **.com**, **.net**, and **.org** domains will be opened on equal terms to all accredited registrars, meaning that any company that meets ICANN's standards for accreditation will be able to enter the market as a registrar and offer customers competitive domain name registration services in these domains.

Meanwhile, ICANN continues to work on the formation of several *supporting organizations,* namely the *Domain Name Supporting Organization* (DNSO), the *Address Supporting Organization* (ASO), and the *Protocol Supporting Organization* (PSO). More information is available at: **www.icann.org**

IETF and Related links

The *Internet Engineering Task Force* (IETF) is responsible for the development of standards for Internet technology. Membership to the IETF is open and you can participate in person or subscribe to the IETF mailing list. The IETF meets three times per year. For a list of future meetings and other IETF information see: **http://www.ietf.org**

From The Editor

More and more of the data traffic on the Internet is due to World Wide Web activity. Given the often-complex graphics contents of Web pages, this traffic represents a significant amount of data and leads to an overall requirement for more bandwidth across the system. But building "bigger pipes" is not the only way to achieve better performance. Generally speaking, Web pages are relatively static objects that reside in *one* location and are accessed repeatedly by *many* users, often from "far away." If the contents of the most frequently accessed pages can be stored by a proxy residing more "local" with respect to the end user, significant reductions in download delay can be accomplished. Since the Internet comprises many expensive international circuits, such local mirroring of content is also highly desirable from the point of view of the Internet Service Providers. Storing information in a proxy server is called *caching,* and it is the subject of our first article. Geoff Huston explains the motivation behind—and the different approaches to—caching.

The most popular Local-Area Network (LAN) technology is *Ethernet.* Invented in 1973 by Bob Metcalfe as a 3-Mbps technology, Ethernet has evolved to the now-familiar 10Base-T and 100Base-T standards. Standardized in 1998, *Gigabit Ethernet* is the subject of our second article. Bill Stallings gives an overview of the Gigabit Ethernet standards and their application in enterprise networks. There is already discussion about 10-Gigabit Ethernet and even 100-Gigabit Ethernet. We will keep you posted on these developments.

Some readers have suggested that we publish a few short articles on limited topics. In this issue we bring you the first in what we hope will become a series of articles under the general heading "One Byte at a Time." The article is by Tom Thomas and he discusses *active* and *passive* modes of the File Transfer Protocol (FTP). If you have suggestions for future topics in this series, please contact us at **ipj@cisco.com**

The so-called "Millennium Bug" or "Y2K Problem" has been well reported in all the media. Our *Fragments* section gives some specific information relating to Y2K and the Internet.

Web Caching

by Geoff Huston, Telstra

Web browsing dominates today's Internet. More than two-thirds of the traffic on the Internet today is generated by the Web. In looking at how to improve the quality of service delivered by the Internet, a very productive way to start is examining the performance of Web transactions. It is here that Web caching can play a valuable role in improving service quality for a large range of Internet users.

There are two types of Web caches—a *browser cache* and a *proxy cache*. A browser cache is part of all popular Web browsers. The browser keeps a local copy of all recently displayed pages, and when the user returns to one of these pages, the local copy is reused. By contrast, a proxy cache is a shared network device that can undertake Web transactions on behalf of a client, and, like the browser, the proxy cache stores the content. Subsequent requests for this content, by this or any other client of the cache, will trigger the cache to deliver the locally stored copy of the content, avoiding a repeat of the download from the original content source. In this article we look at proxy caches in further detail, particularly at the aspects of deployment of proxy caches in Internet Service Provider (ISP) networks.

What Is Proxy Web Caching?

When a browser wishes to retrieve a URL, it takes the host name component and translates that name to an IP address. A HTTP session is opened against that address, and the client requests the URL from the server.

When using a proxy cache, not much is altered in the transaction. The client opens a HTTP session with the proxy cache, and directs the URL request to the proxy cache instead (Figure 1).

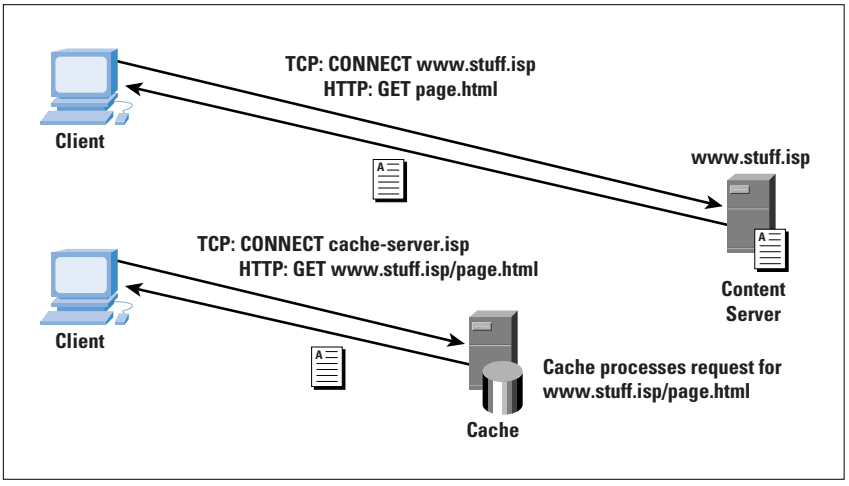

Figure 1: A Proxy Web Transaction

If the cache contains the referenced URL it is checked for freshness by comparing with the "Expires:" date field of the content, if it exists, or by some locally defined freshness factor. Stale objects are revalidated with the server, and if the server revalidates the content, the object is re-marked as fresh. Fresh objects are delivered to the client as a *cache hit*.

If the cache does not have a local copy of the URL, or the object is stale, this is a *cache miss*. In this case the cache acts as an agent for the client, opens its own session to the server named in the URL, and attempts a direct transfer to the cache.

The Pros and Cons of End-to-End Web Access

The original design principle of the Internet architecture is that of the end-to-end model[2, 3]. Within this model the network is a passive instrument that undertakes a best effort to forward packets to the specified destination. Each packet generated by a host is assumed to be forwarded to the addressed destination, and any response to the datagram is assumed to come from that destination address.

The World Wide Web transaction protocol, the *Hypertext Transfer Protocol* (HTTP)[4, 5], is constructed upon this model, where a client's Web fetch causes a TCP session to be opened with the specified target host. The ensuing HTTP conversation identifies the requested data on the destination host, and this data is then passed back to the client. This delivery model is best expressed as a *just-in-time delivery model,* where the data is passed to the client on demand.

This delivery model has many significant advantages. The content server can modify the content, and all subsequent client requests are provided with the updated information, so that updates are immediately reflected in the delivered data. The content server is also able to track all content requests, allowing the content provider to track which particular content is being requested, the identity of each requestor, and how often each content item is referenced. The content provider can also differentiate between various clients, and, using some form of security model, the content provider can authenticate the client and deliver privileged information to certain clients. In this model the content provider can also differentiate between clients, delivering certain information to some clients, and *different* information to other clients of the content server.

Many web systems have been constructed based on the capability of this end-to-end delivery model. Continuously updating Web pages that use either *server push* or *client pull* to regularly update the content on the client's display are used to display stock market prices, weather maps, or network management screens. Client identification can be used to create combined public and virtual private information servers, where a class of identified users can be directed to internal content environments, while other clients are passed to a default public content environment. Such systems form the basis of extranet environments, and can also be used to form part of a virtual private network.

Where information has a defined locality, this tool is very useful. Security and authentication is also used to provide services where the transaction requires some level of privacy. Electronic trading systems, credit card transactions, and related financial systems on the Web make use of such client authentication capabilities. The individual transaction can be encrypted using socket-level encryption,[13] or the entire TCP session can be encrypted using an IP session-level encryption tool such as IP Security (IPSec).

For all these benefits available in an end-to-end model of Web content delivery, there are some balancing drawbacks. A server providing very popular content is placed under considerable stress, both in the number of simultaneous client connections active at any time and in the total volume of data being delivered from the server in the surrounding network. This load is expressed both as a server system load, and as load on the surrounding network. Improving the performance of such systems may entail improving the server throughout, increasing the number of servers through the use of server farms and a traffic manager, and improving the capacity of the local network to deliver the increased volume. However, all these measures may not address all the problems in maintaining quality of the content delivery. Modem-based client systems, and low-bandwidth wireless-based client systems are constrained by a combination of the restricted bandwidth of this last hop and the associated imposed end-to-end delay in conversing with the server. Improving the capacity of the server may not necessarily reduce the number of simultaneously active client connections. Reducing the delay between the client and the point of delivery of the content will improve the performance of content delivery.

In addition, the network itself may not be efficiently utilized. Web traffic does have considerable levels of duplication, where a set of clients request copies of the same content, and the network carries duplicates of the data to each client. For a network provider, where transmission capacity is a business cost, importing the content just once, and then passing local copies of this content to each client, is one method of improving the carriage efficiency of the network.

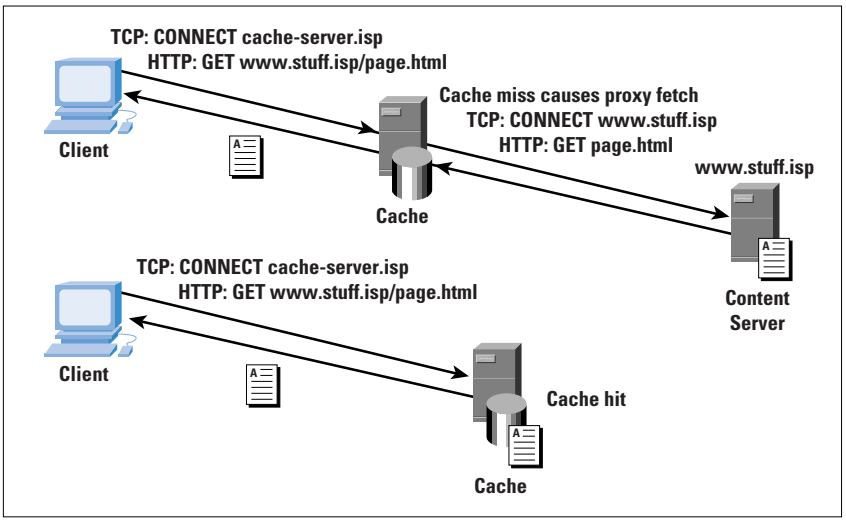
In terms of the ability to improve the service performance of delivery of content to a global network of clients, and in terms of the ability to improve the carriage efficiency of the network, caching of content makes some sense to the content provider, to the ISP, and to the end client.

The Pros and Cons of Web Proxy Caching

The same benefits of improved performance and reduced outbound traffic loads can be realized for World Wide Web traffic through the deployment of Web caches. Web caches are basically no different from any other form of caching. The client request is passed through a *cache agent,* which makes the request to the original source as a proxy for the client. The response of the server is retained in a local cache, and a copy

is passed to the client. If the same request is passed to the cache agent soon after the original request was serviced, the response can be generated from the cache without further reference to the original source. The operation of a Web cache is shown in Figure 2.

Figure 2: A Web Cache



Measurements of ISP traffic profiles indicate that some 70 percent of a typical ISP's traffic is Web-based traffic. An analysis of Web requests indicates that the typical level of similarity of requests (for the same object as one previously requested) can be as high as 50 percent of all Web-based traffic.

There are two hit-rate measures, a *page hit rate* and a *byte hit rate*. A page hit rate measures the proportion of individual HTTP requests that can be served from the cache, irrespective of the size of the page. A byte hit rate measures the ratio of the number of bytes delivered from the cache in hits against the number of bytes in misses. Experience to date has indicated that page hit rates of somewhere between 40 to 55 percent are achievable for a well-configured cache. In such circumstances the associated byte hit rate is between 20 and 35 percent. The major contributor to the hit rate is in image files.

For many ISPs, particularly those operating outside of North America, transmission costs dominate the cost profile of the ISP's operation. If the cache performed at even 60 percent of a theoretical maximum caching performance, the ISP could reduce its external traffic volume requirements by some 13 percent. When the costs of caching are compared to the costs of transmission, this difference can be a significant one in the cost base of the ISP's operation.

For example, if the average cost of transmission is $150 per gigabyte, and the ISP has a typical carriage profile of purchasing 1000 gigabytes per month from an upstream ISP with a 70-percent Web traffic profile, then a cache operating at a 25-percent byte hit rate can save the ISP a recurrent expenditure of $26,250 per month. If the cache costs $100,000

as a capital expenditure and $2000 per month in operational costs to support the service, then a business case analysis would see the cache activity return some $18,000 per month to the business, net of annualized capital and operational expenditures.

The other benefit is to the client, where the reduced network delay between the client and the local cache results in an increase in speed of Web page delivery for cached content.

The average size of a Web transaction is some 16 data packets within the TCP flow. Within a TCP slow-start flow-control process, the first cycle will transmit one packet and wait for an ACK. The reception of the ACK will trigger transmission of two more packets in the second round-trip cycle, and then the sender will await two ACKs. Reception of these two ACKs will trigger a further four packets in the third cycle and eight in the next cycle, and the remaining single packet in the fifth cycle. Therefore, allowing for optimal behaviour of the TCP slow-start algorithm, this average Web transaction takes some five round-trip times. If a user is located some distance away from the Web page, and the round-trip time to the source is 300 ms, the propagation delay of the page load will be 1.5 seconds. In comparison, if the round-trip time to the local Web cache is 2 ms, then the propagation delay of the page load will be 10 ms. These latency figures assume an uncongested network in both cases. In this case, as long as the Web cache search can complete within 1 second, the cache will appear to be far faster to the user.

A slightly different analysis is possible when comparing the performance of a cache configured at the headend of a cable-IP system versus the performance of direct access. The difference in latency in this case is due to both the closer positioning of the cache to the user and the greatly increased effective bandwidth from the cache to the user. A cache download can operate at speeds of megabits per second, as compared to kilobits or tens of kilobits per second when using dialup modem or ISDN services. For a 100K image download, the dial user may experience a 60-second delay, and the same delivery from a local cache via cable-IP may take less than half a second.

The trade-off with caching is that of balancing the the cost of carriage capacity, both in terms of monetary cost of the carriage and the performance cost of the transaction time of the application, against the cost of the use of caching. For non-North American ISPs, in which there is typically a large cache hit rate against North American server locations, the benefits of widespread use of caching are quite substantial. For cable-IP operators, the benefits of local cache operation lie in the ability to exploit the benefits of the very-high-speed final hop from the headend to the end user. For other ISPs, the benefits of caching may be less dramatic, but nevertheless, there are tangible positive outcomes of caching in terms of performance and cost that can be exploited.

As with direct-access models, this approach also has drawbacks. We have already noted the various ways in which the end-to-end model of Web content delivery has been exploited to provide time-based content, client-based content, and secure delivery of content. Caches insert themselves within the end-to-end semantics of the original transaction model, and intercept the transaction by presenting a proxy of the original endpoint. The content delivered from the cache is the content based on the time the cache undertook its request to the server, and the content delivered from the server is based on the server's view of the identity of the cache, rather than the identity of the end client.

With cached content in operation, the cached-content server no longer has an accurate picture of the number of times an item of content is viewed, and by whom. The server cannot authenticate the client, nor can the server deliver any information that is based on the supposed identity of the client. Equally, the client has potential problems, because the client may not be aware that the content has been delivered by the proxy cache. The content may not properly reflect the client's identity, and the information may be based on the security trust model of the server to the cache, rather than the server to the end client, and again the client may not be aware of such a change in security domains. If the content is time-dependent, the content will reflect the time at which the cache retrieved the content, rather than the time the client made the request.

All of this tends to suggest that caching is not a universally applicable tool. Part of the challenge in deploying cache servers is to understand the models of cache deployment and Web content delivery, and ensure that the cache does not intrude in ways that distort the integrity of content delivered to the end user.

Web Cache Hits Versus Web Server Hits

One of the biggest tensions is the balance between the cache operator's desire to maximize the hit rate of the cache system and the desire of many Web page publishers to maintain an accurate count on the number of hits of the page and from where those hits occur. In most cases, it is the requests that are of interest here, rather than the control of delivery of the content. The Web publisher is not necessarily interested in absorbing the hits for Web content. Indeed, many Web publishers see value in distributing the load of content delivery of fixed-content material further out toward the client base, rather than the Web publisher bearing the cost of the distribution load from the local site.

Static pages, composed of plain text and images, are readily cached. As a consequence, the original page publisher may not obtain an accurate count of the number of times the page was displayed by users if the Web server's log was analysed. Some Web page designers place information in the Web page directives; this information directs the Web cache server not to reuse a cached page. The most common way of doing this is to set the "Expires:" Web page information header to the current date and

time, so the next time the page is referenced, a new fetch will be undertaken. One of the more common hacks to cache servers to attempt to improve the hit rate is to allow this directive to be ignored.

This server hit-count problem has plagued cache deployment for many years now. Although there are real requirements in the areas of authentication and security, time-based content, and client-based content that mandate certain types of content being flagged as non-cacheable, much of the data that is marked as non-cacheable has been marked in this way simply for the server to capture the identity of the client. Such "cache-busting" practices are unnecessarily wasteful of network resources, and can overload the content server. There is an Internet Proposed Standard extension to HTTP[6] intended to provide a "Meter" header, where a cache can communicate demographic information relating to client "hits" back to the original content server. The extension also proposes usage limiting, where a server can provide content with a limit on the number of times the information can be used by the proxy cache before revalidating the content with the server.

Web-Caching Models

There are many models of how to invoke a proxy cache.

Explicit Caching

Some proxy cache systems are deployed as a user-invoked option, in which the user nominates a cache server to the browser as a proxy agent, and the browser then directs all Web requests to the proxy cache. At any stage, the user can instruct the browser to turn off the use of the proxy cache, and request the browser to undertake the transaction directly with the client. Modern browsers when configured with a proxy cache may also use the approach of attempting direct access when a request via a proxy cache results in a fetch error. In the proxy cache mode of operation, the destination address of the underlying transport session is then the address of the cache server, while the HTTP content of the transaction remains unaltered. Such caches can be deployed within a client's local network, with the intent of minimizing the amount of traffic passed to the external provider ISP. Additionally, The ISP can operate such a voluntary cache for use by its clients. If the ISP operates in this mode, the benefits to the user in using the cache need to be clearly stated and understood by both the client and the ISP, and the client must be made aware of the location of the cache in configuring his or her local browser.

Forced Explicit Caching

Some ISPs, notably in the dialup service provider sector, operate in a highly cost-competitive market. In such a market service performance and service price are critical business factors, and the provider may choose to operate its network in a forced-cache mode. Here, all Web traffific on TCP port 80 (the port used by the HTTP Web transport protocol) is blocked from direct outbound access, and the ISP's clients are forced to configure their browsers to use the provider's cache for external Web access. This technique is commonly termed *forced caching*.

Transparent Caching

The use of a cache for all Web traffic also can be undertaken by the ISP, without the explicit configuration of the identity of the proxy cache into the user's browser. Irrespective of precisely how this setup is engineered, and there are numerous ways of engineering it, this technique is termed *transparent caching*. With transparent caching the user, and the user's browser, may not be explicitly aware that caching is being undertaken when processing the user's requests. Here the network has to intercept HTTP packets destined to remote Web servers, and present these packets to the proxy cache. Once the page is located, either as a cache hit or a cache miss, the cache must then respond to the original requestor by assuming the identity of the original destination (Figure 3).

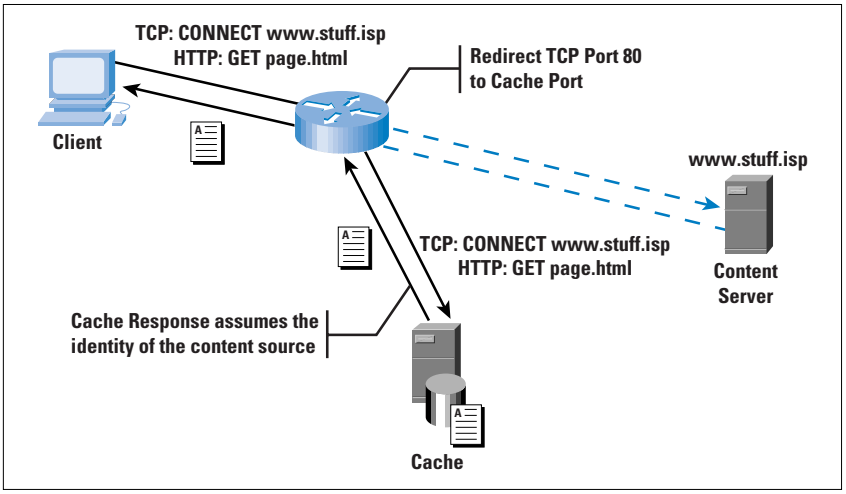


Figure 3: Transparent Caching

It should be noted that no mechanism to date of explicit or transparent caching is completely transparent to both the Web client and the Web server. Where the Web server uses an end-to-end security access model the transparent cache may fail, because the cache will present its address as the source of the request, rather than that of a client. This scenario may result in a page-denied error to the cache request, whereas the client could have completed the transaction directly with the server. In those situations where the use of the cache is mandated, either through filters and a forcing function, or through transparent network redirection, there is no user-visible workaround to the error, and the level of user frustration with the entire cache service rises dramatically.

Under some circumstances it may be possible to work around transparent cache fetch errors. One approach is for a cache fetch error to trigger the cache subsystem to establish an HTTP session with the content server using the source address of the client, and then pass the original HTTP GET request to the server. The server's response is then passed to the client using a TCP bridge. (A TCP bridge is where the connecting device is required to translate the sequence numbers of the TCP headers between the two TCP sessions). Having the cache subsystem intercept the server's packets addressed to the client does require careful coordination with the cache router, and TCP bridging is also quite complex in its

operation, so such solutions tend to be somewhat unstable under load stress. An alternative approach is for the cache to pass a TCP RST back to the client, and instruct the cache router to insert a temporary entry in its redirection filter so that any subsequent TCP port 80 connection from the client to the server's address is not redirected to the cache.

If the sole benefit to the client is improved speed of response, then the ISP must understand that the performance of the Web cache systems must be continually tuned to be highly responsive to Web requests under all load conditions experienced by the ISP. Performance of cache hits must be maintained at a level consistently faster than the alternative of direct client access to the original client site. Performance of cache misses must be at a level that is not visibly slower than that of direct access to the original site. If the user's perception of performance of the cache drops, the benefit to the user also drops. In the case of user-selected caching, the users will turn off the cache option in their browser and return to a mode of direct access.

The business model of a cache is that the capital and operational costs associated with localizing traffic to the cache result in cost reductions to the ISP, when compared to the operation of a noncached network. These cost reductions can be passed on to all users through operation of the entire service at a lower price point or selectively passed on to those clients who make use of the cache through some form of cache-use tariff. The generic model of applying the cost reduction to the ISP's service tariff is certainly an advantage in a price-competitive marketplace. However, unless the performance of the cache is consistently very high, and the transparency of the cache is close to perfect, each individual user may attempt to use direct-access methods.

The alternate business model is to pass on the marginal cost savings to those clients who make use of the cache, and at a level that corresponds to the client's use of the cache and its effectiveness in operating at a high cache hit rate. If, for example, the ISP uses a charging model that includes a tariff component based on the amount of data delivered to the client during the accounting period, this tariff component could be adjusted by the amount of use the client made of the cache system and the relative operating efficiency of the cache in generating cache hits.

As an example, if traffic is tariffed at $100 per gigabyte as delivered to the customer, a discounted value can be derived for traffic delivered from the Web cache. If the average cache byte hit rate is 30 percent, then after factoring in the costs of capital equipment and operational support, the traffic from the cache could be tariffed at $80 per gigabyte. Here, the benefit of using the Web cache is passed directly to those clients who make use of the cache, who both enjoy lower tariffs in direct proportion to their use of the cache and derive superior performance through using the cache. The accounting for this marketing model is certainly a more involved process, involving additional accounting systems and processing to undertake an accurate per-client view of cache usage.

It is becoming increasingly evident that a robust business model associated with a model of discretionary use of a Web cache is that of access to a lower unit price of traffic. In this way, the user sees the incentive of immediate financial benefit in choosing to use the cache system. When the provider deploys transparent or forced caching, translating the benefits of caching into an overall reduced tariff structure for all clients is a more robust business model.

Web-Cache Systems

Cache systems can take a variety of forms. The original Web server from CERN, the original location of the development of Web software, allowed a mode of proxy behaviour. This cache server model was developed significantly in the Harvest Project, a research project at the University of Colorado. As an evolutionary path, the *Harvest* cache server is being further developed within the scope of the development of the *Squid* cache server software and the associated *Internet Caching Protocol* (ICP).

Currently numerous freely available proxy cache systems are available, such as Squid, and many systems are available commercially, such as the Cisco Systems *Cache Engine*. Some of these systems are software packages that operate on a conventional operating system platform, while some use a customized platform kernel, which is optimized for the demands of a cache-delivery environment.

Many of the characteristics of Web caching systems are relevant to the performance of the caching environment. The first is the *size* of the cache server. The relationship between the size of the cache and its hit rate is not a linear relationship. For typical patterns of Web use generated from a relatively large user population, a cache of 1 gigabyte or so will yield reasonable hit rates. Further increase of the cache size will yield incremental improvements in the cache hit rate, where the incremental rate is best described by a negative exponential relationship. Thus, caching systems with 10 gigabytes of storage do not produce performance characteristics markedly different from larger 100-gigabyte caching systems. No objective best size of cache system can be determined, because local environments differ, but every environment exhibits the law of diminishing returns, in which the addition of further cache capacity yields no tangible difference in the cache effectiveness. Large caches take some time, in the order of days or even weeks, to build up a sufficiently large repository of cached data to produce an improved cache hit rate. Generally, 10- to 100-gigabyte cache systems provide extremely effective cache performance, as long as the cache is allowed to stabilize for some weeks following startup. Memory demands in a cache also need to be carefully configured. The URL index of the storage system is stored in memory in most cache architectures in order to perform fast cache lookups, so that the more disk storage configured, the larger the memory requirements.

The next parameter is the *number of simultaneous cache requests* that the cache server can manage efficiently. Note that this metric is different from the number of requests per second that the cache server can manage. The number of simultaneous sessions that the cache server can support is related to the amount of resources allocated to the cache request and the total resource capacity of the box.

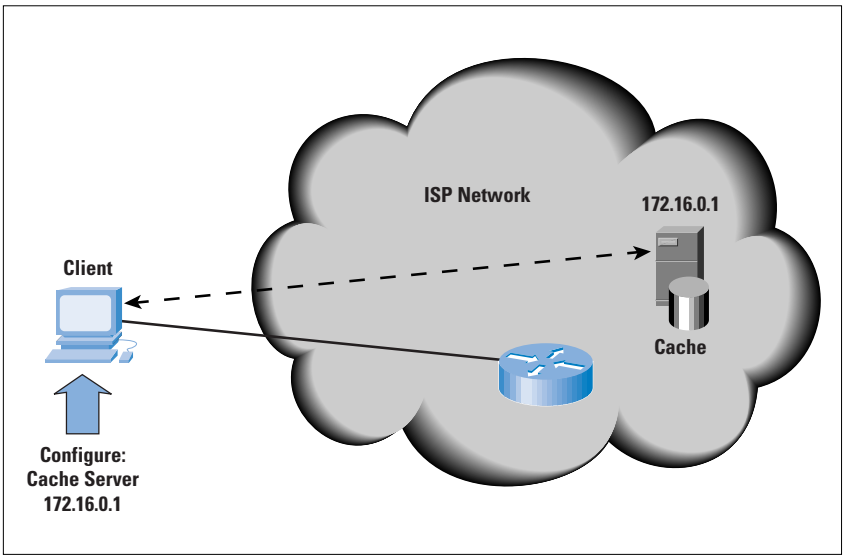
The environment of deployment is very relevant to the performance of the cache environment. The related metric to the number of simultaneous requests that can be managed is the average time to process a request. Combining these two metrics provides the number of requests per second that the cache system can process. The same unit will have a different performance metric of requests per second when deployed in different parts of the Internet. If the cache system is deployed with a satellite-based feed, then the average time to process a cache miss is considerably longer because of the higher latency of the satellite path. This scenario leaves the process of managing the original request open for a longer period, blocking other requests from using this process slot. If the same unit is deployed in a location where cache misses take fractions of a second to process, the process slot can be quickly reused. Each active client connection also consumes memory, and the client connection will remain open for as long as it takes to complete the Web transaction, either for a hit or a miss. The greater the mean round-trip delay for a miss, the greater the number of concurrent active sessions held in the cache. Similarly, the greater the number of low-speed modem or wireless-based clients, the greater the number of concurrent active sessions in the cache. Whether the client operates in transparent mode or in explicit proxy caching mode is also an important consideration. Browser clients use an explicit proxy cache with a persistent connection, while if the cache is a transparent cache, the cache will see clients bring up and drop HTTP connections each time the base URL changes. This session reestablishment, together with the additional Domain Name System (DNS) resolution load imposed on the client, can add up to half a second to the transparent cache response time as compared to the explicit cache response.

Web Cache Deployment Models

In this section we first examine scaling issues for explicitly referenced cache configurations, and then look at the changes to the model introduced through transparent caching.

The simplest deployment model of an explicit cache is that of deployment of a single cache system as a browser-selectable resource. This system can be deployed within an ISP's server environment with a TCP port-80 interface opened for client access. Such a deployment model is shown in Figure 4.

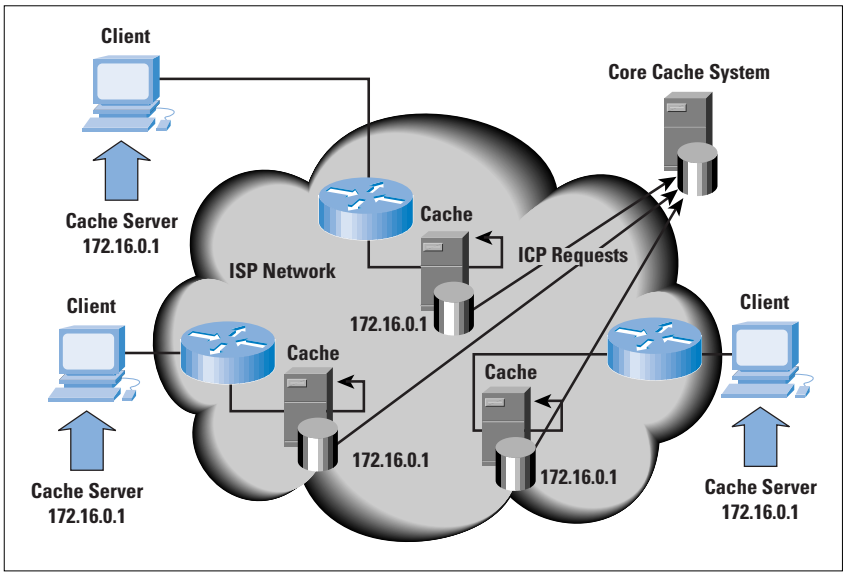
Figure 4: A Selectable Web Cache



Single Web proxy cache systems can be placed under some significant load, and an overloaded and poorly performing cache is perhaps worse than no cache at all. However, scaling this deployment model can prove challenging. Where an ISP operates multiple access points, or points of presence (POPs), one scaling solution is to deploy a server at each POP and use the same IP address for each server. This solution allows the ISP to provide a consistent configuration to all clients and to augment capacity at any location seamlessly. If the cache itself is responsible for advertising the common IP address into the routing system, the caches can also act in a mutual backup role. Failure of a single server will shut down the local route advertisement. Traffic directed to this address will then be carried by the routing system to the next closest proxy cache. There may be some level of TCP session resets for sessions that were active on the failed unit, but in all other respects the switchover is seamless to the client base, and the recovery of an operational state among a set of such servers can be left to the routing system. This deployment model is indicated in Figure 5. Such servers can be configured as a set of local satellite systems to a larger caching core, using an *Internet Cache Protocol* (ICP) configuration to set up a caching hierarchy.

ICP is a lightweight message format for communicating between Web caches[7]. The message format is a simple two- packet exchange, where a Web cache passes a URL query to another cache. The response is either a hit or a miss, indicating the presence of the URL object on the remote cache. On top of this protocol can be constructed cache hierarchies, to allow multiple neighboring caches to pool their resources effectively.

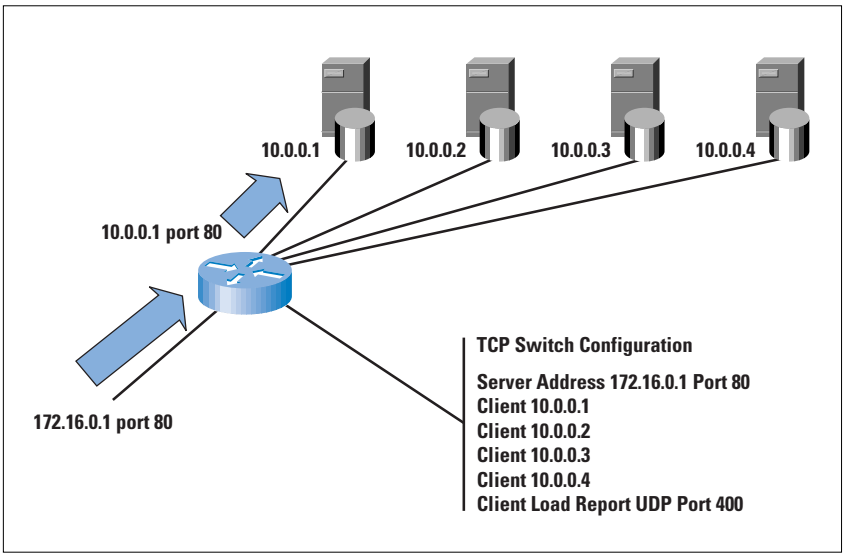
Figure 5: Replicated Web Caches



The proposed mode of configuration of caches is into a tree-structured hierarchy[8]. In such a hierarchy every participating cache is organized with a connection of neighboring peers and an ICP parent. When a cache request cannot be serviced from the local cache, the cache first uses a set of local configuration rules to determine if the server is local. If so, the cache queries the server directly for the content. If the server is remote, the cache issues a set of simultaneous ICP queries to all its cache peers. If any peer responds with an ICP hit, the cache then requests the peer to provide the referenced content. If all peers respond negatively to the ICP query, or a two-second timeout elapses, the cache then requests the URL from its designated parent. The parent may use a peer referral, or the parent may refer the query to its parent, or perform a cache retrieval on behalf of the original request. The intent of this mode of operation is to use a lightweight query response protocol to allow a local collection of caches to pool their cached data. ICP has also been used with additional policy constraints, although the protocol itself is not capable of describing or carrying overly complex retrieval policies. Other intercache protocols are available, including the *Hyper Text Caching Protocol* (HTCP) and the *Cache Array Routing Protocol* (CARP), which offer functionality in terms of intercache cooperation similar to that of ICP[9].

Another scaling measure is to alter the single server to multiple servers, using a TCP-based, load-sharing mechanism in the switching system to ensure that the servers are evenly loaded. This setup is shown in Figure 6. Such a simple load-sharing system may even the load on each server, but it will cause each server to act independently of its sibling servers. It is essential in such an environment to use ICP to coordinate the servers so that they will refer to each other before initiating a new fetch from the content server.

Figure 6: Load-Balancing Web Caches



In such a configuration each cache will contain content also held in neighboring caches. Although this scenario may allow some form of server load balancing, particularly when the servers continually communicate their current load conditions to the load-balancing switch, there is still some inefficiency in the cache farm operation through the potential replication of content on each of the component caches. One direction of scaling the cache servers is to take a collection of cache servers and allow each cache server to specialize in the content it holds. However, the outer TCP destination address does not help the server determine which URL is being requested. In an explicit cache configuration, the browser is directing the TCP session to the externally advertised TCP address of the server farm. The URL information is embedded within the HTTP payload. Some developments have been made in this area, where, with a combination of TCP spoofing and TCP session bridging, a server switch can select the appropriate cache for each HTTP-referenced URL, and then logically connect the client's TCP session to a TCP session to the selected cache to deliver the URL to the client.

Transparent caching presents some further deployment challenges. The functional requirement is to pass all Web requests through a proxy cache server without the explicit knowledge of the client. Two generic techniques exist to achieve this goal:

- *Inline caches:* The first of these approaches is to pass all traffic through a two-port cache server. All non-HTTP traffic is simply passed straight through the device without alteration. HTTP traffic is intercepted and passed to a cache module. The major concern with this approach is the introduction of a single point of failure with an active network element. Any failure of the cache may well prevent all further traffic from entering or leaving the served subnetwork.

- *Redirection caches:* A technique that does not place the cache as a critical point of potential failure is to use policy redirection within the router, redirecting all port-80 traffic to the attached cache. Normally such a policy redirect would infer that the cache is located one hop away from the router, so that such a redirection is normally a local solution. Redirection to a tunnelled interface does allow some greater flexibility in this setup, and the one cache farm could, in such an approach, service a collection of redirecting routers. The failure mode of this form of operation remains a concern, because the redirection mechanism in the router would not normally be aware of the operational status of the cache.

Transparent caches need to ensure that the full URL is inserted into the HTTP level request. When the browser assumes that the request is directed to the content server, the GET request may specify a URL relative to the server. In such cases, the transparent server will need to perform a DNS lookup of the destination IP address of the TCP session in order to reconstruct the complete URL.

Although the DNS lookup does have some performance implications to transparent caches, the major issue for transparent caches is to devise a fail-safe mechanism, so that if the cache server fails for any reason, the caching redirection is disabled. One solution is to use a redirection function within the router in conjunction with a keepalive-based Web cache management protocol. This scenario is the basis of the *Web Cache Coordination Protocol* (WCCP)[10]. WCCP also adds the ability to load share across multiple cache servers through content distribution. Transparent caching assists in this task because the destination address in the IP packets can be used as the basis of the cache selector. The keepalive exchange between the router and the cache server system allows the router to cease redirecting Web traffic upon failure of the servers.

Alternative solutions rely on the cache itself participating in a local routing environment. The redirecting router uses policy-based redirection to forward all port-80 traffic to an address announced by the cache system at a high routing priority. The same address is also announced by the default path router at a low routing priority. Failure of the cache system will result in a withdrawal of the high-priority route, and while the redirection will remain in place on the router, the redirection will be in the direction of the default route.

Another challenge is to process cache misses at a speed comparable with normal noncached Web retrieval. A process of pulling the document into the cache and then serving the document to the original requestor does not meet that objective. The transparent cache has to feed the document to the requestor while simultaneously creating a stored copy for subsequent cache serving.

However, the largest challenge to the transparent cache is that it can serve only documents that are not dependent on the identity of the requestor being preserved. Web servers that use an end-to-end model of access, based on source address identification, or Web servers that attempt to present different documents to the client based on the client's source address, do not fit within the transparent caching model. There is much interest in solutions that allow a transparent cache to effectively shut down in the case of a Web retrieval error, and allow the original requestor the ability to conduct a HTTP conversation directly with the server in such situations. Although there is interest in a network-only solution, it appears at this stage that some level of assistance from the browser may be required. One model of operation is that a transparent cache records the network-level flow identification of a failed Web retrieval, and passes a retry signal back to the requesting browser, and also passes this flow identifier back to the redirector as a temporary filter entry. When the requestor retries the query, as per the signal from the cache, the redirecting router will refrain from redirecting the flow to the cache, and allow an end-to-end session to operate.

Accounting for Web Cache Use

These deployment systems allow for user-optional cache configuration. If the ISP wants to account for the use of the cache, then the cache server or the switch that feeds the cache server must play an active role in accounting collection.

If every network address is uniquely advertised to the ISP by a particular client, then the task of accounting for cache use can be performed using the logged records of the cache system itself. Because every IP address can be uniquely mapped to an ISP client, it is possible to also associate the volume of bytes delivered by the cache to the identified client.

Unfortunately, two factors make this supposition of address uniqueness somewhat weak. First, dialup address assignment implies that the association of an IP address to a client is held only within dialup accounting records in the first instance, and the binding is valid only between the times referenced in the start and stop records. This scenario can be configured into an accounting model by simultaneously processing the dial accounting records when attempting to associate a particular IP address at a particular time to a client.

The second factor is slightly more challenging. For an ISP that offers permanent access transit services, the potential exists that any particular IP address may not be uniquely routed. Normally, such multiple access environments are part of a Border Gateway Protocol (BGP)-based interaction with multiple clients. Knowing the IP address of the query agent is not enough. Ascertaining the next-hop Autonomous System (AS) number as well as the IP address is now necessary to determine the client using the cache.

The implication is that the accounting records now need to be generated on the router that is also the entry point to the cache. In addition, the router must participate in the interior BGP (iBGP) core mesh to maintain current AS path-selection choices. Given the considerable overheads that such an engineering design entails, an alternative approach is to restrict the cache accounting role to account for those cases where the cache client is readily identified. A common measure is that the lower tariff is available only to customers who are "singly homed" with the ISP. Not only is this a strong market incentive for customer loyalty, it also allows simple engineering solutions for cache accounting, because the lookup from the IP address in the cache log to a customer account is then relatively straightforward. Such measures allow a cache-use tariff to be very competitively positioned in the market.

As well as accounting issues, another component for the consideration of optional use of Web caches is that of the necessity of restricting the use of the cache to clients of the ISP. The motive for so doing is to ensure that the cache is available only to clients of the service and not to clients of peer ISPs. It may not be an issue worth the effort of solving, and the first questions ISPs should ask is, "To what extent does this happen, and what impact does it have on the operation of the Web cache systems?" In most cases, the accounting of cache usage may reveal that this issue is one of negligible proportions, and any effort expended in devising an engineering solution would far outweigh the loss to the ISP through such use of the service.

If the measurement of such usage is considered sufficient to warrant engineering solutions, then the mechanisms available to the ISP are to ensure that the Web cache access is filtered at the edges of the ISP network and to ensure that access is possible only by ISP clients, or that the address of the cache is not exported in the routing system to peer ISPs or upstream ISPs.

Further Deployment Challenges

It is highly likely that further development will occur with cache servers in the near future. Large-scale backbone IP networks that use OC-3c (155 Mbps) or OC-12c (622 Mbps) transport cores may carry tens of thousands of requests per second. Designing transparent caches that fit within a transport core at such a scale does present dramatic scaling issues in terms of cache system performance. This factor continues to elude many of today's products available on the market. The generic architecture today is to use a cache network that attempts to place the cache systems closer to the access edge of the network, where the Web request volumes are within the scale of today's cache systems.

Transparency of the cache remains an issue, and it is perhaps an area of further refinement within the specification of the underlying HTTP Web server protocol, as well as further refinement of the operation of Web browsers and transparent cache systems. A potential implementation within Web browsers may allow the user to state the acceptability of using a cache to complete a request, and allow noncache Web page retrieval attempts on cache failure, in the same way that the provider can use page expiration directives to direct a cache not to store the presented data.

Gigabit Ethernet

by William Stallings

In late 1995, the IEEE 802.3 committee formed a High-Speed Study Group to investigate means for conveying packets in Ethernet format at speeds in the gigabit-per-second range. A set of 1000-Mbps standards have now been issued.

The strategy for Gigabit Ethernet is the same as that for 100-Mbps Ethernet. While defining a new medium and transmission specification, Gigabit Ethernet retains the carrier sense multiple access collision detect (CSMA/CD) protocol and frame format of its 10- and 100-Mbps predecessors. So it is compatible with the slower Ethernets, providing a smooth migration path. As more organizations move to 100-Mbps Ethernet, putting huge traffic loads on backbone networks, demand for Gigabit Ethernet is intensifying.

Figure 1 shows a typical application of Gigabit Ethernet. A 1-Gbps LAN switch provides backbone connectivity for central servers and high-speed workgroup switches. Each workgroup LAN switch supports both 1-Gbps links, to connect to the backbone LAN switch and to support high-performance workgroup servers, and 100-Mbps links, to support high-performance workstations, servers, and 100-Mbps LAN switches.

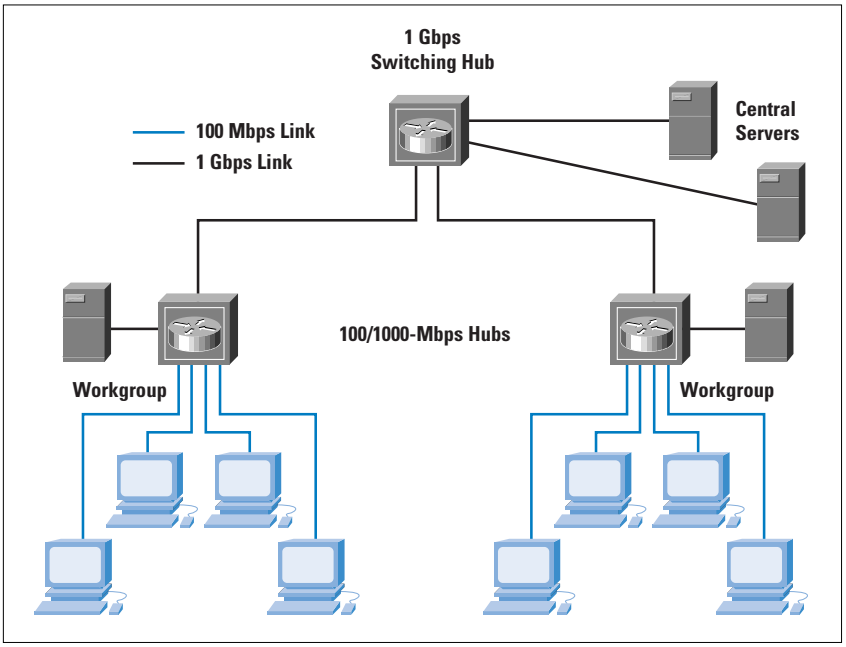

Figure 1: Example Gigabit Ethernet Configuration

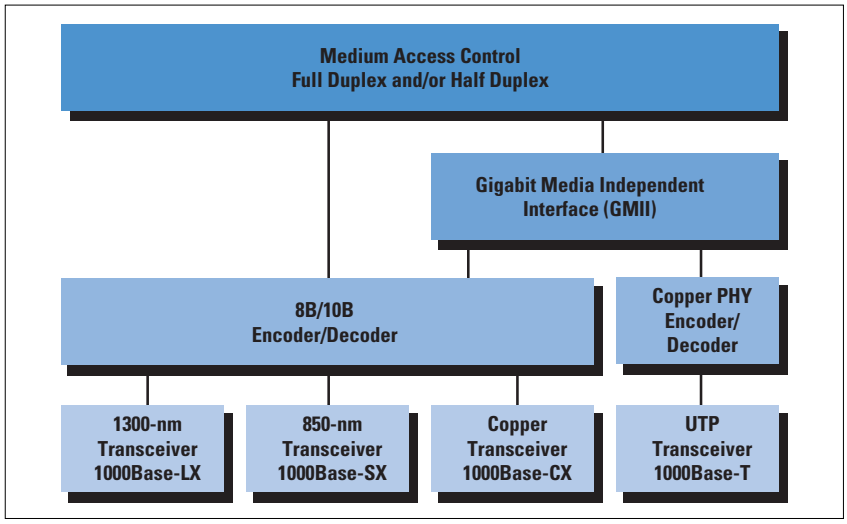
Protocol Architecture

Figure 2 shows the overall protocol architecture for Gigabit Ethernet. The Media Access Control (MAC) layer is an enhanced version of the basic 802.3 MAC algorithm. A separate gigabit medium-independent interface (GMII) has been defined and is optional for all the medium options except unshielded twisted-pair (UTP).

The GMII defines independent 8-bit-parallel transmit and receive synchronous data interfaces. It is intended as a chip-to-chip interface that lets system vendors mix MAC and physical sublayer (PHY) components from different manufacturers.

Two signal encoding schemes are defined at the physical layer. The 8B/10B scheme is used for optical fiber and shielded copper media, and the pulse amplitude modulation (PAM)-5 is used for UTP.

Figure 2: Gigabit Ethernet Layers



Media Access Layer

The 1000-Mbps specification calls for the same CSMA/CD frame format and MAC protocol as used in the 10- and 100-Mbps versions of IEEE 802.3. For traditional Ethernet hub operation, in which only one station can transmit at a time (half-duplex), the basic CSMA/CD scheme has two enhancements:

- *Carrier extension:* Carrier extension appends a set of special symbols to the end of short MAC frames so that the resulting block is at least 4096 bit-times in duration, up from the minimum 512 bit-times imposed at 10 and 100 Mbps. This extension makes the frame length of a transmission longer than the propagation time at 1 Gbps.
- *Frame bursting:* This feature allows for multiple short frames to be transmitted consecutively, up to a limit, without relinquishing control for CSMA/CD between frames. Frame bursting avoids the overhead of carrier extension when a single station has a number of small frames ready to send. extension when a single station has numerous small frames ready to send.

With a LAN switch (full-duplex operation), which provides dedicated rather than shared access to the medium, the carrier extension and frame bursting features are not needed. They are unnecessary because data transmission and reception at a station can occur simultaneously without interference and with no contention for a shared medium. All the gigabit products on the market use a switching technique, and so do not implement the carrier extension and frame bursting.

With a switching technique, full-duplex operation is employed, and the CSMA/CD protocol is not needed. The gigabit specification expands on the pause protocol that is defined for 100-Mbps Ethernet by allowing asymmetric flow control. Using the autonegotiation protocol, a device may indicate that it may send pause frames to its link partner but will not respond to pause frames from its partner.

Physical Layer

The current 1-Gbps specification for IEEE 802.3 includes the following physical-layer alternatives (Figure 3):

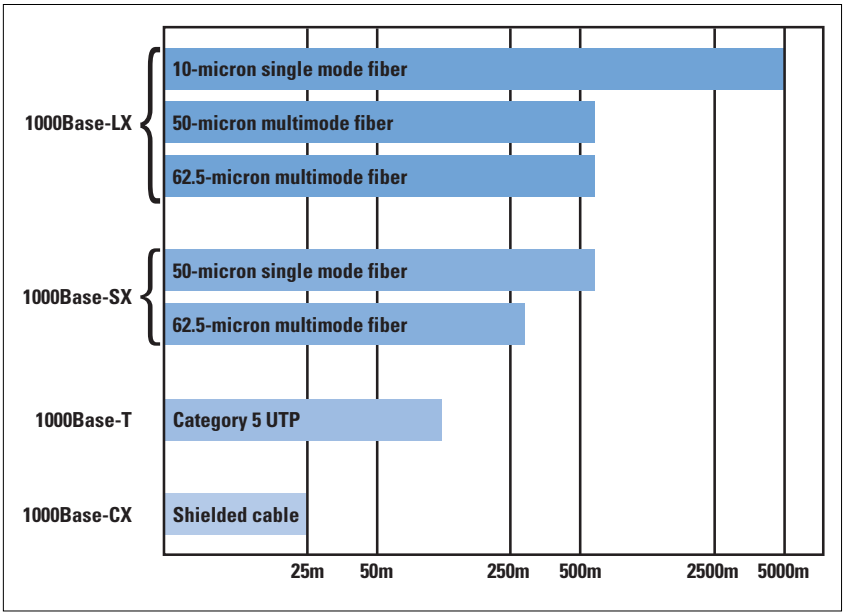


Figure 3: Gigabit Ethernet Media Options (log scale)

- *1000Base-LX:* This long-wavelength option supports duplex links of up to 550 m of 62.5-μm or 50-μm multimode fiber or up to 5 km of 10-μm single-mode fiber. Wavelengths are in the range of 1270 to 1355 nm.
- *1000Base-SX:* This short-wavelength option supports duplex links of up to 275 m using 62.5-μm multimode or up to 550 m using 50-μm multimode fiber. Wavelengths are in the range of 770 to 860 nm.
- *1000Base-CX:* This option supports 1-Gbps links among devices located within a single room or equipment rack, using copper jumpers (specialized shielded twisted-pair cable that spans no more than 25 m). Each link is composed of a separate shielded twisted-pair running in each direction.
- *1000Base-T:* This option makes use of four pairs of Category 5 unshielded twisted-pair copper wires to support devices over a range of up to 100 m.

Digital Signal Encoding Techniques for Gigabit Ethernet

The encoding scheme used for all the Gigabit Ethernet options except twisted-pair is 8B/10B. This scheme is also used in Fibre Channel. With 8B/10B, each 8 bits of data is converted into 10 bits for transmission. The 8B/10B scheme was developed and patented by IBM for use in its 200-megabaud ESCON interconnect system.

- The developers of this code list the following advantages:
- It can be implemented with relatively simple and reliable transceivers at low cost.
- It is well balanced, with minimal deviation from the occurrence of an equal number of 1 and 0 bits across any sequence.
- It provides good transition density for easier clock recovery.
- It provides useful error-detection capability.

The 8B/10B code is an example of the more general *m*B*n*B code, in which *m* binary source bits are mapped into *n* binary bits for transmission. Redundancy is built into the code to provide the desired transmission features by making $n > m$. Figure 4 illustrates the operation of this code. The 8B/10B code actually combines two other codes, a 5B/6B code and a 3B/4B code. The use of these two codes is simply an artifact that simplifies the definition of the mapping and the implementation; the mapping could have been defined directly as an 8B/10B code. In any case, a mapping is defined that maps each of the possible 8-bit source blocks into a 10-bit code block. There is also a function called *disparity control*. In essence, this function keeps track of the excess of zeros over ones or ones over zeros. An excess in either direction is referred to as a disparity. If there is a disparity, and if the current code block would add to that disparity, then the disparity control block complements the 10-bit code block. This complement has the effect of either eliminating the disparity or at least moving it in the opposite direction of the current disparity.

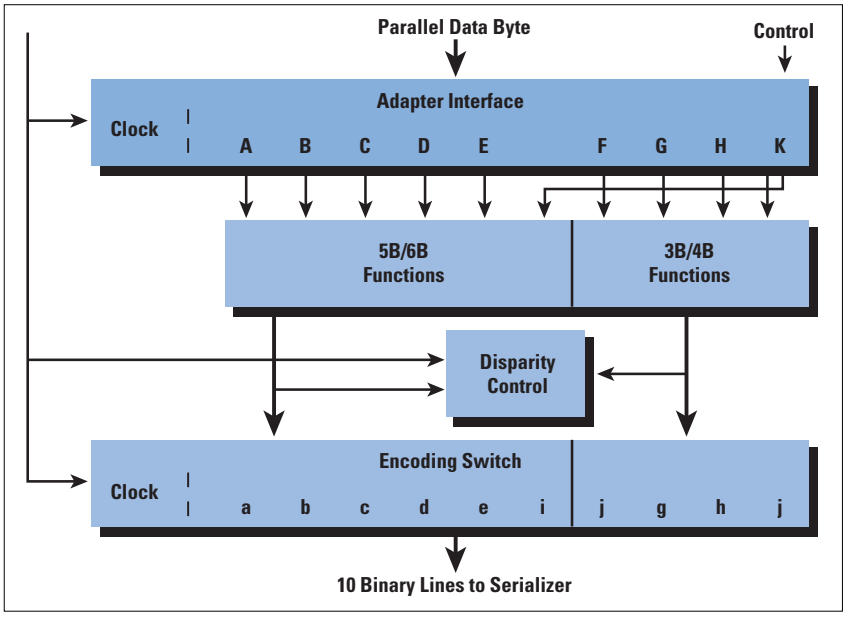

Figure 4: 8B/10B Encoding

The encoding mechanism also includes a control line input, K, which indicates whether the lines A through H are data or control bits. In the latter case, a special nondata 10-bit block is generated. A total of 12 of these nondata blocks are defined as valid in the standard. These blocks are used for synchronization and other control purposes.

For 1000Base-T, the encoding scheme used is PAM-5, over four twisted-pair links. Therefore, each link must provide a data rate of 250 Mbps. PAM-5 provides better bandwidth utilization than simple binary signaling by using five different signaling levels. Each signal element can represent two bits of information (using four signaling levels). In addition, a fifth signal level is used in a forward error correction scheme.

One Byte at a Time: Is Your FTP Active or Passive?

by Thomas M. Thomas, NetCerts

What many people don't know is that the *File Transfer Protocol* (FTP) has multiple modes of operation that can dramatically affect its operation and, as a result, the security of your network. These modes of operation determine whether the FTP server or FTP client initiates the TCP connections that are used to send information from the server to the client. The FTP protocol supports two modes of operation, as follows:

- The first FTP mode of operation is known as *normal,* though it is often referred to as *active*. This mode of operation is typically the default.
- The second FTP mode of operation is known as *passive*.

In active (normal) FTP, the client opens a control connection on port 21 to the server, and whenever the client requests data from the server, the server opens a TCP session on port 20. In passive FTP, the client opens the data sessions, using a port number supplied by the server.

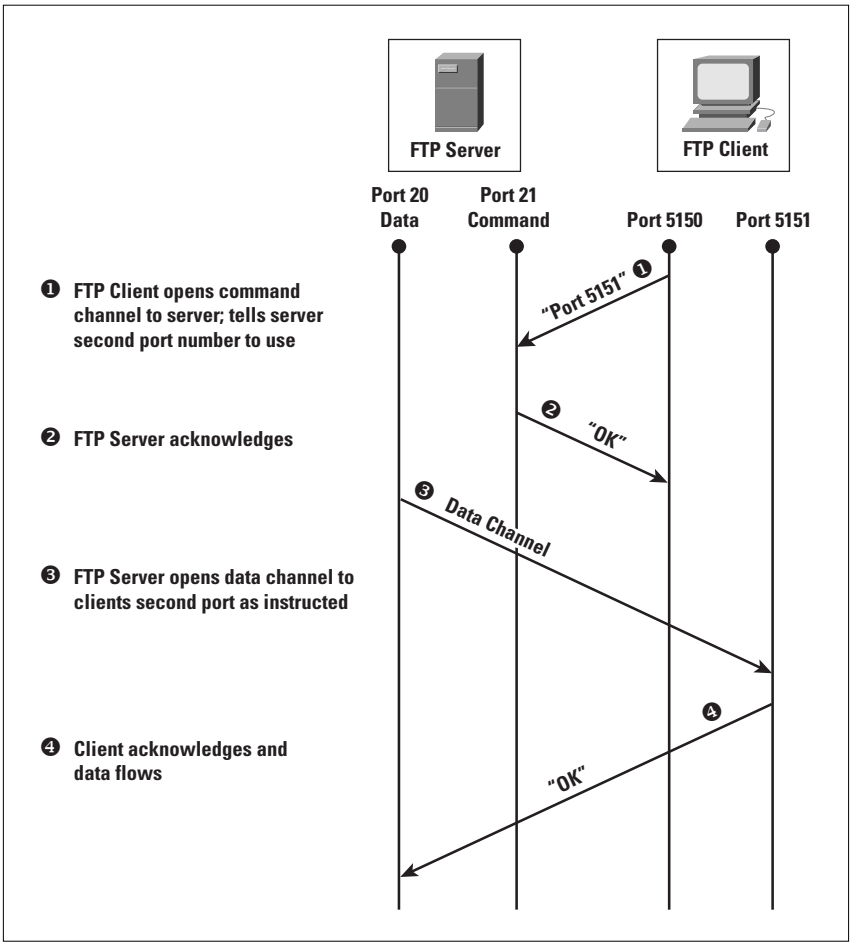
Active FTP Operation

The active mode of operation is less secure than the passive mode. This mode of operation complicates the construction of firewalls, because the firewall must anticipate the connection from the FTP server back to the client program. The steps of this mode of operation are discussed below and are shown in Figure 1.

- The client opens a control channel (port 21) to the server and tells the server the port number to respond on. This port number is a randomly determined port greater than 1023.
- The server receives this information and sends the client an acknowledgement "OK" (ack). The client and server exchange commands on this control connection.
- When the user requests a directory listing or initiates the sending or receiving of a file, the client software sends a "PORT" command that includes a port number > 1023 that the client wishes the server to use for the data connection.
- The server then opens a data connection from port 20 to the client's port number, as provided to it in the "PORT" command.

The client acknowledges and data flows.

Figure 1: Active-Mode FTP Connection



Passive FTP Operation

This mode of operation is assumed to be more secure because all the connections are being initiated from the client, so there is less chance that the connection will be compromised. The reason it is called passive is that the server performs a "*passive open.*" The steps of this mode of operation are discussed below and are shown in Figure 2.

- In passive FTP, the client opens a control connection on port 21 to the server, and then requests passive mode through the use of the "PASV" command.
- The server agrees to this mode, and then selects a random port number (>1023). It supplies this port number to the client for data transfer.
- The client receives this information and opens a data channel to the server-assigned port.

The server receives the data and sends an "OK" (ack).

Figure 2: Passive-Mode FTP Connection

Letter to the Editor

The article "Was the Melissa Virus so Different?" (*The Internet Protocol Journal*, Volume 2, Number 2, June 1999) by Barbara Y. Fraser et al makes an interesting comparison between events in our real and virtual lives, comparing e-mail borne viruses with commercial samples delivered to our physical mail boxes. While I think the comparison is a useful exercise, the authors fail to point out one of the fundamental differences between these two worlds.

An electronic message contains a finite amount of information: a careful sender can make sure his identity cannot be revealed. In contrast, a physical "message" (i.e., mail bomb, extortion letter, etc.) contains an essentially unlimited amount of information: from finger prints and material analysis to DNA traces, a potential perpetrator can never be certain that he can deny his involvement. For cyberspace crimes the chance to be caught is (and is perceived to be) much smaller. As a result, many virus authors have but the slimmest motive for their deed.

The fact that the Melissa author was quickly identified because of a hidden signature in Microsoft Word is little comfort. For reasons of privacy, this feature has been disabled: it was a bug, not a feature.

To extend the analogy: suppose a simple device would become available that can look up a person's full ID based on a DNA trace (a few molecules) on any object touched or handled. Move the scanner over the door handle and you know who's been visiting. The ramifications would be extensive. Most likely, the as-yet hypothetical device would be illegal except for police use.

We look forward to hearing your comments and suggestions regarding anything you read in this publication. Send us e-mail at: **ipj@cisco.com**

Changes at the IPJ Web Site

Now you can find every issue of *The Internet Protocol Journal* in both PDF and HTML format at **www.cisco.com/ipj**. We are also pleased to announce that Nikkei Business Publications in Tokyo has provided an introduction to IPJ in Japanese, as well as translation of some of the titles from previous issues at: **http://nit.nikkei.co.jp/ipj.html**. We hope to set up similar links with other publications around the world.

Book Reviews

DHCP *DHCP—A Guide to Dynamic TCP/IP Network Configuration,* by Berry Kercheval, ISBN 0-13-099721-8, Prentice Hall PTR, 1998, **http://www.prenhall.com/ptrbooks/ptr_0130997218.html**

First, I should note that this book arrived at the perfect time for me: I am involved in adding *Dynamic Host Configuration Protocol* (DHCP) support to a software product and needed a quick, thorough understanding of DHCP that went into sufficient detail to support some key design decisions. The book provided me with exactly what I wanted. However, as to whether or not this is a book you should own or even want to read, that is a much more difficult question to answer.

Organization

The author begins with a chapter of general background information. Then, in a logical progression, he goes through an overview of DHCP and on to explicit details of both the client and server aspects of the protocol. In other sections he covers server administration, DHCP and IP Version 6 (IPv6), and the future of DHCP. He then briefly reviews a few available implementations. In supporting sections he covers the relationship between DHCP and the *Domain Name System* (DNS), specifically Dynamic DNS. In one chapter he discusses the relationship between directory services and DHCP, in particular, the *Lightweight Directory Access Protocol* (LDAP). He then concludes with three appendices: one lists DHCP vendors, another covers the available DHCP options, and a final appendix provides the DHCP RFCs, RFC 2131 and RFC 2132.

Presentation

Overall, the book is well planned and easy to read. The background information is clearly written and gives sufficient material to assure that even novice readers will not get left behind. The author clearly explains the origins of DHCP in BOOTP and the continuing relationship between the two protocols. He also provides many examples that help make the more difficult aspects of DHCP easier to grasp. The chapters tend to progress in a logical order, making absorption of the fairly technical subject almost easy.

The presentation, however, is somewhat marred by minor errors and omissions. None of these mistakes would confuse an expert, but they will make it harder for the novice to be sure what he or she is to understand. In one example, a client workstation on net 10.0.1.0 is offered, and selects, an address of 10.0.2.32. This scenario is, however, clearly unroutable, and the example only confuses the reader. The author also makes a good effort at defining terms the first time they are used, and then again in an extensive glossary. However, for some reason he never defines two key terms: *broadcast* and *multicast*. Since both techniques are core to understanding DHCP, this oversight is difficult to understand.

The chapters on DHCP are fairly exhaustive in their examination of the protocol from overview to minutiae. The roles of clients, servers, and relay agents are well described and documented with sample packets. Each packet field is thoroughly explained and easy to grasp. However, the sections of LDAP and Dynamic DNS could have been presented better. The reader is left with a glimpse of possible relationships between the protocols, but without enough information to really pull it all together. Notably missing is any mention of remote access and the *Remote Authentication Dial-In User Service* (RADIUS) protocol. DHCP and RADIUS perform similar functions in different situations, and there has been much discussion in the past year or two about use of DHCP to manage RADIUS IP address assignments.

Summary

This book sets out to accomplish a limited goal: informing the reader about the basics of DHCP. A couple of detours along the way provide useful information about related technologies (such as DNS and LDAP). The author makes no assumptions about the user's technical capability and level of knowledge. This is perhaps the book's major strength and its biggest weakness. Because of his assumptions about the reader's technical ability, a lot of space is devoted to giving background and reference information assuring that the reader has the necessary foundation to understand the more complex aspects of DHCP. If the background information and appendices (all of which are available on the net and consist mostly of the RFCs anyway) are removed from the book, little is left: without the appendices there are only 144 pages. Given that the book costs $45, and that the 144 pages are essentially a guided explanation of the RFCs anyway, the technically competent reader might do just as well to download the RFCs and slog through them.

However, for the non-technical reader, or someone who just wants it all in one convenient volume, the author's approach is well worth the cost of the book and the (short) time required to read it. Explanations are clear and concise, terms are well defined, and everything the reader needs to grasp about the complexities of DHCP is right there, in a logical order.

Information Warfare

Information Warfare and Security, Dorothy E. Denning, ISBN 0-201-43303-6, Addison-Wesley, 1999, **http://www.awl.com/cseng/0-201-43303-6/**

It has been said that "information is power," and they who control the information control the power. Whether the information is broadcast on the evening news, printed in a newspaper, etched on stone tablets, or published on a USENET newsgroup or Internet Web page, we rely on information in our daily lives, and trust that most of the information we receive and process is accurate.

"Information warfare." What images does it conjure up for you? Propaganda wars via pamphlets dropped from airplanes, or "cyber-terrorists" versus the FBI on the Internet—or something else entirely? Dr. Denning covers all bases in this, her latest book. The "warfare" of the title is specifically the battle between the good guys and "information terrorists."

This book is a textbook for a course by the same name at Georgetown University. No one, however, should be scared off by this knowledge. This book is incredibly approachable, intended for a broad audience. It is an introduction to information warfare, but really concentrates on computer- and network-based information. Anyone involved or interested in computer and network security would benefit from this book. Many sections are self-contained, so a reader can jump back and forth among the sections. All the sections are interesting and informative, and should be to both the highly technical reader as well as those for whom technology is peripheral to their jobs, but who require or desire deeper and broader knowledge of information warfare.

About the Author

Dorothy E. Denning is Professor of Computer Science at Georgetown University. She is a well-known expert in the areas of computer security and cryptography, and has been called as an expert witness to testify before the U.S. Congress. She is the author of over 100 papers on computer and Internet security, and has written three other books in addition to this one: *Cryptography and Data Security* (a coeditor with Peter Denning), *Rights and Responsibilities of Participants in Networked Communities,* with Herbert S. Lin, and *Internet Besieged: Countering Cyberspace Scofflaws*. She is also a frequent contributor to security-related publications.

Organization

Information Warfare and Security has three parts. Part 1 starts with a very exciting (and still timely) discussion of the role information warfare played in the Gulf War in the early 1990s. The tone and flavor of this opening chapter continues throughout the book. Randomly put your finger in the book and you will be able to start an enjoyable and interesting read (though I recommend reading beginning to end). Part 1 introduces basic concepts upon which the work is built. Chapters 2 and 3 present a taxonomy of information warfare, relating it to information security and assurance, and suggesting four arenas of activity: play, crime, individual rights, and national security. The author discusses goals, motivations, culture, and concerns. Included is the no-doubt apocryphal, but always fun, quote attributed to Secretary of State for War Henry Stimson, upon the 1929 "discovery" of the Black Chamber codebreaking operation: "Gentlemen, do not read one another's mail."

Part 2 focuses on offense. This section covers topics that, for the most part, will be new to many readers. The chapters cover open source material and privacy (and piracy of information), "social engineering," and its kin. The threat from insiders—legitimate and those who have broken in, gets a thorough treatment. Eavesdropping also is examined, from cellular and pager intercepts, to the mysterious-to-most-people area of traffic analysis, to surveillance, packet-sniffing, and other electronic eavesdropping attacks.

Chapter 8 looks in detail at well-known computer hacking techniques and the tools that implement the attacks. Chapter 9 discusses identity theft, including forged e-mail and stolen accounts, IP-spoofing (stealing the identity of a computer), and Trojan Horse attacks. Finally, Part 2 ends with a chapter dedicated to computer viruses, both real and hoaxes.

Topics discussed in Part 3, "Defensive Information Warfare," will be familiar to most readers who understand computer and network security. Chapter 11 not only describes cryptographic techniques for protecting information, but also covers *steganography,* or "the practice of hiding a message in such a manner that its very existence is concealed"—and anonymity. Chapter 12, "How to Tell a Fake," deals with methods for determining identity or trustworthiness of entities or information. Chapter 13 talks about access control mechanisms, including firewalls, and intrusion detection. Covering vulnerability monitoring and analysis, risk analysis, risk management, and incident response, Chapter 14 possibly should have started Part 3. Devices, mechanisms, and methods should be deployed after an understanding of what is contained in this chapter. Part 3, and the book, end with a chapter dedicated to discussing the role of government in defensive information warfare. Also included are descriptions of recent (1990s) actions, laws, and initiatives of the U.S. Government in this area.

Throughout, the book is seasoned with stories—infowar stories, if you will—and background information, allowing the novice not only to understand, but also to enjoy learning what is contained within.

A Book for the Lecture Hall or Armchair

It is not surprising that *Information Warfare and Security* so thoroughly covers the space of information warfare theory, measures, and countermeasures, not because it weighs in at over 500 pages, but because it was written as a text for a course that had to cover all of this material. What may be surprising to readers unfamiliar with Dr. Denning is that such complete coverage could be done in such an easy-to-read way. I have no doubt that this book is and will continue to be useful and effective in the classroom. In addition, the reader studying for accreditation in a field requiring this knowledge, or the professional wanting to "brush up," "fill in," or just "kick back," will find much here to commend itself.

Cryptonomicon

Cryptonomicon, Neal Stephenson, ISBN 0-380-97346-4, Avon Books, 1999. **http://www.cryptonomicon.com/main.html**

It isn't often that you find reviews of works of fiction in these pages, but *Cryptonomicon* deserves special treatment. Neal Stephenson's latest work is a 918-page science fiction World War II thriller that I couldn't put down. You have to love a novel that has plot points that depend on the technical details of prime number theory, Pretty Good Privacy (PGP), public key infrastructure (PKI), Secure Shell (SSH), Global Positioning System (GPS), secure e-mail, and other Internet applications. Truly this is an epic novel of techno-epic proportions.

The story takes places during both World War II and modern times. The contemporary action revolves around an offshore data haven created by a Silicon Valley startup with the usual coterie of managers, venture capitalists, lawyers with class-action suits, marketeers, and nerds that you'll easily recognize. These entrepreneurs think nothing of flying across the Pacific to attend a meeting and then flying home to get in some quality family time.

The war setting revolves around a small group of code crackers who travel around the globe planting misinformation behind German and Japanese lines. The two groups are literally related: the modern generation is the progeny of the wartime crackers. Both groups are going after hidden caches of gold, among other things, buried near the Philippines.

Technology

There is much technology here for any self-respecting computer geek to digest. Think of Tom Clancy playing with the latest laptops and the Internet rather than with the latest guns. There is even an appendix describing the technical details of one of the crypto algorithms using synchronized decks of playing cards (a key plot point in the book). Stephenson blends in descriptions of undersea cable laying and salvage operations with the cracking of the *Enigma*[1] codes and hunting down German submarines. At one point, the code-cracking wartime division has to change its numerical designation because it can be factored into two prime numbers—too obvious.

One of my favorite scenes happens early in the book, when the modern-day principals of the crypto firm are meeting some of their backers and potential clients for the first time. The firm's engineer (using the built-in pinhole camera of the laptop) programs his UNIX laptop to surreptitiously capture a photo of whoever is using the keyboard during a demo of the firm's crypto technology, but hides his program in a way that any UNIX hacker would appreciate. He then e-mails the collected digital photos to a friend to try to confirm their identity.

Balance

Unlike Clancy, this book has characters with some depth to them and doesn't overdo the technology. The relationship of the war and modern-day periods is nicely tied together in the end, and the familiarity of the modern-day business relationships is sometimes almost too painful to read.

—David Strom, publisher of Web Informant

Would You Like to Review a Book for IPJ?

We receive numerous books on computer networking from all the major publishers. If you've got a specific book you are interested in reviewing, please contact us and we will make sure a copy is mailed to you. The book is yours to keep if you send us a review. We accept reviews of new titles, as well as some of the "networking classics." Contact us at **ipj@cisco.com** for more information.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and appli-cation management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

Fragments

More ICANN News

The *Internet Corporation for Assigned Names and Numbers* (ICANN) recently announced that seven additional applicant companies have met its registrar accreditation criteria.

As accredited registrars, these seven companies will compete in the market for domain name registration services in the **.com**, **.net**, and **.org** domains. In addition, they will be able to participate the ongoing testbed program for the *Shared Registry System,* which allows multiple ICANN-accredited registrars to provide domain name registration services in these domains. Under an agreement announced August 6 by the U.S. Department of Commerce and Network Solutions, Inc. (NSI—the developer of the Shared Registry System), new registrars that have signed an accreditation agreement with ICANN will be eligible to join the initial five testbed registrars as participants in the testbed operation. The testbed phase is currently scheduled to conclude on September 10, 1999.

The seven new companies join the 57 companies that have already been accredited by ICANN starting in April, 1999. Until the initial introduction of competition in June, registration services in the **.com**, **.net**, and **.org** domains were provided solely by NSI under a 1992 Cooperative Agreement with the U.S. Government.

The additional seven companies named are: CommuniTech.Net, Inc. (United States), GANDI (France), iDirections, Inc. (United States), InterNeXt (France), ProBoard Technologies (United States), PSI-USA (United States), and Signature Domains, Inc. (United States). Further information about these companies will be made available on the ICANN Web site:

http://www.icann.org/registrars/accreditation.html

Under an October 6, 1998 amendment to the Cooperative Agreement between NSI and the U.S. Government, the process of opening the Internet Domain Name System's three largest domains to competition was launched with a testbed phase that began on April 26. Five companies were initially accredited to use the NSI Shared Registry System in a test operation designed to ensure that the introduction of competition occurs in a smooth, coordinated manner.

By qualifying to be accredited as registrars, the seven new registrars join the five original testbed registrars, as well as the 52 other companies that have already qualified for ICANN accreditation. The Shared Registry System testbed program has been expanded to extend to all accredited registrars that sign the standard testbed registrar agreements with NSI and meet technical certification requirements.

ICANN is a non-profit, international corporation formed in September 1998 to oversee a select set of Internet technical management functions currently managed by the U.S. Government, or by its contractors and volunteers. Specifically, ICANN is assuming responsibility for coordinating the management of the *Domain Name System* (DNS), the allocation of IP address space, the assignment of protocol parameters, and the management of the root server system. For more information, see **`http://www.icann.org`**. Here you will also find information about ICANN's upcoming public meetings.

INET 2000

INET 2000: The Internet Global Summit, is a special INET. Hosted by the Internet Society, the Summit will be held 18–21 July 2000, in Yokohama, Japan. The place, the date, and the fact that it is the 10th anniversary of this important event all mark it as an exceptional year.

To be considered as a speaker, panelist, tutorial instructor, or poster presenter, please see **`http://www.isoc.org/inet2000/callforabstracts.shtml`** for submission instructions and to read about this year's theme, "Global Distributed Knowledge for Everyone."

INET is the premier international event for Internet and internetworking professionals. Nowhere can such a broad cross-section of important movers of the Internet be found in one single location.

We look forward to receiving your abstract and seeing you in Japan!

—Jean-Claude Guedon and Jun Murai
Co-Chairs, INET 2000 Program Committee

Y2K and The Internet

As the countdown to the Year 2000 continues, a number of efforts are underway to ensure that the Internet continues to operate normally on January 1, 2000. Here we include some pointers to recent activities.

On July 30, 1999, the *President's Council on Year 2000 Conversion,* convened a roundtable meeting to examine the readiness of the Internet for the Year 2000 date change, and to coordinate efforts to maintain Internet performance and reliability during the transition to the new millennium. The roundtable brought together roughly 100 prominent organizations and individuals from different parts of the Internet community to discuss the Internet's Y2K readiness. Meeting participants included small and large ISPs, equipment vendors, root name server and domain registries, exchange points, network time servers, industry associations, and government officials. For more information see:
`http://www.y2k.gov/` and **`http://www.mids.org/y2k/`**

For small- and medium-sized businesses in the U.S. and in key trading partner countries, the U.S. Department of Commerce (DoC) is providing a strategic management tool to help battle the millennium bug. The *Y2K Self-Help Tool/CD-ROM* contains a software program that enables users to complete an inventory of assets that may be susceptible to Y2K problems, gauge the criticality of business processes, develop contingency plans and conduct remediation activities.

This CD-ROM contains a 10-minute discussion video, the software program for managing your Y2K process, a self-assessment checklist, contingency planning template, user guide and hotlinks to many helpful Y2K sites. It has been produced in several languages including English, Spanish, Mandarin Chinese, Japanese, French, Portuguese, Arabic and Russian. The software was developed by the DoC's National Institute of Standards and Technology Manufacturing Extension Partnership (MEP) in cooperation with the U.S. Department of Agriculture and the U.S. Small Business Administration.

To receive just the software, visit: **www.nist.gov/y2k/software.htm** and download *Conversion 2000: Y2K Jumpstart Kit*. To receive the complete CD-ROM with video and hotlinks, you can call 1-800-Y2K-7557 and ask for the Self-Help Tool in any of the languages listed above. If you are an association or organization interested in multiple copies of the CD-ROM for your members and staff, click on order form, print the form, complete the requested information, and fax it to 202-482-0077. Please note that there is a minimal charge for orders over 100 copies for duplication and shipping.

The *Internet Engineering Task Force* (IETF) has examined all of the protocol standards and related documents to identify any potential inherent Y2K problems in the Internet Protocol Suite. The resulting report, RFC 2626, "The Internet and the Millennium Problem (Year 2000)" can be found at **http://www.ietf.org/rfc/rfc2626.txt**

From The Editor

In June 1992 when I was editor and publisher of *ConneXions—The Interoperability Report*, we published an article entitled "First IETF Internet Audiocast." Steve Casner and Steve Deering wrote: "The March Internet Engineering Task Force (IETF) meeting in San Diego was an exciting one for those interested in teleconferencing. In addition to several sessions on teleconferencing topics, we managed to pull off a 'wild idea' suggested by Allison Mankin from MITRE: live audio from the IETF site was 'audiocast' using IP multicast packet audio over the Internet to participants at 20 sites on three continents spanning 16 timezones."

Multicast has come a long way since 1992. Today, every IETF meeting features several live streams of not only audio but also video and slide presentations. Multicast continues to be developed in the IETF, as protocols and tools are being revised and refined. In two articles, Jon Crowcroft and Mark Handley describe the technologies behind multicast. The first article, included in this issue, looks at the current state of multicast. The second article, to appear in a future issue of IPJ, will look at the problems that need to be solved before multicast can become a truly scalable service for the Internet.

Research into new, high-speed networking technologies and applications is taking place in many parts of the world. One example of such a research effort can be found in the Internet2 Project. Larry Dunn describes some of the technology and application development being conducted by Internet2 members.

Interest in *IP Version 6* (IPv6) is growing as organizations contemplate a world where millions of devices such as cellphones, PDAs, cable TV set-top boxes and so on are "Internet Ready." The formation of the *IPv6 Forum* (**www.ipv6forum.com**) is some indication of this interest. We will look at a particular IPv4-to-IPv6 transition strategy in our next issue. In the meantime, Peter Salus takes a historical look at Internet addressing in our series "One Byte at a Time."

And so we reach the end of 1999 and the end of Volume 2 of *The Internet Protocol Journal*. We wish you a pleasant holiday season and an uneventful transition to Y2K.

—Ole J. Jacobsen, Editor and Publisher
ole@cisco.com

Internet Multicast Today

by Mark Handley, ACIRI and Jon Crowcroft, University College London

When you need to send data to many receivers simultaneously, you have two options: repeated transmission and broadcast. Repeated transmission may be acceptable if the cost is low enough and delivery can be spread out over time, as with junk mail or electronic mailing lists. Otherwise, a broadcast solution is required. With real-time multimedia, repeated delivery is feasible, but only at great expense to the sender, who must invest in large amounts of bandwidth. Similarly, traditional broadcast channels have been very expensive if they cover significant numbers of recipients or large geographic areas. However, the Internet offers an alternative solution: IP multicast effectively turns the Internet into a broadcast channel, but one that anyone can send to without having to spend huge amounts of money on transmitters and government licenses. It provides efficient, timely, and global many-to-many distribution of data, and as such may become the broadcast medium of choice in the future.

The Internet is a datagram network, meaning that anyone can send a packet to a destination without having to preestablish a path. Of course, the boxes along the way must have either precomputed a set of paths, or they must be relatively fast at calculating one as needed, and typically, the former approach is used. However, the sending host need not be aware of or participate in the complex route calculation; nor does it need to take part in a complex *signaling* or *call setup* protocol. It simply addresses the packet to the right place, and sends it. This procedure may be a more complex procedure if the sending or receiving systems need more than the default performance that a path or network might offer, but it is the *default* model.

Adding multicast to the Internet does not alter the basic model. A sending host can still simply send, but now there is a new form of address, the multicast or host group address. Unlike unicast addresses, hosts can dynamically subscribe to multicast addresses and by so doing cause multicast traffic to be delivered to them. Thus the IP multicast *service model* can be summarized:

- Senders send to a multicast address
- Receivers express an interest in a multicast address
- Routers conspire to deliver traffic from the senders to the receivers

Sending multicast traffic is no different from sending unicast traffic except that the destination address is slightly special. However, to receive multicast traffic, an interested host must tell its local router that it is interested in a particular multicast group address; the host accomplishes this task by using the *Internet Group Management Protocol* (IGMP).

Point-to-multipoint communication is nothing new. We are all used to the idea of broadcast TV and radio, where a shared medium (the radio frequency [RF] spectrum) is partitioned among users (transmitter or TV/radio station owners). It is a matter of regulation that there is typically only one unique sender of particular content on any given frequency, although other parts of the RF spectrum are given over to free use for multiparty communication (police radio, citizen band radio, and so on).

The Internet multicast *model*[3] is very similar. The idea is to convert the mesh wide-area network that is the Internet (whether the public Internet, a private enterprise net, or intranet makes no difference to the model), into a shared resource for senders to send to multiple participants, or groups.

To make this group communication work for large-scale systems—in the sense of a large number of recipients for a particular group, or in the sense of a large number of senders to a large number of recipients, or in the sense of a large number of different groups—it is necessary, both for senders and for the routing functions to support delivery, to have a system that can be largely independent of the particular recipients at any one time. In other words, just as a TV or radio station does *not know* who is listening when, an Internet multicast sender does not know who might receive packets it sends. If this scenario sends out alarm bells about security, it shouldn't. A unicast sender has no assurance about who receives its packets either. Assurances about disclosure (privacy) and authenticity of sender/recipient are largely separate matters from simple packet delivery models. Security is a topic of much research and the focus for the recently formed *Internet Research Task Force* (IRTF) research group, *Secure Multicast Group* (SMuG).

The Internet multicast model is an extension of the datagram model; it uses the fact that the datagram is a self-contained communications unit that not only conveys data from source to destination, but also conveys the source and destination address information. In other words, in some senses, datagrams *signal* their own path, both with a source and a destination address in every packet.

By adding a range of addresses dedicated for sending to groups, and providing independence between the address allocation and the rights to send to a group, the analogy between RF spectrum and the Internet multicast space is maintained. Some mechanism, as yet unspecified, is used to dynamically choose which address to send to. Suffice it to say that for now, the idea is that somehow, elsewhere, the address used for a multicast session or group communication activity is chosen so that it does not clash with other uses or users, and is advertised to potential senders and receivers.

Unlike the RF spectrum, an IP packet to be multicast carries a unique source identifier, in that such packets are sent with the normal unicast IP address of the interface of the sending host.

It is also worth noting that an address that is being used to signify a group of entities must surely be a logical address (or in some senses a name) rather than a topological or topographical identifier. We shall see that this means there must be some service that maps such a logical identifier to a specific set of locations in the same way that a local unicast address must be mapped (or bound) to a specific location. In the multicast case, this mapping is distributed. Note also that multicast Internet addresses are in some sense "host group" addresses, in that they indicate a set of hosts to deliver to. In the Internet model, there is a further level of multiplexing, that of transport-level ports, and there is room for some overlap of functionality, since a host may receive packets sent to multiple multicast addresses on the same port, or multiple ports on the same multicast address.

This model raises numerous questions about address and group management, such as how these addresses are allocated. The area requiring most change, though, is in the domain of the routing. Somehow the routers must be able to build a distribution tree from the senders to all the receivers for each multicast group. The senders don't know who the receivers are (they just send their data), and the receivers don't know who the senders are (they just ask for traffic destined for the group address), so the routers have to do something without help from the hosts. We will examine this scenario in detail in the section "Multicast Routing."

Roadmap

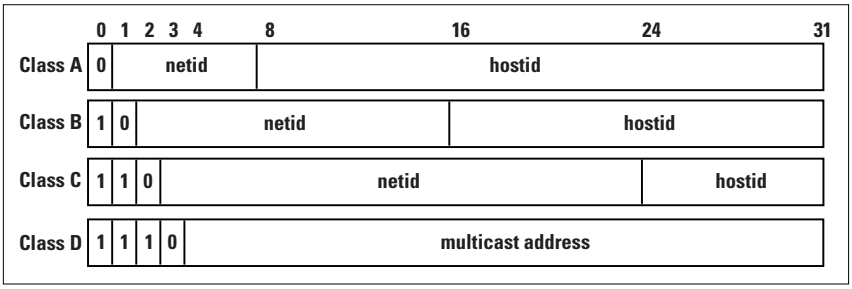
The functions that provide the Standard Internet Multicast Service can be separated into host and network components. The interface between these components is provided by IP multicast addressing and IGMP group membership functions, as well as standard IP packet transmission and reception. The network functions are principally concerned with multicast routing, while host functions also include higher-layer tasks such as the addition of reliability facilities in a transport-layer protocol. That's the order in which we cover each of these functions in the rest of this article. At the end of the article we list the current status of *Internet Engineering Task Force* (IETF) specification for the various components.

Host Functions

As we stated above, host functionality is extended through the use of the IGMP protocol. Hosts and routers, which we will look at later, must be able to deal with new forms of addressing was first designed, it was divided into classes as shown in Figure 1.

Figure 1: Internet Address Classes

A	1.0.0.0	to 126.255.255.255
B	128.0.0.0	to 191.255.255.255
C	192.0.0.0	to 223.255.255.255
D	224.0.0.0	to 239.255.255.255



Originally Class A was intended for large networks, B for midsize networks, and C for small networks. Class D was later allocated for multicast addresses. Since then, classless addressing has been introduced to solve Internet scaling problems, and the rules for Classes A, B, and C no longer hold, but Class D is still reserved for multicast, so all IPv4 multicast addresses start with the high-order 4-bit "nibble": 1110

In other words, from the 2^{32} possible addresses, 2^{28} are multicast, meaning that there can be up to about 270 million different groups, each with as many senders as can get unicast addresses! This number is many orders of magnitude more than the RF spectrum allows for typical analog frequency allocations.

For a host to support multicast, the host service interface to IP must be extended in three ways:

- A host must be able to join a group, meaning that it must be able to reprogram its network level, and possibly, consequentially, the lower levels, to be able to receive packets addressed to multicast group addresses.
- An application that has joined a multicast group and then sends to that group must be able to select whether it wants the host to loopback the packets it sent so that it receives its own packets.
- A host should be able to limit the *scope* with which multicast messages are sent. The Internet Protocol contains a *Time-To-Live* (TTL) field, used originally to limit the lifetime of packets on the network, both for safety of upper layers, and for prevention of traffic overload during temporary routing loops. It is used in multicast to limit how "far" a packet can go from the source. We will see below how scoping can interact with routing.

When an application tells the host networking software to join a group, the host software checks to see if the host is a member of the group. If not, it makes a note of the fact, and sends out an IGMP membership report message. It also maps the IP address to a lower-level address and reprograms its network interface to accept packets sent to that address. There is a refinement here: a host can join "on an interface;" that is, hosts that have more than one network card can decide which one (or more than one) they wish to receive multicast packets via. The implication of the multicast model is that it is "pervasive," so it is usually necessary to join on only one interface.

Taking a particular example to illustrate the IP-level to link-level mapping process, if a host joins an IP multicast group using an Ethernet interface, there is a mapping from the low 24 bits of the multicast address into the low 24 (out of 48) bits of the Ethernet address. Since this mapping is a many-to-one mapping, there may be multiple IP multicast groups occupying the same Ethernet address on a given wire, though it may be made unlikely by the address allocation scheme. An Ethernet LAN is a shared-medium network, thus local addressing of packets to an Ethernet group means that the packets are received by Ethernet hardware and delivered to the host software of *only* those hosts with members of the relevant IP group. Therefore, host software is generally saved the burden of filtering out irrelevant packets. Where there is an Ethernet address clash, software can filter the packets efficiently.

Operation of the IGMP protocol can be summarized as follows:

- When a host first joins a group, it programs its Ethernet interface to accept the relevant traffic, and it sends an IGMP Join message on its local network. This message informs any local routers that there is a receiver for this group now on this subnet.
- The local routers remember this information, and arrange for traffic destined for this address to be delivered to the subnet.
- After a while, the routers wonder if there is still any member on the subnet, and send an IGMP query message to the multicast group. If the host is still a member, it replies with a new message unless it hears someone else do so first. Multicast traffic continues to be delivered.
- Eventually the application finishes, and the host no longer wants the traffic. It reprograms its Ethernet interface to reject the traffic, but the packets are still sent until the router times the group out and sends a query to which no one responds. The router then stops delivering the traffic.

Thus joining a multicast group is quick, but leaving can be slow with IGMP Version 1. IGMP Version 2 reduces the leave latency by introducing a "Leave" message and a set of rules to prevent one receiver from disconnecting others when it leaves. IGMP Version 3 (not yet deployed) introduces the idea of *source-specific* joining and leaving, whereby a host can subscribe (or reject) traffic from individual senders rather than the group as a whole, at the expense of more complexity and extra state in routers.

Multicast Routing

Given the multicast service model described above, and the restrictions that senders and receivers don't know each others' location or anything about the topology, how do routers conspire to deliver traffic from the senders to the receivers?

We shall assume that if a sender and a receiver did know about each other, they could each send unicast packets to the other. In other words, there is a network with bidirectional paths and an underlying unicast routing mechanism already running. Given this network, there is a spectrum of possible solutions. At one extreme, we can flood data from the sender to all possible receivers and have the routers for networks where there are no receivers prune off their branches of the distribution tree. At the other extreme, we can communicate information in a multicast routing protocol conveying the location of all the receivers to the routers on the paths to all possible senders. Neither method is particularly desirable on a global scale, so the most interesting solutions tend to be hybrid solutions that lie between these extremes.

In the real world, there are many different multicast routing protocols, each with its own advantages and disadvantages. We shall explain each of the common ones briefly, because a working knowledge of their pros and cons helps us understand the practical limits to the uses of multicast.

Flood and Prune Protocols

Flood and Prune Protocols are more correctly known as *reverse-path multicast* algorithms. When a sender first starts sending, traffic is flooded out through the network. A router may receive the traffic along multiple paths on different interfaces, in which case it rejects any packet that arrives on any interface other than the one it would use to send a unicast packet back to the source. It then sends a copy of each packet out of each interface other than the one back to the source. In this way, each link in the whole network is traversed at most once in each direction, and the data is received by all routers in the network.

So far, this process describes *reverse-path broadcast*. Many parts of the network will be receiving traffic, even though there are no receivers there. These routers know they have no receivers (otherwise IGMP would have told them) and they can then send prune messages back toward the source to stop unnecessary traffic from flowing. Thus the delivery tree is pruned back to the minimal tree that reaches all the receivers. The final distribution tree is what would be formed by the union of shortest paths from each receiver to the sender, so this type of distribution tree is known as a *shortest-path tree* (strictly speaking, it's a reverse shortest path tree—typically the routers don't have enough information to build a true forward shortest-path tree).

Two commonly used multicast routing protocols fall in the class: the *Distance Vector Multicast Routing Protocol* (DVMRP)[4] and *Protocol Independent Multicast Dense-Mode* (PIM-DM)[5]. The primary difference between these protocols is that DVMRP computes its own routing table to determine the best path back to the source, whereas PIM Dense-Mode uses the routing table of the underlying unicast routing system, hence the term "Protocol Independent."

It should be fairly obvious that sending traffic *everywhere* and getting people to tell you what they don't want is not a particularly scalable mechanism. Sites get traffic they don't want (albeit very briefly), and routers not on the delivery tree need to store prune state. For example, if a group has one member in the UK and two in France, routers in Australia still get some of the packets, and they need to hold prune state to prevent more packets from arriving! However, for groups where most places actually do have receivers (receivers are "densely" distributed), this sort of protocol works well. So although these protocols are poor choices for a global scheme, they might be appropriate within some organizations.

MOSPF

Multicast Open Shortest Path first (MOSPF[12]) isn't really a category, but a specific instance of a protocol. MOSPF is the multicast extension to *Open Shortest Path First* (OSPF[11]), which is a unicast link-state routing protocol.

Link-state routing protocols work by having each router send a routing message periodically listing its neighbors and how far away they are. These routing messages are flooded throughout the entire network, so every router can build up a map of the network. This map is then used to build forwarding tables (using a Dijkstra algorithm) so that the router can decide quickly which is the correct next hop for a particular packet.

Extending this concept to multicast is achieved simply by having each router also list in a routing message the groups for which it has local receivers. Thus given the map and the locations of the receivers, a router can also build a multicast forwarding table for each group.

MOSPF also suffers from poor scaling. With flood-and-prune protocols, data traffic is an *implicit* message about where there are senders, so routers need to store unwanted state where there are no receivers. With MOSPF, there are *explicit* messages about where all the receivers are, so routers need to store unwanted state where there are no senders. However, both types of protocol build very efficient distribution trees.

Center-Based Trees

Rather than flooding the data everywhere, or flooding the membership information everywhere, algorithms in the center-based trees category map the multicast group address to a particular unicast address of a router, and they build explicit distribution trees centered around this particular router. Three main problems need to be solved to get this approach to work:

- How is the mapping from group address to center address performed?
- How is the center location chosen so that the distribution trees are efficient?
- How is the tree actually constructed given the center address?

Different protocols have come up with different solutions to these problems. Three center-based tree protocols are worth exploring because they illustrate different approaches: *Core-Based Trees* (CBT), *PIM Sparse-Mode* (PIM-SM), and the *Border Gateway Multicast Protocol* (BGMP). However, we will leave discussion of BGMP until our second article because it is not currently deployed.

Core-Based Trees

Core-Based Trees (CBT[1]) was the earliest center-based tree protocol, and it is the simplest.

When a receiver joins a multicast group, its local CBT router looks up the multicast address and obtains the address of the Core router for the group. It then sends a Join message for the group toward the Core. At each router on the way to the Core, forwarding state is instantiated for the group, and an acknowledgment is sent back to the previous router. In this way, a multicast tree is built, as shown in Figure 2.

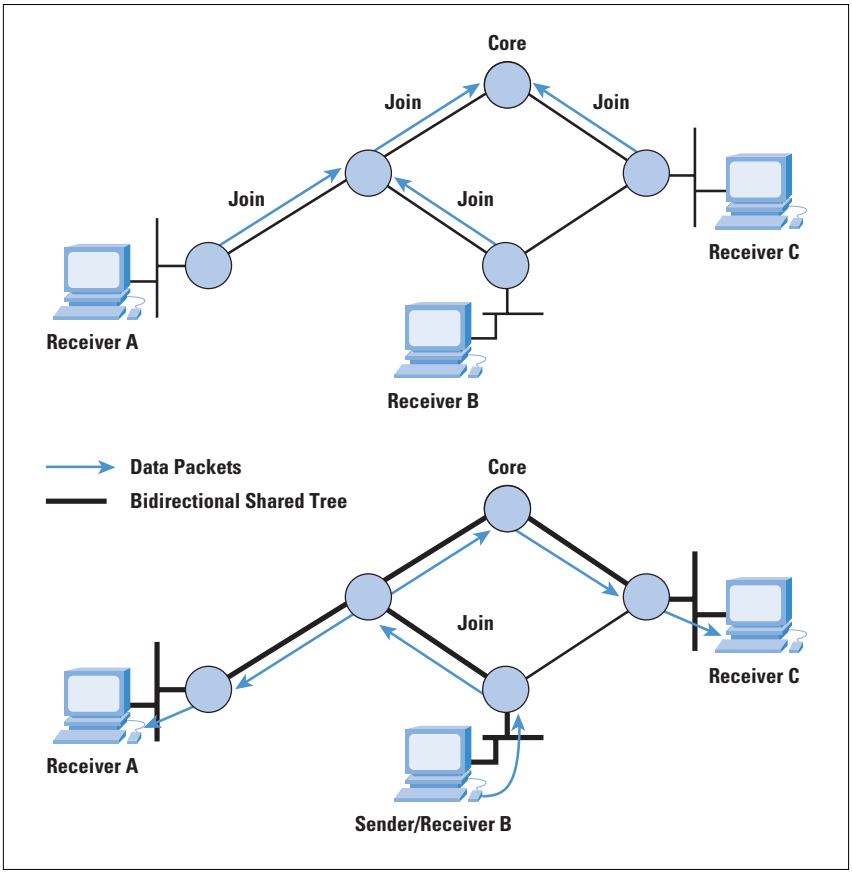


Figure 2: Formation of a CBT Bidirectional Shared Tree

If a sender (that is, a group member) sends data to the group, the packets reach its local router, which forwards them to any of its neighbors that are on the multicast tree. Each router that receives a packet forwards it out of all its interfaces that are on the tree except the one the packet came from. The style of tree CBT builds is called a "bidirectional shared tree," because the routing state is "bidirectional"—packets can

flow both up the tree toward the Core and down the tree away from the Core, depending on the location of the source, and packets are "shared" by all sources to the group. This scenario is in contrast to "unidirectional shared trees" built by PIM-SM as we shall see later.

IP multicast does not require senders to a group to be members of the group, so it is possible that a sender's local router is not on the tree. In this case, the packet is forwarded to the next hop toward the Core. Eventually the packet will either reach a router that is on the tree, or it will reach the Core, and it is then distributed along the multicast tree.

CBT also allows multiple Core routers to be specified, adding a little redundancy in case the Core becomes unreachable. CBT never properly solved the problem of how to map a group address to the address of a Core. In addition, good Core placement is a difficult problem. Without good Core placement, CBT trees can be quite inefficient, and so CBT is unlikely to be used as a global multicast routing protocol.

However, within a limited domain, CBT is very efficient in terms of the amount of state that routers need to keep. Only routers on the distribution tree for a group keep forwarding state for that group, and no router needs to keep information about any source; thus CBT scales much better than flood-and-prune protocols, especially for sparse groups where only a small proportion of subnetworks have members.

PIM Sparse-Mode

The work on CBT encouraged others to try to improve on its limitations while keeping the good properties of shared trees, and *PIM Sparse-Mode*[7] was one result. The equivalent of a CBT Core is called a *Rendezvous Point* (RP) in PIM, but it largely serves the same purpose.

When a sender starts sending, whether it is a member or not, its local router receives the packets and maps the group address to the address of the RP. It then encapsulates each packet in another IP packet (imagine putting one letter inside another, differently addressed, envelope) and sends it unicast directly to the RP.

When a receiver joins the group, its local router initiates a Join message that travels hop-by-hop to the RP instantiating forwarding state for the group. However, this state is unidirectional state—it can be used only by packets flowing from the RP toward the receiver, and not for packets flowing back up the tree toward the RP. Data from senders is de-encapsulated at the RP and flows down the shared tree to all the receivers.

PIM-SM is an improvement on CBT in that discovery of senders and and tree building from senders to receivers are separate functions.

Thus PIM-SM unidirectional trees are not particularly good distribution trees, but they do start data flowing to the receivers. Once this data is flowing, the local router of a receiver can then initiate a transfer from the shared tree to a shortest-path tree by sending a source-specific Join message toward the source, as shown in Figure 3. When data starts to arrive along the shortest-path tree, a prune message can be sent back up the shared tree toward the source to avoid getting the traffic twice.

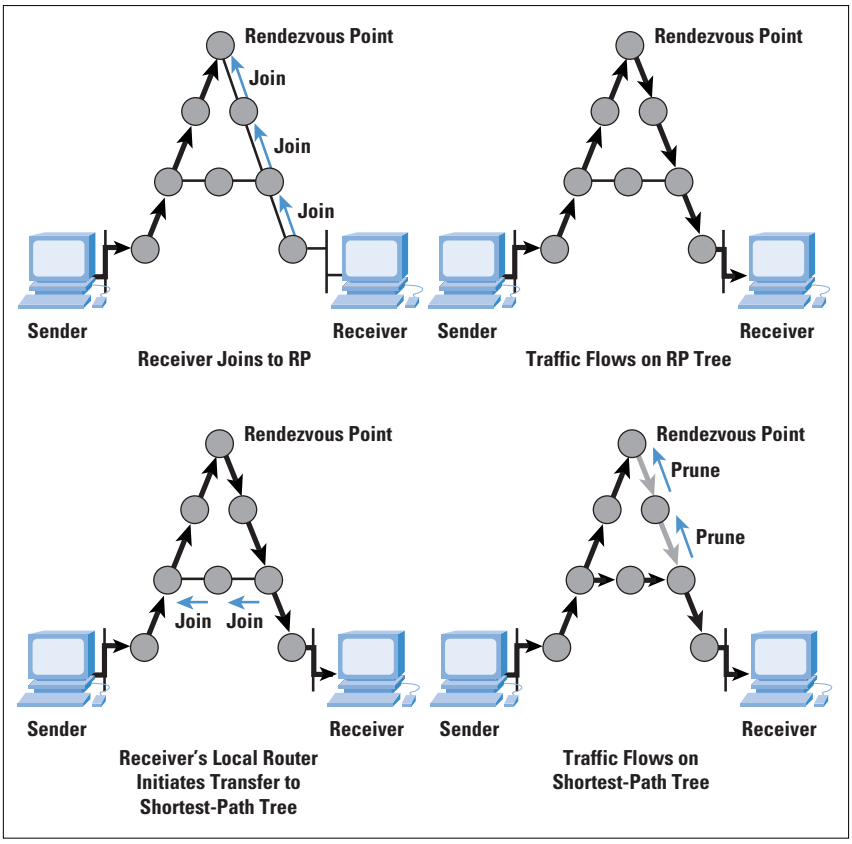

Figure 3: Formation of a PIM Sparse-Mode Tree

Unlike other shortest-path tree protocols such as DVMRP and PIM-DM, where prune state exists everywhere there are no receivers, with PIM-SM, source-specific state exists only on the shortest-path tree. Also, low-bandwidth sources such as those sending *Real-Time Control Protocol* (RTCP) receiver reports do not trigger the transfer to a shortest-path tree, a scenario that further helps scaling by eliminating unnecessary source-specific state.

Because PIM-SM can optimize its distribution trees after formation, it is less critically dependent on the RP location than CBT is on the Core location. Hence the primary requirement for choosing an RP is load balancing. To perform multicast-group-to-RP mapping, PIM-SM predistributes a list of candidates to be RPs to all routers. When a router needs to perform this mapping, it uses a special hash function to hash the group address into the list of candidate RPs to decide the actual RP to join.

Except in rare failure circumstances, all the routers within the domain will perform the same hash, and come up with the same choice of RP. The RP may or may not be in an optimal location, but this situation is offset by the ability to switch to a shortest-path tree.

The dependence on this hash function and the requirement to achieve convergence on a list of candidate RPs does, however, limit the scaling of PIM-SM. As a result, it is also best deployed within a domain, although the size of such a domain may be quite large.

Interdomain Multicast Routing

All the multicast routing schemes described so far suffer from scaling problems of one form or another:

- DVMRP and PIM-DM initially send data everywhere, and require routers to hold prune state to prevent this flooding from persisting.
- MOSPF requires all routers to know where all receivers are.
- PIM-SM needs predistribution of information about the set of RPs. Because traffic needs to flow to the RP, an RP cannot handle too many groups simultaneously, so many RPs are needed globally.

Thus each of these schemes is likely to be best deployed within a domain. How then does interdomain multicast routing take place?

Long-term solutions to this problem will be discussed in the second of these articles. In the meantime, the interim solution currently being deployed consists of multiprotocol extensions to the unicast *Border Gateway Protocol* (BGP) interdomain routing protocol, and a protocol called MSDP to glue PIM-SM domains together.

Multiprotocol BGP

For either technical or policy reasons, not all routers or peerings between Internet Service Providers (ISPs) are multicast capable. This situation complicates the use of PIM-SM for operation between domains because PIM assumes that the route obtained by unicast routing is good for multicast routing (strictly speaking, PIM assumes the reverse unicast path is good for forward-path multicast routing). If, in fact, the reverse unicast path is *not* good for forward-path multicast, then Join messages will often reach routers that do not support multicast, resulting in a lack of multicast connectivity. How then do we solve this problem?

BGP is the unicast interdomain routing protocol that is very widely used to connect unicast routing domains together. The multiprotocol extensions to BGP allow multiple routing tables to be maintained for different protocols. Thus with the *Multiprotocol Extensions for BGP-4* (MBGP)[2], you can build one routing table for unicast-capable routes and one for multicast-capable routes using the same protocol. PIM can then use the multicast-capable routes to forward Join messages and can, therefore, detour around parts of the network that don't support multicast.

Multicast Source Discovery Protocol

In addition to the problem of designing a scalable mechanism for mapping multicast groups to RPs, attempts to use PIM-SM as an interdomain protocol are hindered by ISPs' desire not to be dependent on other ISPs' facilities. For example, consider a multicast group consisting of senders and receivers in two domains, A and B, run by two different ISPs. If the RP is in domain A, and there is some problem in domain A, then senders and receivers in domain B might still be unable to communicate with each other using multicast, even though they are in the same domain, because initial PIM register messages must go via the RP. ISPs do not want to be dependent on other ISPs for connectivity within their own domain, so it appears that using PIM-SM as an interdomain protocol would be unacceptable, even if there were no scalability problems.

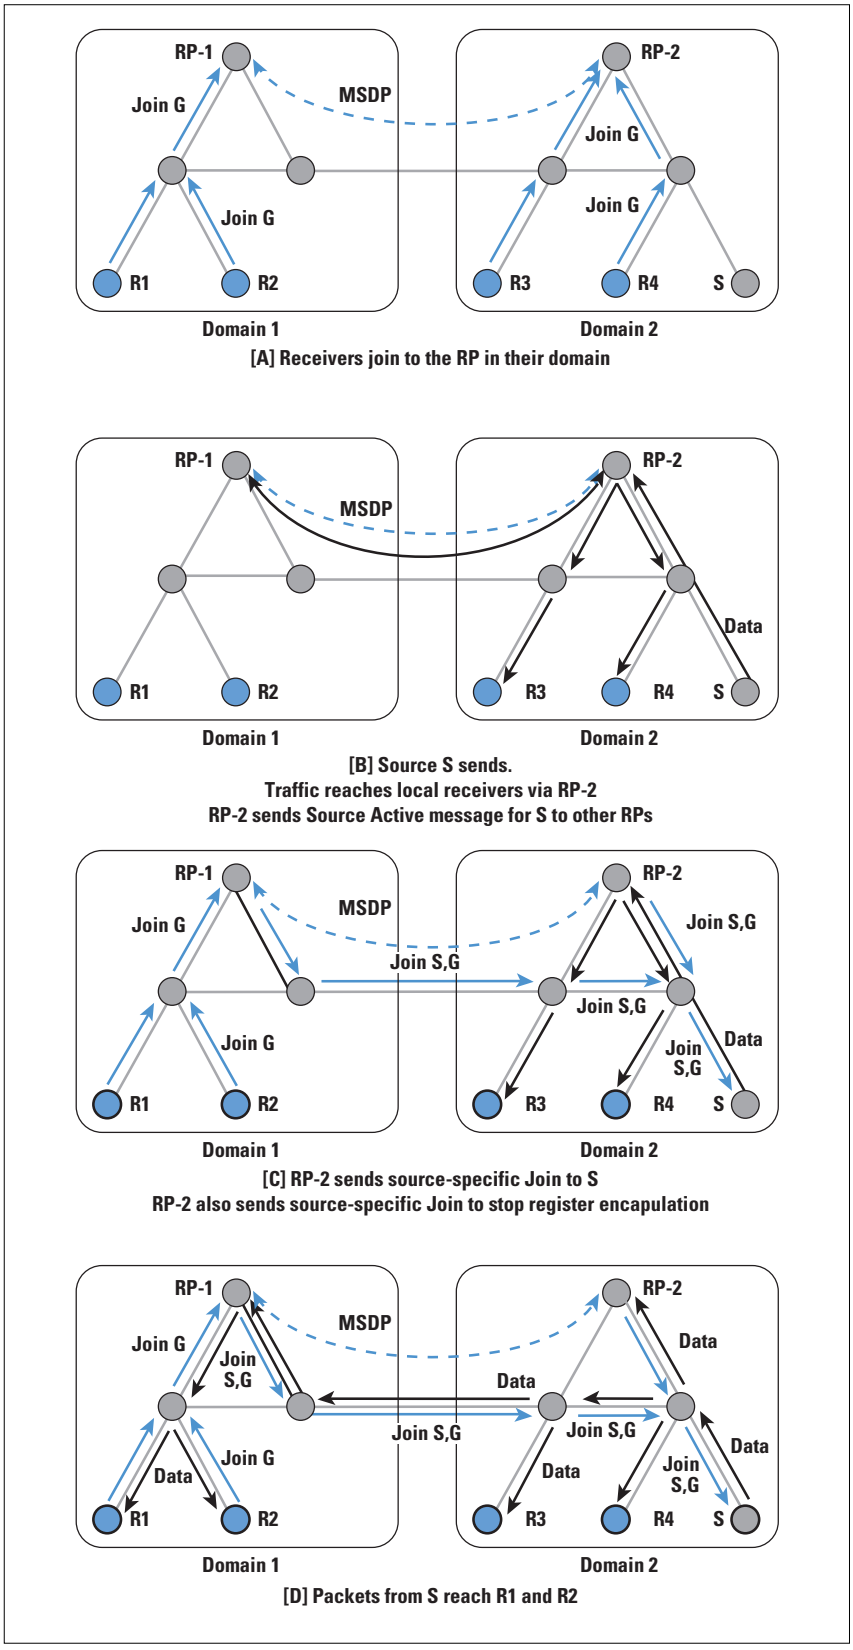
The *Multicast Source Discovery Protocol* (MSDP)[8] is an attempt to work around this problem. It does not provide a long-term scalable solution, but does provide a solution that solves the ISP interdependence problem.

With MSDP, ISPs run PIM-SM within their own domain, and they have their own set of RPs for all groups within that domain. Additionally, the RPs within the domain are interconnected with each other and with RPs in neighboring domains using MSDP control connections to form a loose mesh.

The process is shown in Figure 4. Within domain 1, R1 and R2 send Join messages from group G to RP-1. Similarly, R3 and R4 send Join messages to RP-2. When S starts sending, its packets are encapsulated to RP-2 by its local router in the normal PIM-SM manner. RP-2 decapsulates the packets and forwards them down the group-shared tree within domain 2 to reach R3 and R4. In addition, it sends a *Source Active* message over the MSDP mesh to all other RPs. RPs like RP-1 that have active joiners for this group then send a source-specific Join back across the interdomain boundary toward S. Traffic is then delivered interdomain following the source-specific state laid down by the Join messages, and it is eventually delivered to R1 and R2.

MSDP uses the normal PIM-SM source-specific join mechanism interdomain following the MBGP multicast routes back to the source, but it sets up only a group-shared tree within each domain, avoiding the need to depend on remote RPs in different domains for the delivery of traffic between local members in a domain.

Figure 4: MSDP in Operation



As an interdomain routing protocol, however, MSDP has many shortcomings. In particular, every RP in every domain must be told about every source that starts sending, and a significant subset of the RPs must cache all this information so that receivers that join late can cause source-specific Joins to be sent by their local RP. Thus MSDP does not scale well if there are a large number of senders worldwide.

In addition, to ensure that the first few packets sent by a source do not get lost, they must be encapsulated and sent alongside the *Source Active* message to all the RPs that might possibly have receivers. If they are not encapsulated, then sources that send only a few packets every few minutes might never get any data through to receivers because the source-specific state has timed out after each time they send.

In summary, MSDP is not a scalable long-term solution to interdomain multicast routing. However, it does solve a real short-term problem faced by ISPs, and so it is currently seeing significant deployment.

Multicast Address Allocation

A local protocol for requesting multicast addresses from multicast address allocation servers has recently been standardized. This protocol is called *Multicast Address Dynamic Client Allocation Protocol*, or MADCAP[10]. It is a relatively simple request-response protocol loosely modeled after the *Dynamic Host Configuration Protocol* (DHCP)[6].

MADCAP is intended to be used with interdomain protocols that perform dynamic allocation of parts of the multicast address space between domains, but because these protocols are not yet deployed, they will be discussed in the second of these articles.

As an interim solution for interdomain address allocation, a simple static mechanism has been defined. This mechanism involves embedding the *Autonomous System* (AS) number of the domain as the middle 16 bits of a multicast address. Thus the domain with AS number 16007 would get multicast addresses in the range 233.64.7.0 to 233.64.7.255 (64 and 7 being the upper and lower bytes, respectively, of 16007). Known as *glop addressing*, this mechanism is experimental. It may be superseded by a dynamic mechanism in the longer term.

Multicast Scoping

When applications operate in the global Multicast backbone (MBone), it is clear that not all groups should have global scope. Not only is this constraint especially important for performance reasons with flood and prune multicast routing protocols, but it also is true with other routing protocols for application security reasons and because multicast addresses are a scarce resource. Being able to constrain the scope of a session allows the same multicast address to be in use at more than one place as long as the scopes of the sessions do not overlap. This is analogous to the same radio frequency being used by two radio stations operating far apart from one another—each will only be heard locally.

Multicast scoping can currently be performed in two ways, known as *TTL Scoping* and *Administrative Scoping*. Currently TTL scoping is most widely used, with only a very few sites making use of administrative scoping.

TTL Scoping

When an IP packet is sent, an IP header field called *Time To Live* (TTL) is set to a value between zero and 255. Every time a router forwards the packet, it decrements the TTL field in the packet header, and if the value reaches zero, the packet is dropped. The IP specification also states that the TTL should be decremented if a packet is queued for more than a certain amount of time, but this decrement is rarely implemented these days. With unicast, the TTL is normally set to a fixed value by the sending host (64 and 255 are commonly used) and is intended to prevent packets from looping forever.

With IP multicast, the TTL field can be used to constrain how far a multicast packet can travel across the MBone by carefully choosing the value put into packets as they are sent. However, because the relationship between hop count and suitable scope regions is poor at best, the basic TTL mechanism is supplemented by configured thresholds on multicast tunnels and multicast-capable links. Where such a threshold is configured, the router will decrement the TTL, as with unicast packets, but then will drop the packet if the TTL is less than the configured threshold. When these thresholds are chosen consistently at all of the borders to a region, they allow a host within that region to send traffic with a TTL less than the threshold, and to know that the traffic will not escape that region.

An example is the multicast tunnels and links to and from Europe, which are all configured with a TTL threshold of 64. Any site within Europe that wishes to send traffic that does not escape Europe can send with a TTL of less than 64 and be sure that its traffic does not escape.

However, there are also likely to be thresholds configured within a particular scope zone—for example, most European countries use a threshold of 48 on international links within Europe, and because TTL is still decremented each time the packet is forwarded, it is good practice to send European traffic with a TTL of 63, a scenario that allows the packet to travel 15 hops before it would fail to cross a European international link.

Administrative Scoping

In some circumstances it is difficult to consistently choose TTL thresholds to perform the desired scoping. In particular, it is impossible to configure overlapping scope regions as shown in Figure 5, and TTL scoping has numerous other problems, so more recently, administrative scoping has been added to the multicast forwarding code in *mrouted* and in most router implementations.

Administrative scoping allows the configuration of a boundary by specifying a range of multicast addresses that will not be forwarded across that boundary in either direction.

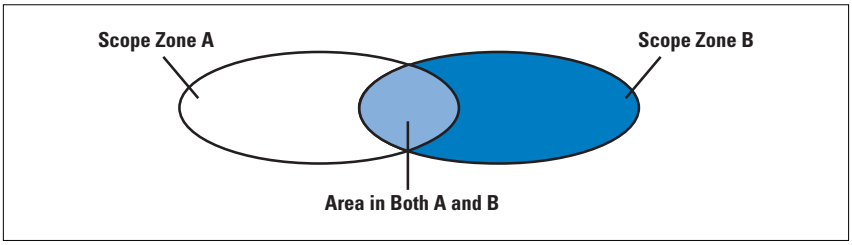


Figure 5: Overlapping Scope Zones possible with Administrative Scoping

Scoping Deployment

Administrative scoping is much more flexible than TTL scoping, but it has many disadvantages. In particular, it is not possible to tell from the address of a packet where it will go unless all the scope zones that the sender is within are known. Also, because administrative boundaries are bidirectional, one scope zone nested within or overlapping another must have totally separate address ranges. This makes address allocation difficult from an administrative point of view, because the ranges ought to be allocated on a top-down basis (largest zone first) in a network where there is no appropriate top-level allocation authority. Finally, it is easy to misconfigure a boundary by omitting or incorrectly configuring one of the routers. With TTL scoping it is likely that in many cases a more distant threshold will perform a similar task, lessening the consequences, but with administrative scoping, there is less likelihood that this scenario will occur.

For these reasons, administrative scoping has been viewed by many network administrators as a speciality solution to difficult configuration problems, rather than as a replacement for TTL scoping, and the Mbone still very much relies on TTL scoping. However, this situation is set to change as a protocol for automatically discovering scope zones (and scope zone misconfigurations) starts to be deployed. This protocol is called the *Multicast Zone Announcement Protocol* (MZAP)[9], and it will shortly become an IETF Proposed Standard. Eventually the use of configured TTL scopes to restrict traffic will cease to be used as a primary scoping mechanism.

Summary

In this article we have looked at the various routing systems that are used to devise delivery trees over which multimedia data can be sent for the purposes of group communication, and at address allocation and scoping mechanisms for this traffic.

After ten years of experimentation, IP multicast is not currently a ubiquitous service on the public Internet, but significant deployment has taken place on private intranets. The existing multicast routing and address allocation mechanisms work well at the scale of domains. However, as we have seen, there are still significant technical problems

concerning scaling to be overcome before multicast can be a ubiquitous interdomain service. In addition to the routing problems, we also still lack deployed congestion control mechanisms for multicast traffic, which are essential if multicast applications are to be safely deployed.

Despite these issues, IP multicast still shows great promise for many applications. Solutions have been devised to many of the remaining problems, although they have not yet been deployed. In the second of these articles, we will look at the proposed solutions for scalable interdomain routing and address allocation. We will also touch on multicast congestion control and the solutions that are currently emerging from the research community.

Document Status

A list of IETF specifications for the protocols discussed in this article is given below. We include the status for each document as of this writing (November 1999). For more information, check the IETF Web pages at **`www.ietf.org`**

Document	Status
IGMP v1	IETF Standard (RFC 1112)
IGMP v2	IETF Proposed Standard (RFC 2236)
IGMP v3	IETF work in progress
DVMRP	IETF Experimental Standard (RFC 1075)
PIM-Dense Mode	IETF work in progress
Multicast OSPF	IETF Proposed Standard (RFC 1584)
Core Based Trees	IETF Experimental Standard (RFC 2201)
PIM Sparse-Mode	IETF Experimental Standard (RFC 2362)
Multiprotocol BGP	IETF Proposed Standard (RFC 2283)
MSDP	IETF work in progress
MADCAP	IETF Proposed Standard (RFC 2730)
Glop Addressing	IETF work in progress

The Internet2 Project

by Larry Dunn, Cisco Systems

Communication, connectivity, education, entertainment, e-commerce—across a broad spectrum of activities, the commodity Internet has made a strong impact on the way we live, work, and play. Nevertheless, many classes of applications do not yet run well, and some don't run at all, over the commodity net. As new applications are developed in disciplines from medicine to engineering to the arts and sciences, their success increasingly depends on an ability to use networks effectively. In research and education collaborations all over the world, efforts are under way to make use of new network technologies and develop network services that will facilitate these advanced applications. One such effort in the United States is called the *Internet2* Project[1].

The Internet2 Project was started in 1996 by 34 U.S. research universities. It has since grown to over 140 universities, and includes several corporate members and international partners. This article examines network technology used in Internet2, and looks at some of the engineering challenges involved in facilitating applications being developed by Internet2 members.

Background

In 1995, the U.S. National Science Foundation (NSF) funded a program to create the *very-high-performance Backbone Network Service* (vBNS)[2]. The NSF provided funding to MCI, who interconnected five U.S. supercomputer centers and 3 *Network Access Points* (NAPs), where it was envisioned that supercomputer clients and other vBNS users would connect.

By 1996, congestion stemming from academic traffic to the commodity Internet had seriously congested the NAPs; it was accordingly recognized that clients of the supercomputer centers might be better served if the Research Universities, where Principal Investigators often resided, were themselves *directly* connected to the vBNS. So in 1996, the NSF accepted proposals as part of the *High-Performance Connections* (HPC) program[3]. Schools applying for an HPC grant might receive $350,000 over a 2-year period, provided their proposals met various criteria, including meritorious research that would benefit from the high-performance connection, a solid network plan, intention to investigate capabilities enabled by such a connection, commitment to share results with the community, matching funds from the University, and so on.

In October 1996, representatives from 34 universities met, and concluded that, while not all the schools had projects involving "meritorious research" that would meet the NSF criteria, they all *did* have a critical interest in deploying the kind of applications that such high-performance connections could enable.

Thus, to facilitate development and deployment of applications that would further the research and education mission of member universities, the Internet2 Project was formed.

From the beginning, the stated intention was to enable applications that could not run, or could not run well, on the "Commodity Internet." Networks would be utilized or constructed only so as to facilitate this applications-enabling goal, and results/methods would be applied to the broader community as rapidly as possible.

Applications Focus

The list of applications being used or developed by Internet2 members is extensive. Several fall in the category of "meritorious research" as mentioned in the NSF HPC criteria. Examples include: remote instrument control (for instance, telescopes, microscopes), high-performance distributed computation, and large-scale database navigation. Other applications that further the education mission of member universities include tools to facilitate multisite collaboration, and asynchronous learning. Many examples in areas from science, engineering, art, language, music, and more can be found at the Internet2 applications Web site[4]. In addition to individual applications, a couple of broad initiatives have a relationship with Internet2, including *The Internet2 Digital Video Initiative,* housed at the *International Center for Advanced Internet Research* (iCAIR)[5], and the *Internet2 Distributed Storage Infrastructure Initiative* (I2-DSI)[6].

The above applications share several challenging requirements, many of which translate to resource commitments that must be met by the network in an end-to-end fashion, including bandwidth and jitter. Additionally, the applications can become scalable only if more-mature middleware and control-plane infrastructure is developed. Necessary components include features such as *Authentication, Authorization, and Accounting* (AAA), scheduling, and coordination of resources managed by multiple administrative domains.

One compelling example of the network challenges present in a virtual collaborative environment is exemplified by a CAVE (*Cave Automated VR Environment*). See [7] for more details, but in brief, a single CAVE is a (10 x 10 x 10)-foot cube, with one wall removed. Users enter through the open wall, and using lightweight stereo-three-dimensional (3D) glasses, and a radio frequency (RF) mouse, can interact with an immersive environment created by rear-screen and direct projection on multiple walls and the floor. As an example, the interconnection of multiple CAVEs allows design teams in remote locations to jointly experience the operating "feel" of a new vehicle, and to dynamically adjust, design, or control parameters to see how the modified vehicle behaves.

The developers of CAVE software at Argonne National Labs have noted that the data flows in a CAVE consist of at least: control, text, audio, video, tracking, database, simulation, haptic, and rendering flows. Additionally, they have estimated the latency, jitter, and bandwidth requirements for these flows. Some of the flows represent a challenge in a single resource dimension, others have strict requirements in multiple resource dimensions.

Backbone Networks

At this time, Internet2 members may connect to either of two backbone networks, or both.

The vBNS is operated by MCI/Worldcom. It consists primarily of an IP-over-ATM network. Most schools connect at DS3 or OC-3c via ATM to a vBNS ATM switch. Interior vBNS links are OC-12c ATM. The schools peer with a Layer 3 router; a router is attached to each of the vBNS ATM switches. The vBNS routers are logically connected to each other via a full mesh of *Unspecified Bit Rate* (UBR) *Virtual Circuits* (VCs). The ATM switches are connected to each other via a second layer of ATM switches, which are part of MCI's commercial Hyperstream offering. While schools pass the vast majority of their traffic via peering at Layer 3 with the nearest vBNS border router, other services are available, including the option to establish *Variable Bit Rate* (VBR) VCs as needed, and the possibility to place some of the ATM-attached hosts of the school directly in a vBNS Classical IP *Logical IP Subnet* (LIS). This setup allows such hosts to send bytes directly to other ATM-attached hosts, bypassing the routers of both the school and the vBNS. The vBNS also carries native IP multicast traffic among members. In addition, the vBNS has a native IPv6 offering, which is achieved by deploying routers that run IPv6, and provisioning VCs to schools also running IPv6. The vBNS has also begun to offer an *IP-over-Synchronous Optical Network* (SONET) service, the first instance of which is an OC-48 *Packet-over-SONET* (POS) link from Northern to Southern California. Because the nominal partnership arrangement with the NSF expires in the year 2000, the vBNS has established a new network offering [called *Next Generation Network* (NGN)], to which schools and other entities may connect if the vBNS/NSF partnership is not renewed.

Measurement Tools in vBNS

One of the outcomes of the vBNS program has been the development of a variety of high-performance measurement tools. One such tool, called *OC-3mon* (and now, *OC-xMon*), was developed to allow passive capture (using optical splitters) of ATM cell and IP header information, to facilitate high-speed flow characterization. More detail is available at the vBNS Web site[2]. Recently, further development of OC-xMon has been undertaken by the *Cooperative Association for Internet Data Analysis* (CAIDA)[8]. CAIDA has perhaps the best collection of high-performance public-domain measurement and analysis tools in the world, and its Web site is definitely worth browsing.

The second backbone network to which Internet2 members can connect is called *Abilene*[9]. Abilene was constructed by the *University Corporation for Advanced Internet Development* (UCAID) in collaboration with three industrial partners and Indiana University (IU). Partner contributions include fiber capacity from Qwest, SONET gear from Nortel, and routers from Cisco. The Abilene Network Operations Center (NOC) is staffed and operated by Indiana University. The network uses OC-48c POS interior links that initially connect ten routers in a partial mesh (a few interior links started as OC-12c, but are being upgraded). Abilene participants can connect at OC-3c or OC-12c, using either POS or ATM. See [10] for details on the router hardware architecture. For an insightful look at a research project that shows how this architecture can scale, see the second link in[10] and also see Stanford Professor Nick McKeown's Tiny Tera homepage at[11].

Measurement Tools in Abilene

It's worth spending a bit of time at the Abilene NOC Web site[12]. One of the interesting tools developed there is the "Abilene Weather Map"[13]. Abilene NOC has indicated that it will make source code for this tool available to Internet2 schools.

Gigapop Technology Survey

Internet2 schools can connect to either vBNS or Abilene directly. However, it is also common for several schools to converge their links at a "gigapop." This gigapop then connects to Abilene and/or vBNS, and possibly to commodity Internet Service Providers (ISPs) (to carry the "Commodity Internet" traffic of the school). Additionally, non-Internet2 schools, libraries, K-12, and state government networks also often converge at gigapops. Non-Internet2 schools typically don't forward traffic over Abilene or vBNS. But the common meeting point allows local exchange of local traffic, often affords larger aggregate commodity Internet connectivity for the gigapop participants, and allows direct access to other services that might be offered at the gigapop (Web caching, and so on).

The connectivity architecture used at gigapops varies widely. Detailed documentation for several gigapops can be found at[14]. Some Gigapops are "Layer 2," meaning that each participant is responsible for exchanging routes and traffic among themselves directly. More often, gigapops are "Layer 3," meaning that the gigapop provides a router with which gigapop participants peer. The gigapop router then typically exchanges traffic with vBNS and/or Abilene, and possible commodity ISPs.

Some gigapops are implemented at a single site (for instance, *Metropolitan Research and Education Network* [MREN], *Southern Crossroads* [SoX]), while others are "distributed gigapops," meaning gigapop equipment exists at multiple locations (for instance, the *California Research and Educational Network* [CalREN-2], and *The Great Plains Network* [GPN]). Following are a couple of specific gigapop examples.

MREN

The MREN[15] is built on a Layer 2 gigapop near Chicago that joins schools and research facilities from Illinois and several states in the Midwest. MREN members typically connect with OC-3c ATM links. Since MREN is a Layer 2 gigapop, the border router of each member peers directly with the border routers of other members. Additionally, each member's border router might peer with the Chicago-area vBNS or Abilene border router. vBNS and Abilene routers (as well as several other national research and international networks) peer here. Physically, the facility is built upon the Network Access Point (NAP) facility provided by Ameritech Advanced Data Services (AADS)[16]. Routers typically peer with each other via ATM UBR *Permanent Virtual Paths* (PVPs), although other arrangements are possible.

CENIC/CalREN-2

The Corporation for Education Network Initiatives in California (CENIC)[17] has constructed CalREN-2. The CalREN-2 distributed gigapop is interesting in several respects. First, as the name implies, it represents a distributed gigapop. In this case, three separate SONET ring facilities provide connectivity for Northern, Central (Los Angeles area), and Southern California schools. These three regions are linked to each other, and also to external networks.

Second, in each ring, there are two sets of OC-12c connections to each adjacent school. CalREN-2 has currently utilized these connections to construct both a ring of ATM connectivity, and a separate, parallel ring of POS connectivity. As a result, CalREN-2 is uniquely positioned to experiment simultaneously with both ATM and POS connectivity, performance, and QoS characteristics.

Third, to take the Northern schools as an example, the ring structure allows for a variety of Layer 3 topologies to be explored. For example, in a ring with these size and bandwidth characteristics, what are the tradeoffs on application-level performance of inducing more hops while keeping the per-hop bandwidth high, versus dividing the bandwidth into smaller slices but creating a partial mesh that reduces the average Layer 3 hop count?

Engineering Challenges

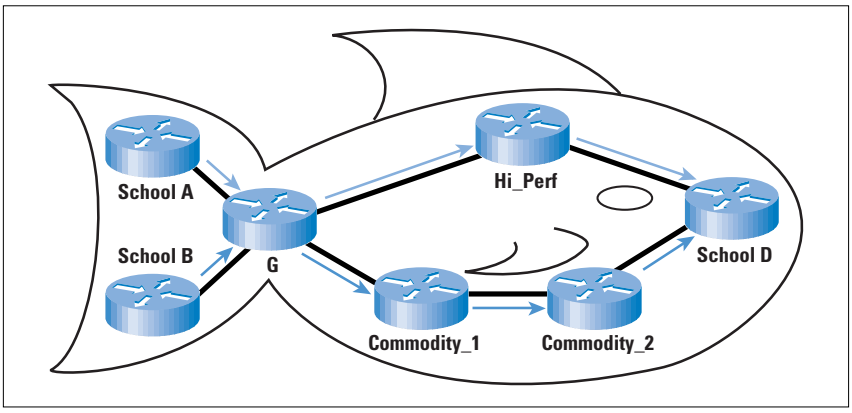
This section looks at some of the engineering challenges present in Internet2. They revolve around enabling applications with new network services, implementing appropriate policy, and doing all of this at high speed. Specifically, we'll look at Explicit Routing, Multicast, and Quality of Service.

Explicit Routing—The Fish Problem

The condition that several schools often converge at a gigapop, combined with the constraint that sometimes the funders of high-performance connectivity require that only the funded schools are allowed to use the high-performance connection, gives rise to a need for

"explicit routing" at the gigapop. The gigapop can forward packets through either a high-performance connection, or through the commodity Internet. Usually, for a single destination, traditional routing would have the gigapop use the "best" path to forward all packets to a particular destination. But when multiple policies must be implemented at the gigapop, the gigapop router must be able to "override" normal routing and forward packets on a path that's not the "best." A concrete example is shown in Figure 1.

Figure 1: The "Fish Problem"



Consider packets from schools A and B, both headed for destination D. Assume both schools are connected to gigapop G, and that G has two paths to D; one along *G-Hi_perf-D*, and the other along *G-Commodity_1-Commodity_2-D*. Further assume that A is allowed to use either path (and would perfer *G-Hi_perf-D*), but that B is prohibited from using *G-Hi_perf-D*. This scenario describes the "Explicit Routing Problem," and since it is often drawn in a shape resembling a fish, is also known as the "Fish Problem." The essence is that a routing decision at G must be made on some other criteria than just the destination IP address.

A couple of solutions to the fish problem have been used in the past, but they tend to have problems with either speed or scalability. For example, "policy routing," which usually includes a method to look at both source and destination address, has historically shown low performance. Inserting ATM switches and using virtual circuits has been used in some cases, but this solution has scaling problems and requires extra equipment. Today, many Internet2 gigapops use a separate router per policy. In the case of needing two policies in the example above, this means two routers. This solution is expensive, but does have high performance.

One promising idea is to implement enough of the "policy routing" process in hardware to allow high-speed *source+destination+other_bits* lookups. While straightforward in concept, some point out that even with line-rate source-address routing capability, the method is flawed because it requires significant manual configuration, and is prone to creating black holes for traffic upon link failure. Proponents suggest that these shortcomings can be overcome.

Another promising mechanism is becoming available as a result of work done to facilitate *Multiprotocol Label Switching* (MPLS) in routers and switches. The idea here is that one of the underlying pieces of technology required for MPLS is "multi-FIB" (multiple *Forwarding Information Bases*). Instead of the traditional "single-FIB," which always uses "the best" route to a destination, multi-FIB allows multiple forwarding tables to exist in a single router. This setup will allow a gigapop to implement multiple policies in one router, rather than the "one box per policy" that several gigapops have used previously. Note that in the case of a gigapop with a single router on which all members converge, multiple policies can be achieved with multi-FIB without actually using MPLS *Label-Switched Paths* (LSPs). For more complex gigapops, where members themselves may converge high-performance-eligible and ineligible traffic before forwarding on a single link to the gigapop, one might consider using simple LSPs to present the gigapop with traffic that is predifferentiated.

Multicast

Many of the applications in Internet2 schools use multicast. In addition to flows for videoconferencing or distance learning that use MPEG-1 (or slower) rates, a wide variety of applications require high-performance, scalable multicast. Examples include high-resolution immersive environments, collaborative real-time medical image diagnosis, and high-fidelity conferencing or distance learning (for instant, digital video camera rates of 30 mbps). When the Internet2 project began, many schools were on the *Multicast Backbone* (Mbone), and used *Distance Vector Multicast Routing Protocol* (DVMRP) tunnels to participate in multicast. Over the past year, one of the strong areas of collaboration between the Internet2 schools and the vendor community has been to develop and implement a migration strategy that allows Internet2 backbones, gigapops, and schools to move toward high-performance, scalable, native multicast support.

At the Internet2 conference in San Francisco in September 1998, the vBNS backbone was exposed to unprecedented levels of multicast stress. In a somewhat painful, but worthwhile, learning experience, it was concluded that *Protocol Independent Multicast-Dense Mode* (PIM-DM) did not scale well in highly meshed, high bitrate backbones. As a result, the vBNS has shifted to *PIM-Sparse Mode* (PIM-SM), and Abilene is being constructed with PIM-SM.

The current set of multicast components being applied in Internet2 (and leading ISPs) include: PIM-SM, *Multicast Border Gateway Protocol* (MBGP), and the *Multicast Source Discovery Protocol* (MSDP). MBGP allows distribution of routing information such that unicast and multicast routing can use noncongruent topologies.

MSDP allows independent domains to exchange information about multicast sources without creating interdomain Rendezvous Point (RP) dependencies. As they become standardized, it is expected that the *Border Gateway Multicast Protocol* (BGMP) and *Multicast Address Set Claim* (MASC) will be added to this infrastructure set.

Quality of Service

An area of broad interest in the Internet2 community centers on *Quality of Service* (QoS). The heart of QoS involves establishing strategies through which applications can be assured access to appropriate network resources when required. Typical examples of resources include end-to-end bandwidth, latency, or jitter. Of course, collateral issues and dimensions abound, including end-to-end vs. segment-only QoS; signaled vs. static provisioning; amount of state required by various approaches; level of granularity, precision, and strength of QoS "guarantee;" AAA issues; and reliability and recovery dynamics.

In an effort to start small, but make concrete progress, the Internet2 QoS working group[18] has launched an experiment called the *Qbone*[19]. Participants include backbone networks, gigapops, and individual schools and research labs worldwide. The Qbone will focus on deploying and using components developed by the Internet Engineering Task Force's (IETF) *Differentiated Services* working group (Diffserv)[20].

The initial Qbone plan is to deploy an approximation to the Expedited Forwarding (EF)[21] forwarding behavior. The Qbone will start by statically allocating a small amount of EF bandwidth across boundaries between Autonomous Systems (ASs) to allow small EF flows among arbitrary combinations of schools/labs. Large flows, in these early stages, will have to be handled manually (much as they are today). In later stages the plan is to use *Bandwidth Brokers* (BBs) currently under development[22] to aid in the automation of adjusting resource commitments between ASs (using interdomain BBs), and to aid in accepting application resource requests (using intradomain BBs, combined with policy servers and AAA mechanisms). The precise mechanics for BB interaction, trade-offs among signaling frequency, amount of state, scalability, and so on are certainly topics of research, but that's part of what makes Qbone participation fun!

Summary

There is no single application or technology that makes Internet2 unique or exciting. Rather, the effort required to enable new applications that have strong bandwidth, latency, jitter, and coordination requirements has resulted in an infusion of energy from a variety of disciplines. Internet2 requires stretching existing technologies (ATM, POS, multicast, measurement), nurturing developing technologies (Quality of Service, explicit routing, Dense Wave-Division Multiplexing [DWDM], mobility), and participating in the invention of new technologies (all-optical infrastructures, extending AAA, and other resource allocation and

scheduling middleware). Internet2 requires attention to maturing components in backbone, gigapop, and campus environments in order to deliver on the promise of speedy transference of lessons learned to the commodity Internet. The effort so far has resulted in demonstration of truly stunning, impactful, and useful applications. It is the convergence of effort and rapid rate of change that makes Internet2 a challenging and rewarding endeavor.

Other Initiatives

Although this article has focused on aspects of Internet2 in the United States, there are many advanced Internet activities around the world. A partial list includes:

One Byte at a Time: Internet Addressing

by Peter H. Salus

The source of all knowledge where the Internet is concerned is the set of *Requests for Comments* (RFCs). Because there are now well over 2,700 RFCs, however, only a few people track history, evolution, and outright paradigm shift.

Each node on the Internet—router or end system (often called "host" or "server")—has a unique identifier attached to it; this identifier is its *address*. Any packet sent between nodes must use the destination address to tell the intervening routers where it should go.

In RFC 1 (April 1969), Steve Crocker laid out a scheme that allotted five bits to address space: enough for 32 addresses. By September 1969, when *Interface Message Processor* (IMP) No. 1 was installed in Kleinrock's lab at UCLA, this number had grown to six bits (63 addresses). By 1972, it had become apparent that this number would be insufficient, and the address space was enlarged to eight bits (255 addresses). In fact, the *Advanced Research Projects Agency Network* (ARPANET) hit only 63 hosts in January 1976. This number was, however, already a lot in terms of the `HOSTS.TXT` tables that were distributed to every site. By August 1983, there were 213 hosts, and the eight-bit address barrier was being pushed.

Cerf's original version of TCP (RFC 675; December 1974) and Postel's of IP (RFC 760; January 1980) increased this "address space" to 32 bits, but the structure of the ARPANET was "flat," that is, the hierarchical distributed name-to-address database we are familiar with only came about with Mills' conceptualization of the *Domain Name System* (DNS) (RFC 799; September 1981), and its implementation by Paul Mockapetris (RFCs 882 and 883; November 1983).

Address Classes

The Internet Protocol uses a 32-bit addressing scheme and originally four classes of networks: A, B, C, D. (See Figure 1 on page 5). There are only 128 Class A networks, but each can have 16,777,216 unique host identifiers. Next, there are 16,384 Class B networks, with 65,535 unique identifiers; 2,097,192 Class C networks, with 255 hosts; and over 268 million Class D multicast groups. (A fifth class, Class E, is reserved and not available for general use).

Address Depletion

Using the 32-bit IP addressing scheme allowed for about 4 billion hosts on 16.7 million networks. Although this number of various kinds of addresses seemed like a lot, the expansion of the use of the Internet over the past decade has been explosive, and the original address classes did not allow for a flexible address assignment based on an organization's particular need.

In August 1990 during the Vancouver *Internet Engineering Task Force* (IETF) meeting, Frank Solensky, Phill Gross, and Sue Hares projected that the current rate of assignment would exhaust the Class B space by March 1994.

CIDR

Classless Inter-Domain Routing or CIDR (RFCs 1518 and 1519; September 1993) was introduced to improve both routing scalability and address space utilization in the Internet. By eliminating the notion of "network classes," CIDR allows for a better match between address requirements and address allocation. This results in expansion of the scope of hierarchical routing, which in turn improves scaling properties of the Internet routing system. CIDR has proven to be the palliative that has enabled the Internet to continue functioning while growth continues.

Even with this palliative, it was predicted in 1994 that, using the current allocation statistics, the Internet will exhaust the IPv4 address space between 2005 and 2011. With five more years of experience, which has also brought greater uncertainty as to gross numbers, we can push these dates out a bit, but exhaustion will come eventually.

Another factor that has slowed down the address depletion rate is the use of *Network Address Translation* (NAT). NAT devices allows an organization to have one external ("public") address and many private (net 10 is often used) addresses internally. Since the internal addresses are not "seen" from the outside, they do not need to be globally unique. This approach has downsides (some protocols weren't designed with NATs in mind), but from the address depletion point of view, it is a win. RFC 1597 describes "Address Allocation for Private Internets."

If you are interested in current Internet addressing, an excellent book is available: *TCP/IP Addressing,* by Buck Graham, AP Professional, 1997. Graham does an excellent job on addressing, routing, and the various bizarries involved in optimal routing, efficient use of address space, and making network management less onerous. This book is, however, not intended to be for elementary instruction; Graham primarily speaks to the professional market.

IPng aka IPv6

In the summer of 1994, the IETF set up an Internet Protocol next generation (IPng) task force, cochaired by Scott Bradner and Allison Mankin. (IPng later became known as IPv6 for "IP version 6"). Recommendations from that task force were released in October 1994 for discussion at the December 1994 IETF meeting. The basic goal was to have something in place before 2000, so that the time limit would not be pushed.

Unfortunately, as Bradner and Mankin stated in their recommendation: "Some people pointed out that this type of projection makes an assumption of no paradigm shifts in IP usage. If someone were to develop a new 'killer application,' (for example, cable-TV set top boxes), the resultant rise in the demand for IP addresses could make this an over-estimate of the time available."

IPv6 provides for 128-bit addressing. This number is gigantic: larger than the estimated total number of molecules in the universe.

Books

Two noteworthy books are available on IPv6 itself: Christian Huitema's *IPv6: The New Internet Protocol* (ISBN 0-13-241936-X, Prentice Hall, 1996) and Scott Bradner and Allison Mankin's anthology *IPng* (ISBN 0-201-63395-7, Addison-Wesley, 1996), which provides an explanation of the task force's process and explicates the services that are provided for (as, for example, ATM support). These books are both dated, but they are the best available now. Keeping up with what's going on is easy, thanks to the IETF's Web site **`http://www.ietf.org`**.

An excellent business and technical case for IPv6 is found in the Internet Architecture Board draft by Steve King and several colleagues (**`draft-iab-case-for-ipv6-05.txt`**). Other works in progress deal with the adjustments to Open Shortest Path First (OSPF), multicasting, mobility, and so on.

Transition

The period from 1981 through 1983—the time of conversion to DNS—was painful to all concerned. Over the past 15 years we have learned a lot, but the switch from IPv4 to IPv6 may be yet more painful. The drafts tell the tale of those who are striving to make things easier.

There has been much discussion about various kinds of transition mechanisms, and some of these may be less painful (more automated) than we might at first think. Remember, this pain is not because of the innate difficulty, but veering a ship that carries fewer than 250 passengers is far easier than veering a ship that carries 60 million. Some members of the community think that the pain may not justify the gain. The author is not one of them. It has been nearly 20 years since TCP/IP was made official, yet there are still UUCP networks.

In the author's opinion, IPv6 will be here in a few years, if not sooner.

Book Review

An Engineering Approach to Computer Networking

An Engineering Approach to Computer Networking: ATM Networks, the Internet and the Telephone Network, Srinivasan Keshav, ISBN 0-201-63442-2, Addison-Wesley, 1997, **http://www.awl.com/cseng/titles/0-201-63442-2/**

The rapid convergence of telephone and data networks brings with it a collision of two diverse approaches to fundamental network design. This "New World," as it is often called, requires us to understand both the analog-to-digital evolution of the voice network, with its redundant search for faultless reliability, and the persistent tolerance of the data network. Mirroring the industry trend, this book explores the three major networking technologies: ATM, the Internet, and telephone networks, with the idea that the design of any modern network requires consideration of the influence of at least two of the three technologies.

This book is a textbook. Keshav himself declares in the preface that "textbooks, almost by definition, tend to be boring," and the reader will recall this subtle warning shortly into Chapter 2. This is definitely a book for those who have at least an intermediate knowledge of data networking and a need to understand the component parts of network implementations. Keshav takes a true engineering approach, in that he attempts to teach the building blocks of the major networking technologies—and this approach is what makes the book one of my all-time favorites. By examining the component parts and why they are required, Keshav leaves you prepared to engineer a network that meets any number of diverse criteria.

Organization

The book is organized into three sections. Section 1 gives an introduction to the future of data and voice networks and then introduces three of the major networking technologies. This section also gives an overview of the historic construction of networks, along with some fundamental definitions of some of the engineering principles by which networks function. As early as Chapter 1, Keshav explores the engineering philosophy behind common network technologies, illustrating the theories that underlie their design. My favorite example is his suggestion that the telephone network was engineered to be intelligent because its endpoints, the telephones, are simply dumb. While this sounds obvious, it provides a fundamental perspective on the design of the system that proves invaluable to understanding the origin of the various "components" of the network.

Section 2 begins with a short but requisite review of protocol layering and, after a brief discussion of common design constraints, begins to dissect the major components required of almost any network implementation. Chapter 8 is a fairly comprehensive review of switching and, as the book's title suggests, the chapter is full of comparative anatomy. Read this chapter for its valuable insight into why various switching mechanisms have emerged and for its comparison of how various switching functions are handled on three major networking technologies. Chapter 9 deals with scheduling network resources, with an excellent comparison of the variety of scheduling mechanisms and their effect on connections and packets. It covers policy considerations that are also required of scheduling disciplines, giving the reader a set of strategies for network design. Chapter 11 covers routing of packets as well as routing in the telephone network. In my opinion, this discussion alone makes this book a required part of any networking professional's library. Admittedly, there are books that better explain routing in both of these environments, but because of the proximity of the topics, this presentation helps the reader to understand the mechanics of both systems in a way that provides insight into the inherent issues posed by both technologies.

Section 3 pulls together the various component functions discussed in Section 2 and explains some of their implementation in the form of protocols. Section 3 is a short section, probably not intended as a thorough survey of networking protocols. Keshav documents an excellent set of references for Section 3, however, and leaves it up to the reader to pursue those that are relevant to his or her professional development.

Required Reading

An Engineering Approach to Computer Networking is definitely an A+ book, and should be required reading for anyone interested in the inner workings of data and voice networks. Although the author expects the reader to absorb quite a bit in every chapter, the time spent is well invested. The book is a refreshing alternative in that it provides an answer to the question of "why" the network works rather than being another treatise on "how" the network works.

—Jim LeValley, Cisco Press
levalley@cisco.com

Would You Like to Review a Book for IPJ?

We receive numerous books on computer networking from all the major publishers. If you've got a specific book you are interested in reviewing, please contact us and we will make sure a copy is mailed to you. The book is yours to keep if you send us a review. We accept reviews of new titles, as well as some of the "networking classics." Contact us at **ipj@cisco.com** for more information.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

Fragments

Internet Policy Institute Launched

On November 9th, 1999 a group of distinguished Internet visionaries and scholars announced the creation of the *Internet Policy Institute,* the nation's first independent, nonpartisan think tank devoted exclusively to providing research and hard data on the Internet and society. The group also announced its first research project and an initiative aimed at educating the presidential contenders.

The creation of the new think tank was announced by Jim Barksdale, former CEO of Netscape, Vint Cerf, Senior Vice President of Internet Architecture of MCI WorldCom, Esther Dyson, author and Chairman of EDventure Holdings, Inc., Mario Morino, Chairman of The Morino Institute, and Kimberly Jenkins, President of the Internet Policy Institute.

The new, nonprofit think tank will employ well-known experts and scholars to research subjects ranging from the role of the Internet in privacy to the Internet's impact on taxation and health care.

"The Internet is surrounded by noise, hype, rumors, marketing, IPOs and the hopes of starry-eyed start-ups, but there is very little hard data on which policymakers can base critical decisions that will determine the future of the new medium and how it affects society," said Barksdale, co-chairman of the Internet Policy Institute's Board of Directors. Wayne Clough, President of Georgia Tech, is his co-chairman.

"The speed at which society has adopted the Internet is unprecedented," said Cerf, who was Chairman and founding president of the Internet Society, as well as one of the designers of the TCP/IP protocol. "If, as we expect, half the world will be online within the next four years, we must make sure that the policy decisions we make now are based on solid, well-researched data."

The Institute announced its first research project, to be undertaken in collaboration with The Brookings Institution, on "The Economic Payoff from the Internet Revolution." The research will be led by Alice Rivlin, former vice chair of the Federal Reserve System's Board of Directors and former Office of Management and Budget director, now with the Brookings Institution, and Robert E. Litan, Vice President and Director of Economic Studies at The Brookings Institution and former associate director of the Office of Management and Budget. The research will produce the first comprehensive, systematic economic study by an independent research group of the subject.

The nature and extent of the impact is of special importance to macroeconomic policy—specifically monetary policy—to the extent that the Net is having or will have a material and sustained impact on the growth rate of productivity. The impact the Net has on specific industries, and the way it affects barriers to entry, has important implications for antitrust and regulatory policy.

Exactly one year before the next presidential election, the Internet Policy Institute also announced its first publications project, "Briefing the President: What the Next President of the United States Needs to Know About the Internet and Its Transformative Impact on Society." The Institute also released the introduction to the project by Barksdale, while Cerf outlined the contents of the next paper, "What is the Internet (and What Makes It Work)" that will be released December 1. Over the course of the coming months, the Institute will release 13 papers to be presented in briefings to all the leading presidential contenders and later compiled into a book.

"We didn't know five years ago the direction that the Internet would take," Barksdale said. "I'll bet that five years from now, we'll be surprised by its new directions. We need to assure that an honest, objective approach is taken on Internet issues, to prevent decision making that hinders the potential of this amazing medium," he said. For more information see: **http://www.internetpolicy.org**

APRICOT 2000

The *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT) will be held in at the Intercontinental Hotel in Seoul, Korea from February 28th to March 2nd, 2000. APRICOT provides a forum for key Internet builders in the region to learn from their peers and other leaders in the Internet community from around the world. The week-long summit consists of seminars, workshops, tutorials, conference sessions, and birds-of-a-feather sessions—all with the goal of spreading and sharing the knowledge required to operate the Internet within the Asia Pacific region. For more information see:
http://www.apricot.net

More on Web Caching

If you enjoyed the article on Web Caching in our September 1999 issue, you might find the following paper of interest: "A Survey of Web Caching Schemes for the Internet," by Jia Wang. You can find this article in the October 1999 issue of ACM SIGCOMM's *Computer Communications Review* (Volume 29, Number 5). The paper is also available on line in either PostScript or PDF format:
http://www.acm.org/sigcomm/ccr/archive/1999/oct99/ccr9910-jia-wang.html

ICANN Update

On September 28, 1999, the United States Department of Commerce, Network Solutions, Inc. (NSI), and The Internet Corporation for Assigned Names and Numbers (ICANN) announced a series of agreements they had tentatively reached to resolve outstanding differences among the three parties. On November 4, 1999, based on public comment in writing and at a public forum held at the 1999 ICANN annual meeting, the ICANN Board approved revised versions of these agreements. The agreements were signed by the three parties on November 10, 1999. The full text of the agreements can be found on the ICANN Web site at **`www.icann.org`**. Here we include some highlights:

- NSI will operate the registry for the **`.com`**, **`.net`**, and **`.org`** top-level domains according to requirements stated in the agreement and developed in the future through the ICANN consensus-based process. All accredited registrars will have equal access to this registry.
- A revised registrar accreditation agreement between ICANN and registrars was adopted. To continue to register names with the **`.com`**, **`.net`**, and **`.org`** registry operated by NSI after November 30, 1999, registrars must have entered a new Registrar License and Agreement with NSI and the revised ICANN accreditation agreement.
- A revised NSI-Registrar License and Agreement was created under which competitive ICANN-accredited registrars are permitted to place and renew registrations in the registry.
- An amendment was made to Cooperative Agreement #NCR 92-18742 originally entered between NSI and the National Science Foundation (NSF) in 1992. On October 7, 1998, NSI and the United States Department of Commerce (which by then had assumed the NSF's role as lead agency of the U.S. Government) entered an Amendment 11 to that Cooperative Agreement under which NSI agreed to implement a shared registration system in which competitive registrars would enter registrations into the **`.com`**, **`.net`**, and **`.org`** registry on an equitable basis. Amendment 19 solidifies those arrangements and provides that in operating the registry NSI will abide by consensus policies adopted in the ICANN process.

At the annual meeting in early November, nine new directors joined the ICANN Board of Directors. They are Robert Blokzij, Ken Fockler and Pindar Wong named by the The Address Supporting Organization (ASO); Amadeu Abril i Abril, Jonathan Cohen and Alejandro Pisanty named by the Domain Name Supporting Organization (DNSO); Jean-François Abramatic, Vinton G. Cerf and Philip Davidson named by the Protocol Supporting Organization (PSO).

The newly expanded ICANN Board will take on a major challenge in 2000 in its consideration of contending proposals for the future of Top Level Domains. After years of vociferous argument, the DNS community is no closer than it ever has been to a consensus on whether new name registries should be created, and if so, with what structure and registration rules.

Interplanetary Internet Special Interest Group Formed

The Internet Society (ISOC) recently announced the formation of the Interplanetary Internet Special Interest Group (IPNSIG). The IPNSIG exists to allow public participation in the evolution of the Interplanetary Internet. The technical research into how the Earth's Internet may be extended into interplanetary space has been underway for several years as part of an international communications standardization body known as the Consultative Committee on Space Data Systems (CCSDS). (See **http://www.ccsds.org/**)

The CCSDS organization is primarily concerned with communications standardization for scientific satellites, with a primary focus on the needs of near-term missions. In order to extend this horizon out several decades, and to begin to involve the terrestrial internet research and engineering communities, a special Interplanetary Internet Study was proposed and subsequently funded in the United States.

The Interplanetary Internet Study is funded by the Defense Advanced Research Projects Agency's Next Generation Internet Initiative, and presently consists of a core team of researchers from the NASA Jet Propulsion Laboratory, MITRE Corporation, SPARTA, Global Science & Technology and consulting researchers from The University of Southern California Information Sciences Institute, University of California Los Angeles and the California Institute of Technology. The primary goal of the study is to investigate how terrestrial internet protocols and techniques may be extended and/or used as-is in the exploration of deep space. The study team has also founded the IPNSIG and has formed the core of an Interplanetary Internet Research Group under the sponsorship of the Internet Research Task Force (IRTF).

The NASA IPN Study Team will act as liaison between the satellite and space communities and the ISOC/IRTF communities. The NASA IPN Study Team will assist with requirements and understanding of the deep space environment and missions, while the primary research on new or modified protocols will be conducted by the IRTF. In addition, the NASA Study Team will also act as liaison with the CCSDS.

The NASA Study Team will also enable simulated and actual opportunities to test protocols and the use of internet techniques in the space environment. For more information, visit: **ipn.jpl.nasa.gov/**

From The Editor

Work on a new version of the Internet Protocol, known as IPv6, has been under way for several years in the IETF. There is still some debate about when and how IPv6 will be deployed. Proponents of IPv6 argue that the demand for new IP addresses will continue to rise to a point where we will simply run out of available IPv4 addresses and that we should, therefore, start deploying IPv6 *today*. Opponents argue that such a protocol transition will be too costly and painful for most organizations. They also argue that careful address management and the use of *Network Address Translation* (NAT) will allow continued use of the IPv4 address space for a very long time. Regardless of the timeframe, a major factor in the deployment of IPv6 is an appropriate transition strategy that allows existing IPv4 systems to communicate with new IPv6 systems. A transition mechanism, known as "6to4," is described in our first article by Brian Carpenter, Keith Moore, and Bob Fink.

In previous editions of this journal, we have looked at various security technologies for use in the Internet. Security mechanisms have been added at every layer of the protocol stack, and IP itself is no exception. IP Security, commonly known as "IPSec," is being deployed in many public and private networks. In our second article, William Stallings describes the main features of IPSec and looks at how IPSec can be used to build Virtual Private Networks.

Our final article is a critical look at *Quality of Service* (QoS) in the Internet. The need to provide different priorities to different kinds of traffic in a network is well understood and the technical community has been hard at work developing numerous systems to address this need. Geoff Huston looks at the prospects of deploying QoS solutions that will operate across the Internet as a whole.

The Y2K transition has been described as a "nonevent" by many. However, the lessons learned and the collaborative coordination efforts that were put in place for this transition can hopefully be used in the future. A colleague of mine had to call a plumber to his house on New Year's Eve. When he tried to pay for the repair with a credit card which had "00" as the expiration year, the plumber insisted that this meant the card was invalid. So while most systems were "Y2K compliant," this particular plumber was clearly not. Do you have a Y2K story to share? Drop us a line at **ipj@cisco.com**

Connecting IPv6 Routing Domains Over the IPv4 Internet

by Brian E. Carpenter, IBM & iCAIR
Keith Moore, University of Tennessee
Bob Fink, Energy Sciences Network

A next-generation Internet Protocol[1], known first as IPng and then as IPv6, has been under development by the *Internet Engineering Task Force* (IETF) for several years to replace the current Internet Protocol known as IPv4. The reasons behind the need for IPv6 are not covered here, but interested readers are encouraged to read "The Case for IPv6"[2] for this background.

Of major importance during the development of IPv6 has been how to do the transition away from IPv4, and towards IPv6. The work on transition strategies, tools, and mechanisms has been part of the basic IPv6 design effort from the beginning. The current transition efforts, taking place at the *IETF IPng Transition Working Group* (ngtrans)[3], will continue until it is clear that the transition will be successful.

These transition design efforts resulted in a basic Transition Mechanisms specification for IPv6 hosts and routers[4] that specifies the use of a Dual IP layer providing complete support for both IPv4 and IPv6 in hosts and routers, and IPv6-over-IPv4 *tunneling*, encapsulating IPv6 packets within IPv4 headers to carry them over IPv4 routing infrastructures.

These concepts are heavily relied on for transition from the traditional IPv4-based Internet as we know it today, to an IPv6-based Internet. It is expected that IPv4 and IPv6 will coexist for many years during this transition.

Of great concern to transition strategy planners is how to provide connectivity between IPv6-enabled end-user sites (also known as *routing domains*) when they do not yet have a reasonable (or any) choice of *Internet Service Provider* (ISP) that provides native IPv6 transport services. One way to provide IPv6 connectivity between end-user sites (when native IPv6 service does not exist) is to use IPv6-over-IPv4 encapsulation (tunneling) between them, similar to the technique currently used in the 6bone[5] IPv6 testbed network. This requires complexity for both end-user sites, and the networks providing the tunneling service (for instance, the 6bone backbone ISPs), in creating, managing, and operating manually configured tunnels.

The "6to4" transition mechanism, "Connection of IPv6 Domains via IPv4 Clouds without Explicit Tunnels"[6], provides a solution to the complexity problem of using manually configured tunnels by specifying a unique routing prefix for each end-user site that carries an IPv4 tunnel endpoint address.

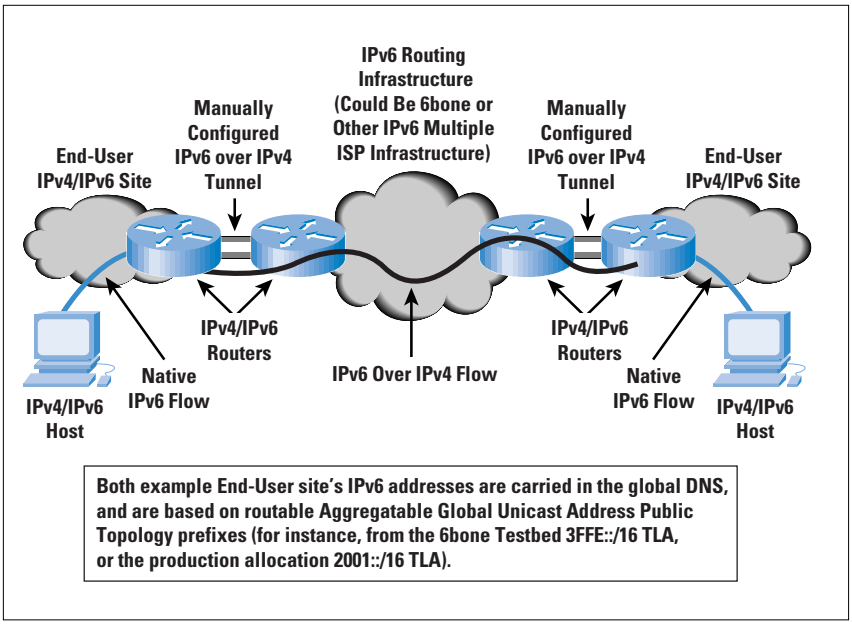
It should also be noted that each end-user site with as little as a single IPv4 address has a unique, routable, IPv6 site routing prefix thanks to the 6to4 transition mechanism.

Connecting IPv6 Routing Domains

When end-user site networks enable IPv6 in their local host and router systems, but have no native IPv6 Internet service, connectivity to other IPv6 routing domains across a worldwide Internet must be accomplished another way, or the value of a connected Internet is lost. Prior to the 6to4 transition mechanism, a site's network staff would have to rely on the manual configuration of IPv6-over-IPv4 tunnels to accomplish this connectivity.

This connectivity could be accomplished by arranging tunnels directly with each IPv6 site to which connectivity is needed, but more typically is done by arranging a tunnel into a larger IPv6 routing infrastructure that could guarantee connectivity to all IPv6 end-user site networks. (See Figure 1.) The 6bone IPv6 testbed was the first IPv6 routing infrastructure to provide worldwide IPv6 connectivity (starting in 1996), while more recently (late 1999) networks providing production IPv6 Internet service have also interconnected to provide this connectivity. In fact, the 6bone and production IPv6 routing infrastructures are well interconnected to guarantee worldwide IPv6 connectivity.

Figure 1: Configured Tunnel Overview



However, even given a solid, reliable, worldwide IPv6 routing infrastructure (similar to the IPv4-based Internet today), if an end-user site does not have a reasonable (or any) local choice for native IPv6 Internet service, a tunnel must be used.

The 6to4 mechanism addresses many of the practical difficulties with manually configured tunneling:

- The end-user site network staff must choose an IPv6 Internet service to tunnel to. This entails a process of at least three parts:
  - Finding candidate networks when the site's choice of IPv4 service does not provide IPv6 service (either tunneling or native),
  - Determining which ones are the best IPv4 path to use so that an IPv6-over-IPv4 tunnel doesn't inadvertently follow a very unreliable or low-performance path,
  - Making arrangements with the desired IPv6 service provider for tunneling service, a scenario that may at times be difficult if the selected provider is not willing to provide the service, or if for other administrative/cost reasons it is difficult to establish a business relationship.

Clearly it is easiest to use the site's own service provider, but in the early days of IPv6 transition this will often not be an option.

- An IPv6-over-IPv4 tunnel must be built to the selected provider, and a peering relationship must be established with the selected provider. This requires establishing a technical relationship with the provider and working through the various low-level details of how to configure tunnels between two routers, including answering the following questions:
  - Are the site and provider routers compatible early on in this process?
  - What peering protocol will be used (presumably an IPv6-capable version of the *Border Gateway Protocol Version 4* [BGP4]), and are the versions compatible and well debugged?
  - Have all the technical tunnel configuration issues between the site and provider been addressed?

Again, it is clearly easiest to perform all these steps if they are taken with the site's own IPv4 service provider.

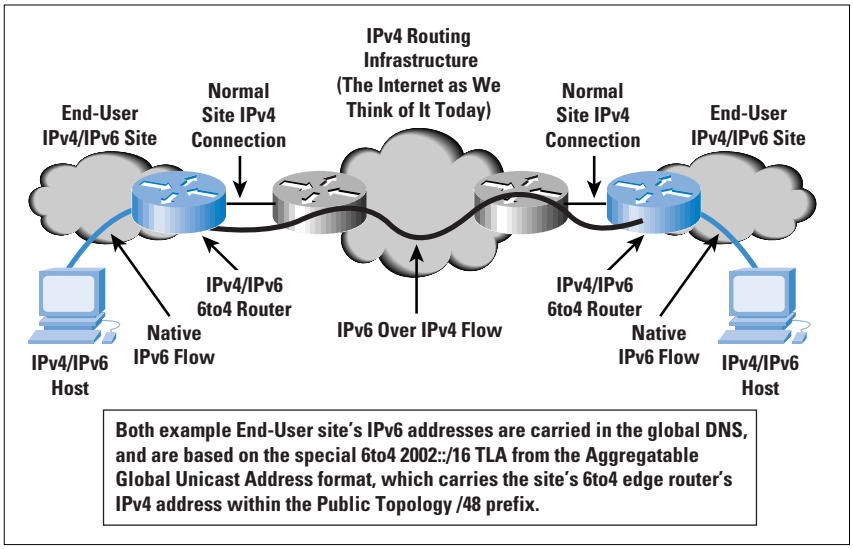


Figure 2: 6to4 Tunnel Overview

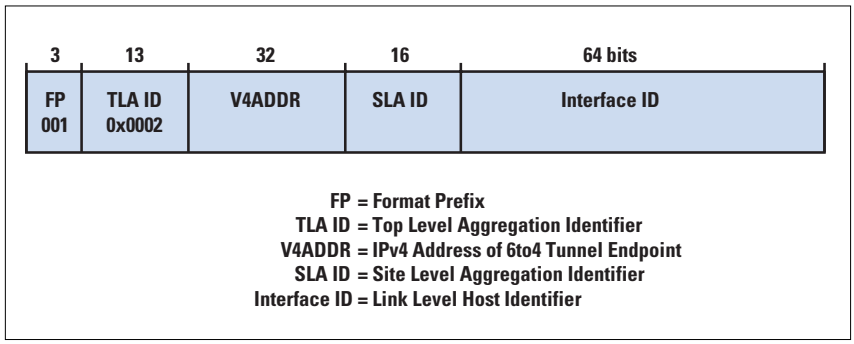
6to4 Eliminates Complex Tunnel Management

The 6to4 transition mechanism provides a solution to the complexity problem of building manually configured tunnels to an ISP by advertising a site's IPv4 tunnel endpoint (to be used for a dynamic tunnel) in a special external routing prefix for that site. Thus one site trying to reach another will discover the 6to4 tunnel endpoint from a *Domain Name System* (DNS) name to address lookup and use a dynamically built tunnel from site to site for the communication. (See Figure 2.) The tunnels are transient in that there is no state maintained for them, lasting only as long as a specific transaction uses the path. A 6to4 tunnel also bypasses the need to establish a tunnel to a wide-area IPv6 routing infrastructure, such as the 6bone.

The specification of a 48-bit external routing prefix in the IPv6 *Aggregatable Global Unicast Address Format* (AGGR)[7] (see Figure 3) that provides just enough space to hold the 32 bits required for the 32-bit IPv4 tunnel endpoint address (called V4ADDR in Figure 3) makes this setup possible.

Thus, this prefix has exactly the same format as normal prefixes assigned according to the AGGR. Within the subscriber site it can be used exactly like any other valid IPv6 prefix, for instance, for automated address assignment and discovery according to the normal IPv6 mechanisms for this.

Figure 3: 6to4 Prefix Format



The Simplest Use of 6to4

The simplest scenario for 6to4 is when several sites start to use IPv6 alongside IPv4, and have no native IPv6 ISP service available. Thus each site identifies a router to run dual stack (that is, IPv4 and IPv6 together) and 6to4 tunneling, ensuring that this router has a globally routable IPv4 address (that is, not in private IPv4 address space).

It is assumed that this new 6to4 router is reachable by IPv6-capable hosts within the site. Although the various ways in which these hosts may be reached are not discussed in detail here, they include using IPv6-enabled site IPv4 routers, operating special IPv6-only routers in parallel with site IPv4 routers, using the "6over4" mechanism[8], and employing other tunneling methods.

A new 6to4 site advertises the 6to4 prefix to its site via the *Neighbor Discovery* (ND) protocol[9], which will cause IPv6 hosts at this site to have their DNS name/address entries to include the 6to4 prefix for the site in them.

In operation, when one IPv6-enabled host at a 6to4 site tries to access an IPv6-enabled host by domain name at another 6to4 site, the DNS will return both an IPv4 and an IPv6 IP address for that host, indicating that it is reachable by both IPv4 and IPv6. The requesting host selects the IPv6 address, which will have a 6to4 prefix, and sends a packet off to its nearest router, eventually reaching its site boundary router, which we assume has 6to4 service as well.

Sending and Receiving Rules for 6to4 Routers

When the requesting site's 6to4 router sees that it must send a packet to another site (that is, there is a nonlocal destination), and that the next hop destination prefix contains the special 6to4 *Top Level Aggregation* (TLA) value of 2002::/16, the IPv6 packet is encapsulated in an IPv4 packet using an IPv4 protocol type of 41, as defined in the *Transition Mechanisms* RFC[4]. The source IPv4 address will be the one in the requesting site's 6to4 prefix (which is the IPv4 address of the outgoing interface to the Internet on the 6to4 router, and contained in the source 6to4 prefix of the IPv6 packet), and the destination IPv4 address will be the one in the next hop destination 6to4 prefix of the IPv6 packet.

When the destination site's 6to4 router receives the IPv4 packet, and recognizes that it has an IPv4 protocol type of 41, IPv4 security checks are made and the IPv4 header is removed, leaving the original IPv6 packet for local forwarding.

The sending rule above is the only modification to IPv6 forwarding, because the receiving rule was already specified for the basic IPv6 Transition Mechanism mentioned earlier[4]. Along with advertisement of the 6to4 prefix by appropriate entries in the DNS, any number of sites can interoperate without manual tunnel configuration.

It is not necessary to operate an exterior routing protocol (for instance, BGP4+) for 6to4 simple scenarios because the IPv4 exterior routing protocol is handling this function. Also, no new entries in IPv4 routing tables result from the use of 6to4.

The Return Path and Source Address Selection

Packets must flow in both directions to be useful; thus it is essential that IPv6 packets sent use a packet with a 6to4 prefix as a source address when talking to a site with a 6to4 prefix; in other words, the destination must have a 6to4 prefix. In the simple example given above, this is not an issue because both sites have only IPv4 connectivity, so they have 6to4 prefixes for their site to communicate with. DNS lookups for host systems at these sites will return only one IPv6 address, which will be the one with a 6to4 prefix. Source address selection is thus not an issue.

As we will soon see, source address selection is an issue for more complex 6to4 usage scenarios; therefore, some source address selection algorithm is necessary in IPv6 hosts. The exact form and method of the algorithm to use is under active study at the IETF IPv6 (ipng) working group[10], and an algorithm is likely to be chosen in early 2000. Meanwhile, for the purposes of understanding 6to4, it is sufficient to realize that when a 6to4 connected sending site is sending to a destination site using that site's 6to4 prefix, the sending host must guarantee that the source IPv6 address uses the sending site's 6to4 prefix.

More Complex 6to4 Usage Scenarios

Several more interesting 6to4 usage scenarios exist when a site has both 6to4 connectivity and native IPv6 connectivity. The simplest of these is when such a site is trying to reach another site that has only 6to4 connectivity, in which case the source address selection algorithm mentioned above is essential to ensure that the site's 6to4 IPv6 address is chosen. No destination selection is required because there is only one choice, that is, 6to4.

Similarly, when a site that has only 6to4 connectivity tries to reach a site with both 6to4 and native IPv6 connectivity, some host rule for choosing among multiple destination addresses must result in the 6to4 address being chosen, because only a local 6to4 IPv6 source address is available. Of course source selection is not an issue in this case because there is only the 6to4 IPv6 address to use.

Another variation of these scenarios is when a site with 6to4 and native IPv6 connectivity is trying to reach another site that has only native IPv6 connectivity, making a source address selection algorithm essential to make sure the site's native IPv6 address is chosen. No destination selection is required, because there is only one choice, that is, the native IPv6 address.

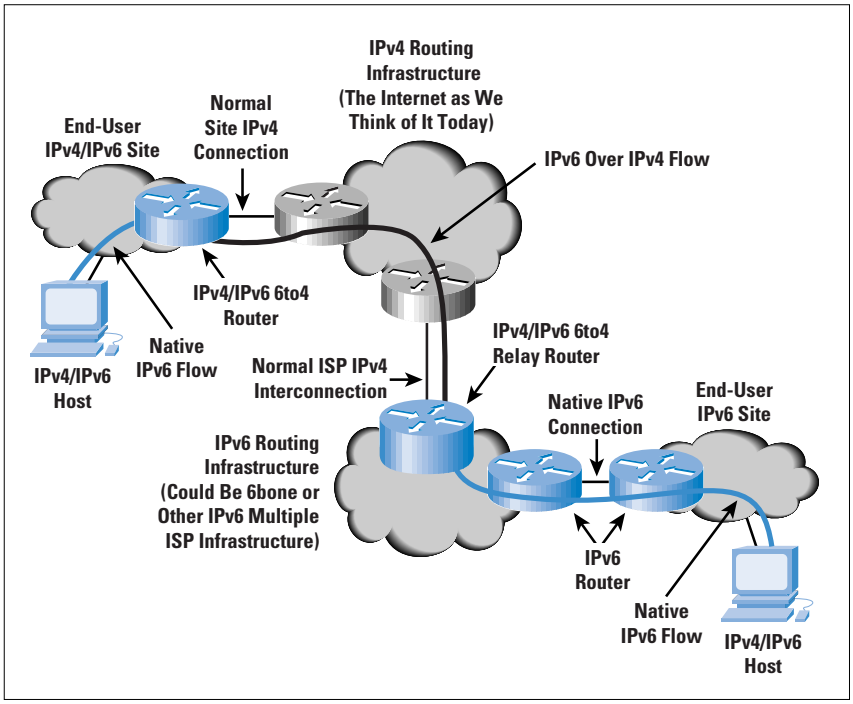
Similarly, when a site that has only native IPv6 connectivity tries to reach a site with 6to4 and native IPv6 connectivity, a host rule is essential for choosing among multiple addresses to ensure that a native IPv6 address is chosen, because only a local native IPv6 source address is available. Again, source selection is not an issue in this case because only the native IPv6 address can be used.

An interesting choice develops in the situation when both sites have 6to4 and native IPv6 connectivity as both 6to4-to-6to4 and native IPv6-to-native-IPv6 connections are a possibility. Current thinking as of the writing of this article is to prefer the native IPv6 connection.

The 6to4 Relay

The most interesting, and most complex, 6to4 scenario is that of sites with only 6to4 connectivity communicating with sites with only native IPv6 connectivity. This is accomplished by the use of a 6to4 relay that supports both 6to4 and native IPv6 connectivity (Figure 4). The 6to4 relay is nothing more than an IPv4/IPv6 dual-stack router.

Figure 4: The 6to4 Relay



The 6to4 relay advertises a route to 2002::/16 for itself into the native IPv6 infrastructure it is attached to. The native IPv6 network operators must filter out and discard any 6to4 (2002:...) prefix advertisements longer than /16. In addition, the 6to4 relay may advertise into its 6to4 connection whatever native IPv6 routes its policies allow, which the 6to4 router at the 6to4-only site picks up with either a BGP4+ peering session, or with a default route, to the 6to4 relay.

Thus the 6to4-only site will try to send a packet to the native IPv6-only site by forwarding an encapsulated (tunneled) IPv6 packet to the 6to4 relay, which removes the IPv4 header (decapsulates) and forwards the packet on to the IPv6-only site.

Potentially, multiple 6to4 relays are needed, one for each separate IPv6 routing realm (collection of IPv6 routing ISPs). In practice, it is expected that all native IPv6 ISP services will be interconnected even if the use of inter-IPv6-ISP manually configured tunnels are required to do so. This is currently the case as of early 2000, because all 6bone 3FFE::/16 TLA networks and all production 2001::/16 subTLA networks are interconnected with each other.

It is expected that native IPv6 service providers will choose to operate 6to4 relays as a simple extension of their service. There are no special rules or exceptions to 6to4 as described here for this to happen because the 6to4 relay is simply operated as part of an end-user site that belongs to the IPv6 ISP.

Other Issues

Several other 6to4 issues are presented below for completeness.

- The IPv6 *Maximum Transmission Unit* (MTU) size could prove too large for some intermediate IPv4 link when a 6to4 tunnel is in use, thus IPv4 fragmentation will occur. Though undesirable, fragmentation is not disastrous, so the IPv4 "Do Not Fragment" bit should not be set in the IPv4 packet carrying the 6to4 tunnel.
- How sites move IPv6 packets internal to a site is not important to the 6to4 process. For illustrative purposes in this article, it is generally assumed that native IPv6 transmission exists within a site. This may not be strictly true because "6over4," manual tunnels, and other methods of moving IPv6 packets could be in use. Nonetheless, it is not important to the 6to4 processes described here.
- Security issues with the 6to4 mechanism are not discussed here. The reader is referred to the current 6to4 draft for an explanation of these issues[6].
- 6to4 sites with IPv6 connectivity must not inject their 6to4 prefix into the IPv6 routing infrastructure via the native IPv6 connection.
- It is not possible to assume the general availability of wide-area IPv4 multicast, so the 6to4 mechanism must assume only unicast capability in its underlying IPv4 carrier network. However, it is expected that IPv6 multicast packets may be sent to, or sourced from, a 6to4 router in the IPv4 encapsulated form, as described above. When IPv6 multicast is supported, an IPv6 multicast routing protocol must be used.
- The use of IPv6 Anycast is compatible with 6to4 prefixes.
- 6to4 for hosts only, as opposed to sites, is possible and will likely be developed in the future. However, details of this feature are not discussed in this article.
- The 6to4 mechanism is unaffected by the presence of a firewall at the border router.
- When using IPv4 *Network Address Translation* (NAT), 6to4 mechanisms remain valid, and the NAT device includes a fully functional IPv6 router with the 6to4 mechanism included. Combining 6to4 and NAT in this way offers the advantages of NAT for IPv4 use, and the additional address space of IPv6.
- There is no significant impact to either IPv4 or IPv6 routing table size caused by the proper implementation of 6to4.

Summarizing 6to4

The 6to4 mechanism allows isolated IPv6 routing domains to communicate with other IPv6 routing domains, even in the total absence of native IPv6 service providers. It is a powerful IPv6 transition tool that will allow both traditional IPv4-based Internet end-user sites and new IPv6-only Internet sites to utilize IPv6 and operate successfully over the existing IPv4-based Internet routing infrastructure.

IP Security

by William Stallings

In 1994, the *Internet Architecture Board* (IAB) issued a report entitled "Security in the Internet Architecture" (RFC 1636). The report stated the general consensus that the Internet needs more and better security, and it identified key areas for security mechanisms. Among these were the need to secure the network infrastructure from unauthorized monitoring and control of network traffic and the need to secure end-user-to-end-user traffic using authentication and encryption mechanisms.

These concerns are fully justified. As confirmation, the 1998 annual report from the *Computer Emergency Response Team* (CERT) lists over 1,300 reported security incidents affecting nearly 20,000 sites. The most serious types of attacks included IP spoofing, in which intruders create packets with false IP addresses and exploit applications that use authentication based on IP address; and various forms of eavesdropping and packet sniffing, in which attackers read transmitted information, including logon information and database contents.

In response to these issues, the IAB included authentication and encryption as necessary security features in the next-generation IP, which has been issued as IPv6. Fortunately, these security capabilities were designed to be usable both with the current IP (IPv4) and IPv6, meaning that vendors can begin offering these features now, and many vendors do now have some *IP Security Protocol* (IPSec) capability in their products.

Applications of IPSec

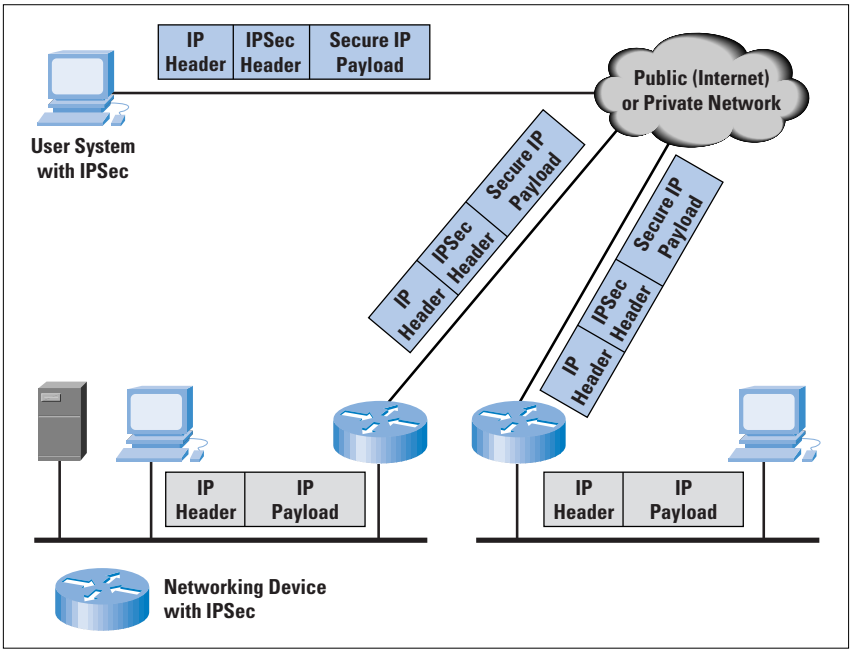
The Internet community has developed application-specific security mechanisms in numerous application areas, including electronic mail (*Privacy Enhanced Mail*, *Pretty Good Privacy* [PGP]), network management (*Simple Network Management Protocol Version 3* [SNMPv3]), Web access (Secure HTTP, *Secure Sockets Layer* [SSL]), and others. However, users have some security concerns that cut across protocol layers. For example, an enterprise can run a secure, private TCP/IP network by disallowing links to untrusted sites, encrypting packets that leave the premises, and authenticating packets that enter the premises. By implementing security at the IP level, an organization can ensure secure networking not only for applications that have security mechanisms but also for the many security-ignorant applications.

IPSec provides the capability to secure communications across a LAN, across private and public WANs, and across the Internet. Examples of its use include:

- Secure branch office connectivity over the Internet: A company can build a secure virtual private network over the Internet or over a public WAN. This enables a business to rely heavily on the Internet and reduce its need for private networks, saving costs and network management overhead.
- Secure remote access over the Internet: An end user whose system is equipped with IP security protocols can make a local call to an *Internet Service Provider* (ISP) and gain secure access to a company network. This reduces the cost of toll charges for traveling employees and telecommuters.
- Establishment of extranet and intranet connectivity with partners: IPSec can be used to secure communication with other organizations, ensuring authentication and confidentiality and providing a key exchange mechanism.
- Enhancement of electronic commerce security: Most efforts to date to secure electronic commerce on the Internet have relied upon securing Web traffic with SSL since that is commonly found in Web browsers and is easy to set up and run. There are new proposals that may utilize IPSec for electronic commerce.

The principal feature of IPSec that enables it to support these varied applications is that it can encrypt or authenticate *all* traffic at the IP level. Thus, all distributed applications, including remote logon, client/server, e-mail, file transfer, Web access, and so on, can be secured. Figure 1 shows a typical scenario of IPSec usage. An organization maintains LANs at dispersed locations. Traffic on each LAN does not need any special protection, but the devices on the LAN can be protected from the untrusted network with firewalls. Since we live in a distributed and mobile world, the people who need to access the services on each of the LANs may be at sites across the Internet. These people can use IPSec protocols to protect their access. These protocols can operate in networking devices, such as a router or firewall that connects each LAN to the outside world, or they may operate directly on the workstation or server. In the diagram, the user workstation can establish an IPSec tunnel with the network devices to protect all the subsequent sessions. After this tunnel is established, the workstation can have many different sessions with the devices behind these IPSec gateways. The packets going across the Internet will be protected by IPSec but will be delivered onto each LAN as a normal IP packet.

Figure 1: An IP Security Scenario



Benefits of IPSec

The benefits of IPSec include:

- When IPSec is implemented in a firewall or router, it provides strong security that can be applied to all traffic crossing the perimeter. Traffic within a company or workgroup does not incur the overhead of security-related processing.
- IPSec is below the transport layer (TCP, UDP), so is transparent to applications. There is no need to change software on a user or server system when IPSec is implemented in the firewall or router. Even if IPSec is implemented in end systems, upper layer software, including applications, is not affected.
- IPSec can be transparent to end users. There is no need to train users on security mechanisms, issue keying material on a per-user basis, or revoke keying material when users leave the organization.
- IPSec can provide security for individual users if needed. This feature is useful for offsite workers and also for setting up a secure virtual subnetwork within an organization for sensitive applications.

Is IPSec the Right Choice?

There are already numerous products that implement IPSec, but it is not necessarily the security solution of choice for a network administrator. Christian Huitema, who at the time of the development of the initial IPSec documents was the head of the IAB, reports that the debates over how to provide Internet-based security were among the most heated that he ever observed. One issue concerns whether security is being provided at the right protocol layer. To provide security at the IP level, it is necessary for IPSec to be a part of the network code deployed on all participating platforms, including Windows NT, UNIX, and Macintosh systems. Unless a desired feature is available on all the deployed platforms, a given application may not be able to use that feature.

On the other hand, if the application, such as a Web browser/server combination, incorporates the function, the developer can guarantee that the features are available on all platforms for which the application is available. A related point is that many Internet applications are now being released with embedded security features. For example, Netscape and Internet Explorer support SSL, which protects Web traffic. Also, many vendors are planning to support *Secure Electronic Transaction* (SET), which protects credit-card transactions over the Internet. However, for a virtual private network, a network-level facility is needed, and this is what IPSec provides.

The Scope of IPSec

IPSec provides three main facilities: an authentication-only function, referred to as *Authentication Header* (AH), a combined authentication/encryption function called *Encapsulating Security Payload* (ESP), and a key exchange function. For virtual private networks, both authentication and encryption are generally desired, because it is important both to (1) assure that unauthorized users do not penetrate the virtual private network and (2) assure that eavesdroppers on the Internet cannot read messages sent over the virtual private network. Because both features are generally desirable, most implementations are likely to use ESP rather than AH. The key exchange function allows for manual exchange of keys as well as an automated scheme.

The IPSec specification is quite complex and covers numerous documents. The most important of these, issued in November 1998, are RFCs 2401, 2402, 2406, and 2408.

Security Associations

A key concept that appears in both the authentication and confidentiality mechanisms for IP is the *Security Association* (SA). An association is a one-way relationship between a sender and a receiver that affords security services to the traffic carried on it. If a peer relationship is needed, for two-way secure exchange, then two security associations are required. Security services are afforded to an SA for the use of AH or ESP, but not both. A security association is uniquely identified by three parameters:

- *Security Parameters Index* (SPI): The SPI assigns a bit string to this SA that has local significance only. The SPI is carried in AH and ESP headers to enable the receiving system to select the SA under which a received packet will be processed.
- *IP destination address:* Currently, only unicast addresses are allowed; this is the address of the destination endpoint of the SA, which may be an end-user system or a network system such as a firewall or router.
- *Security protocol identifier:* This indicates whether the association is an AH or ESP security association.

Hence, in any IP packet, the security association is uniquely identified by the destination address in the IPv4 or IPv6 header and the SPI in the enclosed extension header (AH or ESP).

An IPSec implementation includes a security association database that defines the parameters associated with each SA. A security association is defined by the following parameters:

- *Sequence number counter:* A 32-bit value used to generate the sequence number field in AH or ESP headers
- *Sequence counter overflow:* A flag indicating whether overflow of the sequence number counter should generate an auditable event and prevent further transmission of packets on this SA
- *Anti-replay window:* Used to determine whether an inbound AH or ESP packet is a replay, by defining a sliding window within which the sequence number must fall
- *AH information:* Authentication algorithm, keys, key lifetimes, and related parameters being used with AH
- *ESP information:* Encryption and authentication algorithm, keys, initialization values, key lifetimes, and related parameters being used with ESP
- *Lifetime of this security association:* A time interval or byte count after which an SA must be replaced with a new SA (and new SPI) or terminated, plus an indication of which of these actions should occur
- *IPSec protocol mode:* Tunnel, transport, or wildcard (required for all implementations); these modes are discussed later
- *Path MTU:* Any observed path maximum transmission unit (maximum size of a packet that can be transmitted without fragmentation) and aging variables (required for all implementations)

The key management mechanism that is used to distribute keys is coupled to the authentication and privacy mechanisms only by way of the security parameters index. Hence, authentication and privacy have been specified independent of any specific key management mechanism.

SA Selectors

IPSec provides the user with considerable flexibility in the way in which IPSec services are applied to IP traffic. IPSec provides a high degree of granularity in discriminating between traffic that is afforded IPSec protection and traffic that is allowed to bypass IPSec, in the former case relating IP traffic to specific SAs.

The means by which IP traffic is related to specific SAs (or no SA in the case of traffic allowed to bypass IPSec) is the nominal *Security Policy Database* (SPD). In its simplest form, an SPD contains entries, each of which defines a subset of IP traffic and points to an SA for that traffic. In more complex environments, there may be multiple entries that potentially relate to a single SA or multiple SAs associated with a single SPD entry.

Each SPD entry is defined by a set of IP and upper-layer protocol field values, called *selectors*. In effect, these selectors are used to filter outgoing traffic in order to map it into a particular SA. Outbound processing obeys the following general sequence for each IP packet:

- Compare the values of the appropriate fields in the packet (the selector fields) against the SPD to find a matching SPD entry, which will point to zero or more SAs.
- Determine the SA (if any) for this packet and its associated SPI.
- Do the required IPSec processing (that is, AH or ESP processing).

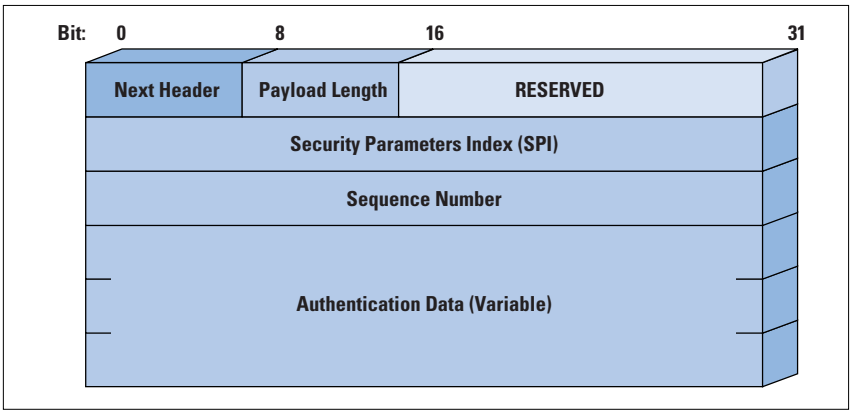
The following selectors determine an SPD entry:

- *Destination IP address:* This may be a single IP address, an enumerated list or range of addresses, or a wildcard (mask) address. The latter two are required to support more than one destination system sharing the same SA (for instance, behind a firewall).
- *Source IP address:* This may be a single IP address, an enumerated list or range of addresses, or a wildcard (mask) address. The latter two are required to support more than one source system sharing the same SA (for instance, behind a firewall).
- *UserID:* UserID is used to identify a policy tied to a valid user or system name.
- *Data sensitivity level:* The data sensitivity level is used for systems providing information flow security (for instance, "Secret" or "Unclassified").
- *Transport Layer protocol:* This value is obtained from the IPv4 protocol or IPv6 *Next Header* field. This may be an individual protocol number, a list of protocol numbers, or a range of protocol numbers.
- *IPSec protoco*l (AH or ESP or AH/ESP): If present, this is obtained from the IPv4 Protocol or IPv6 Next Header field.
- *Source and destination ports:* These may be individual TCP or *User Datagram Protocol* (UDP) port values, an enumerated list of ports, or a wildcard port.
- *IPv6 class:* This class is obtained from the IPv6 header. It may be a specific IPv6 Class value or a wildcard value.
- *IPv6 flow label:* This label is obtained from the IPv6 header. It may be a specific IPv6 flow label value or a wildcard value.
- *IPv4 Type of Service* (TOS): The TOS is obtained from the IPv4 header. It may be a specific IPv4 TOS value or a wildcard value.

Authentication Header

The authentication header provides support for data integrity and authentication of IP packets. The data integrity feature ensures that undetected modification to the content of a packet in transit is not possible. The authentication feature enables an end system or network device to authenticate the user or application and filter traffic accordingly; it also prevents the address spoofing attacks observed in today's Internet. The AH also guards against the replay attack described later.

Figure 2: IPSec Authentication Header



Authentication is based on the use of a *Message Authentication Code* (MAC); hence the two parties must share a secret key. The authentication header consists of the following fields (Figure 2):

- *Next Header* (8 bits): This field identifies the type of header immediately following this header.
- *Payload Length* (8 bits): This field gives the length of the authentication header in 32-bit words, minus 2. For example, the default length of the authentication data field is 96 bits, or three 32-bit words. With a three-word fixed header, there are a total of six words in the header, and the Payload Length field has a value of 4.
- *Reserved* (16 bits): This field is reserved for future use.
- *Security Parameters Index* (32 bits): This field identifies a security association.
- *Sequence Number* (32 bits): This field contains a monotonically increasing counter value.
- *Authentication Data* (variable): This variable-length field (must be an integral number of 32-bit words) contains the *Integrity Check Value* (ICV), or MAC, for this packet.

Anti-Replay Service

A replay attack is one in which an attacker obtains a copy of an authenticated packet and later transmits it to the intended destination. The receipt of duplicate, authenticated IP packets may disrupt service in some way or may have some other undesired consequence. The *Sequence Number* field is designed to thwart such attacks.

When a new SA is established, the *sender* initializes a sequence number counter to 0. Each time that a packet is sent on this SA, the sender increments the counter and places the value in the Sequence Number field. Thus, the first value to be used is 1. If anti-replay is enabled (the default), the sender must not allow the sequence number to cycle past $2^{32} - 1$ back to zero. Otherwise, there would be multiple valid packets with the same sequence number. If the limit of $2^{32} - 1$ is reached, the sender should terminate this SA, and negotiate a new SA with a new key.

Because IP is a connectionless, unreliable service, the protocol does not guarantee that packets will be delivered in order and does not guarantee that all packets will be delivered. Therefore, the IPSec authentication document dictates that the *receiver* should implement a window of size *W*, with a default of $W = 64$. The right edge of the window represents the highest sequence number, *N*, so far received for a valid packet. For any packet with a sequence number in the range from $N - W + 1$ to N that has been correctly received (that is, properly authenticated), the corresponding slot in the window is marked. Inbound processing proceeds as follows when a packet is received:

- If the received packet falls within the window and is new, the MAC is checked. If the packet is authenticated, the corresponding slot in the window is marked.
- If the received packet is to the right of the window and is new, the MAC is checked. If the packet is authenticated, the window is advanced so that this sequence number is the right edge of the window, and the corresponding slot in the window is marked.
- If the received packet is to the left of the window, or if authentication fails, the packet is discarded; this is an auditable event.

Message Authentication Code

The message authentication algorithm is used to calculate a message authentication code, using an algorithm known as *HMAC*. HMAC takes as input a portion of the message and a secret key and produces a MAC as output. This MAC value is stored in the Authentication Data field of the AH header. The calculation takes place over the entire enclosed TCP segment plus the authentication header. When this IP packet is received at the destination, the same calculation is performed using the same key. If the calculated MAC equals the value of the received MAC, then the packet is assumed to be authentic. The authentication data field is calculated over:

- IP header fields that either do not change in transit (immutable) or that are predictable in value upon arrival at the endpoint for the AH SA. Fields that may change in transit and whose value on arrival are unpredictable are set to zero for purposes of calculation at both source and destination.
- The AH header other than the Authentication Data field. The Authentication Data field is set to zero for purposes of calculation at both source and destination.
- The entire upper-level protocol data, which is assumed to be immutable in transit (for instance, a TCP segment or an inner IP packet in tunnel mode).

For IPv4, examples of immutable fields are *Internet Header Length* and *Source Address*. An example of a mutable but predictable field is the Destination Address (with loose or strict source routing). Examples of mutable fields that are zeroed prior to ICV calculation are the *Time to Live* (TTL) and *Header Checksum* fields.

Note that both source and destination address fields are protected, so that address spoofing is prevented. For IPv6, examples in the base header are *Version* (immutable), *Destination Address* (mutable but predictable), and *Flow Label* (mutable and zeroed for calculation).

Encapsulating Security Payload

The encapsulating security payload provides confidentiality services, including confidentiality of message contents and limited traffic flow confidentiality. As an optional feature, ESP can also provide the same authentication services as AH.

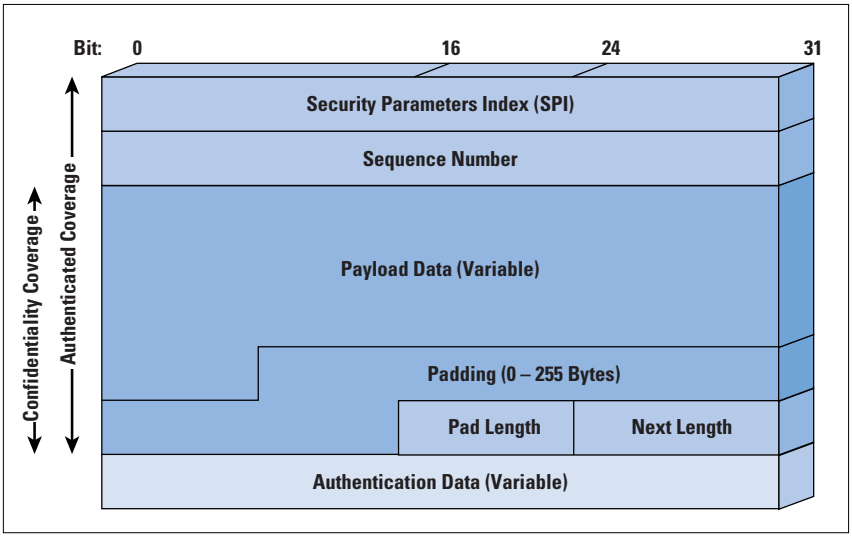


Figure 3: IPSec ESP Format

Figure 3 shows the format of an ESP packet. It contains the following fields:

- *Security Parameters Index* (32 bits): Identifies a security association
- *Sequence Number* (32 bits): A monotonically increasing counter value
- *Payload Data* (variable): A transport-level segment (transport mode) or IP packet (tunnel mode) that is protected by encryption
- *Padding* (0–255 bytes): Extra bytes that may be required if the encryption algorithm requires the plaintext to be a multiple of some number of octets
- *Pad Length* (8 bits): Indicates the number of pad bytes immediately preceding this field
- *Next Header* (8 bits): Identifies the type of data contained in the payload data field by identifying the first header in that payload (for example, an extension header in IPv6, or an upper-layer protocol such as TCP)
- *Authentication Data* (variable): A variable-length field (must be an integral number of 32-bit words) that contains the integrity check value computed over the ESP packet minus the Authentication Data field

Encryption and Authentication Algorithms

The Payload Data, Padding, Pad Length, and Next Header fields are encrypted by the ESP service. If the algorithm used to encrypt the payload requires cryptographic synchronization data, such as an *Initialization Vector* (IV), then this data may be carried explicitly at the beginning of the Payload Data field. If included, an IV is usually not encrypted, although it is often referred to as being part of the ciphertext. The current specification dictates that a compliant implementation must support the *Data Encryption Standard* (DES). A number of other algorithms have been assigned identifiers and could, therefore, be used for encryption; these include:

- Three-key triple DES
- RC5
- International Data Encryption Algorithm (IDEA)
- Three-key triple IDEA
- CAST
- Blowfish

It is now well known that DES is inadequate for secure encryption, so it is likely that many future implementations will use triple DES and eventually the *Advanced Encryption Standard* (AES). As with AH, ESP supports the use of a MAC, using HMAC.

Padding

- The Padding field serves several purposes: If an encryption algorithm requires the plaintext to be a multiple of some number of bytes (for instance, the multiple of a single block for a block cipher), the Padding field is used to expand the plaintext (consisting of the Payload Data, Padding, Pad Length, and Next Header fields) to the required length.
- The ESP format requires that the Pad Length and Next Header fields be right aligned within a 32-bit word. Equivalently, the ciphertext must be an integer multiple of 32 bits. The Padding field is used to assure this alignment.
- Additional padding may be added to provide partial traffic flow confidentiality by concealing the actual length of the payload.

Figure 4 indicates the scope of ESP encryption and authentication in both transport and tunnel modes.

Transport and Tunnel Modes

Both AH and ESP support two modes of use: *transport* and *tunnel* mode.

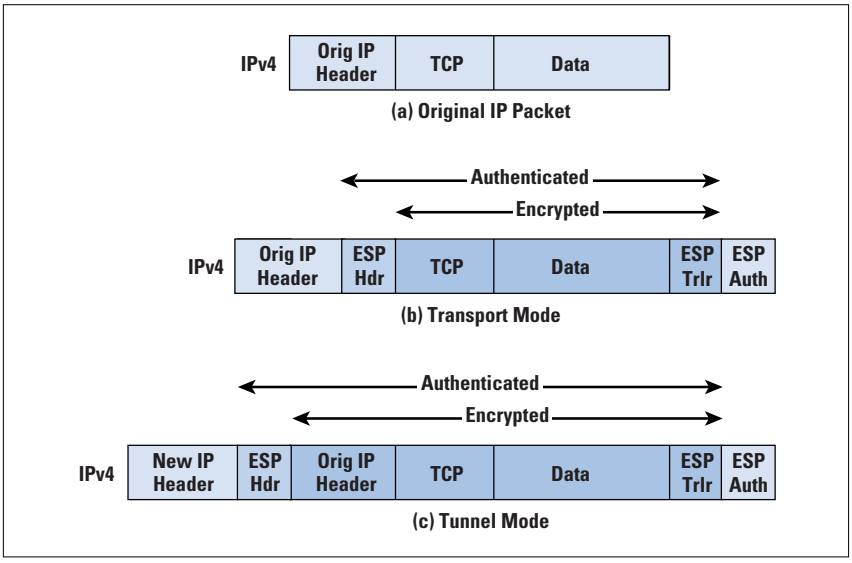

Figure 4: Scope of ESP Encryption and Authentication

Transport Mode

Transport mode provides protection primarily for upper-layer protocols. That is, transport mode protection extends to the payload of an IP packet. Examples include a TCP or UDP segment, or an *Internet Control Message Protocol* (ICMP) packet, all of which operate directly above IP in a host protocol stack. For this mode using IPv4, the ESP header is inserted into the IP packet immediately prior to the transport-layer header (for instance, TCP, UDP, ICMP) and an ESP trailer (Padding, Pad Length, and Next Header fields) is placed after the IP packet. This setup is shown in Figure 4b. If authentication is selected, the ESP Authentication Data field is added after the ESP trailer. The entire transport-level segment plus the ESP trailer are encrypted. Authentication covers all of the ciphertext plus the ESP header.

Typically, transport mode is used for end-to-end communication between two hosts (for instance, communications between a workstation and a server, or two servers). When a host runs AH or ESP over IPv4, the payload is the data that normally follows the IP header. For IPv6, the payload is the data that normally follows both the IP header and any IPv6 extensions headers that are present, with the possible exception of the destination options header, which may be included in the protection.

ESP in transport mode encrypts and optionally authenticates the IP payload but not the IP header. AH in transport mode authenticates the IP payload and selected portions of the IP header. All IPv4 packets have a *Next Header* field. This field contains a number for the payload protocol, such as 6 for TCP and 17 for UDP. For transport mode, the IP Next Header field is decimal 51 for AH, or 50 for ESP. This tells the receiving machine to interpret the remainder of the packet after the IP header as either AH or ESP. Both the AH and ESP headers also have a Next Header field.

As an example, let's examine a Telnet session within an ESP packet in transport mode. The IP header would contain 51 in the Next Header field. In the ESP header, the Next Header field would be 6 for TCP. Within the TCP header, Telnet would be identified as port 23.

Transport mode operation may be summarized for ESP as follows:

- At the source, the block of data consisting of the ESP trailer plus the entire transport-layer segment is encrypted and the plaintext of this block is replaced with its ciphertext to form the IP packet for transmission. Authentication is added if this option is selected.
- The packet is then routed to the destination. Each intermediate router needs to examine and process the IP header plus any plaintext IP extension headers but will not need to examine the ciphertext.
- The destination node examines and processes the IP header plus any plaintext IP extension headers. Then, on the basis of the SPI in the ESP header, the destination node decrypts the remainder of the packet to recover the plaintext transport-layer segment. This process is similar for AH, however the payload (upper layer protocol) is not encrypted.

Transport mode operation provides confidentiality for any application that uses it, thus avoiding the need to implement confidentiality in every individual application. This mode of operation is also reasonably efficient, adding little to the total length of the IP packet. One drawback to this mode is that it is possible to do traffic analysis on the transmitted packets.

Tunnel Mode

Tunnel mode encapsulates an entire IP packet within an IP packet to ensure that no part of the original packet is changed as it is moved through a network. The entire original, or inner, packet travels through a "tunnel" from one point of an IP network to another; no routers along the way need to examine the inner IP header. For ESP, this is shown in Figure 4c. Because the IP header contains the destination address and possibly source routing directives and hop-by-hop option information, it is not possible simply to transmit the encrypted IP packet prefixed by the ESP header. Intermediate routers would be unable to process such a packet. Therefore, it is necessary to encapsulate the entire block (ESP header plus ciphertext plus Authentication Data, if present) with a new IP header that will contain sufficient information for routing but not for traffic analysis. Tunnel mode is used when one or both ends of an SA is a security gateway, such as a firewall or router that implements IPSec. With tunnel mode, a number of hosts on networks behind firewalls may engage in secure communications without implementing IPSec. The unprotected packets generated by such hosts are tunneled through external networks by tunnel mode SAs set up by the IPSec process in the firewall or secure router at the boundary of the local network.

Whereas the transport mode is suitable for protecting connections between hosts that support the ESP feature, the tunnel mode is useful in a configuration that includes a firewall or other sort of security gateway that protects a trusted network from external networks. In this latter case, encryption occurs only between an external host and the security gateway or between two security gateways. This setup relieves hosts on the internal network of the processing burden of encryption and simplifies the key distribution task by reducing the number of needed keys. Further, it thwarts traffic analysis based on ultimate destination.

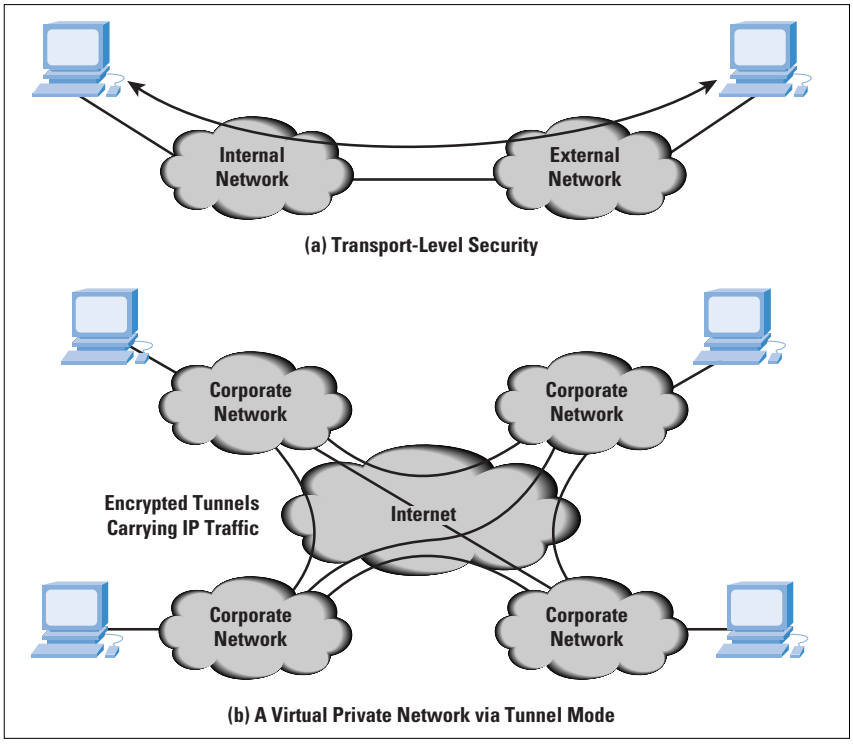
Let's use the diagram in Figure 1 as an example of how tunnel mode IPSec operates. The following steps occur for transfer of a transport-layer segment from the user system to one of the servers on one of the protected LANs.

- The user system prepares an inner IP packet with a destination address of the target host on the internal LAN. For a Telnet session, this packet would be a TCP packet with the original SYN flag set with a destination port set to 23. This entire IP packet is prefixed by an ESP header; then the packet and ESP trailer are encrypted and Authentication Data may be added. The Next Header field of the ESP header would be decimal 4 for IP-in-IP, indicating that the entire original IP packet is contained as the "payload." The resulting block is encapsulated with a new IP header (base header plus optional extensions such as routing and hop-by-hop options for IPv6) whose destination address is the firewall; this forms the outer IP packet. The Next Header field for this IP packet is 50 for ESP.
- The outer packet is routed to the destination firewall. Each intermediate router needs to examine and process the outer IP header plus any outer IP extension headers but does not need to examine the ciphertext.
- The destination firewall examines and processes the outer IP header plus any outer IP extension headers. Then, on the basis of the SPI in the ESP header, the gateway decrypts the remainder of the packet to recover the plaintext inner IP packet. This packet is then transmitted in the internal network.
- The inner packet is routed through zero or more routers in the internal network to the destination host. The receiver would have no indication that the packet had been encapsulated and protected by the "tunnel" between the user system and the gateway. It would see the packet as a request to start a Telnet session and would respond back with a TCP SYN/ACK, which would go back to the gateway. The gateway would encapsulate that packet into an IPSec packet and transport it back to the user system through this "tunnel." That return packet would be processed to find the original packet, which would contain the SYN/ACK for the Telnet session.

Common Uses of IPSec in Real Networks

Figure 5 shows two ways in which the IPSec ESP service can be used. In the upper part of the figure, encryption (and optionally authentication) is provided directly between two hosts. Figure 5b shows how tunnel mode operation can be used to set up a *Virtual Private Network* (VPN). In this example, an organization has four private networks interconnected across the Internet. Hosts on the internal networks use the Internet for transport of data but do not interact with other Internet-based hosts. By terminating the tunnels at the security gateway to each internal network, the configuration allows the hosts to avoid implementing the security capability. The former technique is supported by a transport mode SA, while the latter technique uses a tunnel mode SA.

Figure 5: Transport-Mode versus Tunnel-Mode Encryption



Key Management

The key management portion of IPSec involves the determination and distribution of secret keys. The IPSec Architecture document mandates support for two types of key management:

- *Manual:* A system administrator manually configures each system with its own keys and with the keys of other communicating systems. This is practical for small, relatively static environments.
- *Automated:* An automated system enables the on-demand creation of keys for SAs and facilitates the use of keys in a large distributed system with an evolving configuration. An automated system is the most flexible but requires more effort to configure and requires more software, so smaller installations are likely to opt for manual key management.

The default automated key management protocol for IPSec is referred to as *Internet Key Exchange* (IKE). IKE provides a standardized method for dynamically authenticating IPSec peers, negotiating security services, and generating shared keys. IKE has evolved from many different protocols and can be thought of as having two distinct capabilities. One of these capabilities is based on the *Internet Security Association and Key Management Protocol* (ISAKMP). ISAKMP provides a framework for Internet key management and provides the specific protocol support, including formats, for negotiation of security attributes. ISAKMP by itself does not dictate a specific key exchange algorithm; rather, ISAKMP consists of a set of message types that enable the use of a variety of key exchange algorithms. The actual key exchange mechanism in IKE is derived from Oakley and several other key exchange protocols that had been proposed for IPSec. Key exchange is based on the use of the Diffie-Hellman algorithm, but provides added security. In particular, Diffie-Hellman alone does not authenticate the two users that are exchanging keys, making the protocol vulnerable to impersonation. IKE includes mechanisms to authenticate the users.

Public Key Certificates

An important element of IPSec key management is the use of public key certificates. In essence, a public key certificate is provided by a trusted *Certificate Authority* (CA) to authenticate a user's public key. The essential elements include:

- Client software creates a pair of keys, one public and one private. The client prepares an unsigned certificate that includes a user ID and the user's public key. The client then sends the unsigned certificate to a CA in a secure manner.
- A CA creates a signature by calculating the hash code of the unsigned certificate and encrypting the hash code with the CA's private key; the encrypted hash code is the signature. The CA attaches the signature to the unsigned certificate and returns the now signed certificate to the client.
- The client may send its signed certificate to any other user. That user may verify that the certificate is valid by calculating the hash code of the certificate (not including the signature), decrypting the signature using the CA's public key, and comparing the hash code to the decrypted signature.

If all users subscribe to the same CA, then there is a common trust of that CA. All user certificates can be placed in the directory for access by all users. In addition, a user can transmit his or her certificate directly to other users. In either case, once B is in possession of A's certificate, B has confidence that messages it encrypts with A's public key will be secure from eavesdropping and that messages signed with A's private key are unforgeable.

If there is a large community of users, it may not be practical for all users to subscribe to the same CA. Because it is the CA that signs certificates, each participating user must have a copy of the CA's own public key to verify signatures. This public key must be provided to each user in an absolutely secure (with respect to integrity and authenticity) way so that the user has confidence in the associated certificates. Thus, with many users, it may be more practical for there to be many CAs, each of which securely provides its public key to some fraction of the users. In practice, there is not a single CA but rather a hierarchy of CAs. This complicates the problems of key distribution and of trust, but the basic principles are the same.

Whither IP Security

The driving force for the acceptance and deployment of secure IP is the need for business and government users to connect their private WAN/LAN infrastructure to the Internet for (1) access to Internet services and (2) use of the Internet as a component of the WAN transport system. Users need to isolate their networks and at the same time send and receive traffic over the Internet. The authentication and privacy mechanisms of secure IP provide the basis for a security strategy.

Because IP security mechanisms have been defined independent of their use with either the current IP or IPv6, deployment of these mechanisms does not depend on deployment of IPv6. Indeed, it is likely that we will see widespread use of secure IP features long before IPv6 becomes popular.

Quality of Service—Fact or Fiction?

by Geoff Huston, Telstra

Much has been written about the potential of *Quality of Service* (QoS) and the Internet. However, much of the material is strong on promise, but falls short in critical analysis. In an effort to balance the picture, we present here a brief status report on the QoS effort, exposing some of the weaknesses in the current QoS architectures.

The QoS Service

The default service offering associated with the Internet is a *best-effort* service, where the network treats all traffic in exactly the same way. There is no consistent service outcome from the Internet best-effort service model. When the load level is low, the network delivers a high-quality service. The best-effort Internet does not deny entry to traffic, so as the load levels increase, the network congestion levels increase, and service-quality levels decline uniformly. This decline in service is experienced by all traffic passing through a congestion point, and is not limited to the most recently admitted traffic flows. For many applications, this best-effort response is perfectly acceptable. When network capacity is available, the application can make use of the resource, whereas when the level of contention for network bandwidth is high, each application will experience similar levels of congestion. A best-effort network service is a good match to opportunistic applications that can vary their data transfer rate in response to signaled network load.

The objective of various Internet QoS efforts is to augment this service with a number of selectable service responses. These service responses may be different from the best-effort service by some form of superior service response, such as lower delay, lower jitter, or greater bandwidth. These responses are relative, where the service outcome is claimed to be no worse than best effort at any time, and superior to best-effort under congestion load. Alternatively, QoS service responses may be distinguished by providing a consistent, and therefore predictable, service response that is unaffected by network congestion levels. These are quantitative service responses, where the characteristics of the service can be measured against a constant outcome. A quantitative service many be one that constrains jitter to a maximum level, or one that makes a certain bandwidth available, within parameters of bounded jitter, similar to a conventional leased line. Such constant-rate services may be superior to best-effort services when the network is under load, but they may also offer inferior service when the network is under negligible load. The essential attribute of these services is one of consistency.

Why is there a need for relative or consistent service profiles within the Internet? The underlying reasons for introducing QoS into the Internet appear to be threefold: First is the desire to provide high-quality support for IP voice and video services, second is the desire to manage the ser-

vice response provided to low-speed access devices, such as Internet mobile wireless devices, and third is the desire to provide a differentiated Internet access service, providing a network client with a range of service-quality levels at a range of prices.

Obviously this is a broad agenda, where there are requirements to extend specific network services to applications, requirements to adapt network services to particular transmission characteristics, and requirements to manage network resources to achieve particular response characteristics for an aggregated collection of traffic.

Approaches to QoS

The relevant efforts within the *Internet Engineering Task Force* (IETF) have been addressing standards for QoS mechanisms within the network.

The initial approach to QoS was that of the *Integrated Services* architecture. This approach focuses on the application as the trigger for QoS. Here, the application first signals its service requirements to the network in the form of a reservation, and the network responds to this request. The application proceeds only if the network has indicated that it is able to carry the additional load at the requested service level by committing to the reservation. The reservation remains in force until the application explicitly requests termination of the reservation, or the network signals to the application that it is unable to continue the reservation. The essential feature of this model is the "all-or-nothing" nature of the service model. Either the network commits to the reservation, in which case the application does not have to monitor the level of network response to the service, or the network indicates that it cannot meet the reservation. This approach imposes per-application state within the network, and for large-scale networks, such as the global Internet itself, this approach alone does not appear to be viable (see Figure 1).

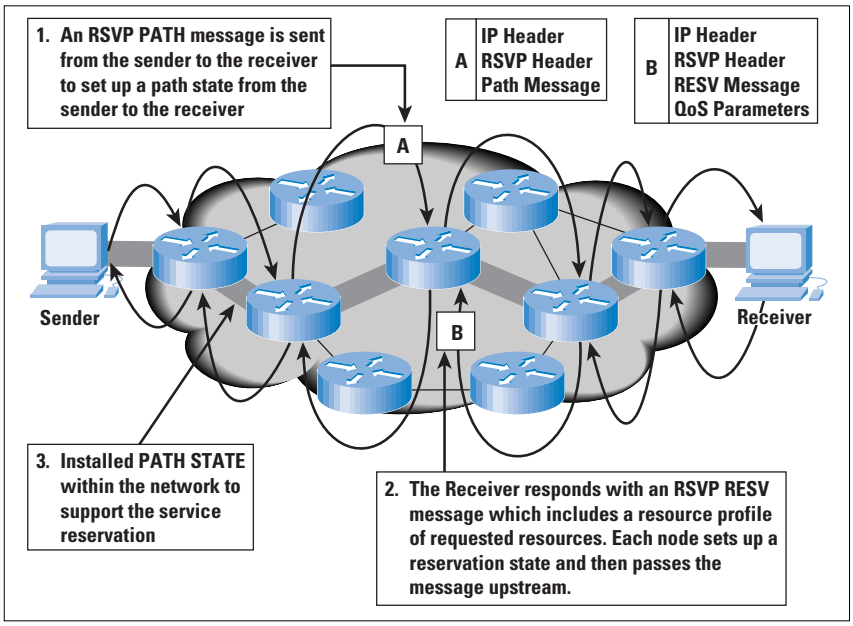

Figure 1: The Integrated Services QoS Architecture

The subsequent approach to QoS mechanisms has been to look at the core of the network, and examine those mechanisms that can provide differentiated service outcomes with appropriate scaling properties. This approach, the *Differentiated Services* architecture, includes dropping the concept of a per-application path state across the network using instead the concept of aggregated service mechanisms. Within the aggregated service model, the network provides a smaller number of different service classes and aggregates similar service demands from a set of applications into a single service class. Aggregated services are typically seen as an entry filter, where on entry to the network each packet is classified into a particular service profile. This classification is carried within the IP packet header, using 6 bits from the deprecated IP *Type of Service* (TOS) header to carry the service coding. The network then uses this service code in the packet header to treat this packet identically to all other packets within the same service code. While this approach does possess the ability to scale across the entire Internet, there are numerous unresolved issues relating to the quality signaling between individual applications and the network. The aggregated service model does not allow an individual application to sense if it is receiving the necessary service response from the network (see Figure 2).

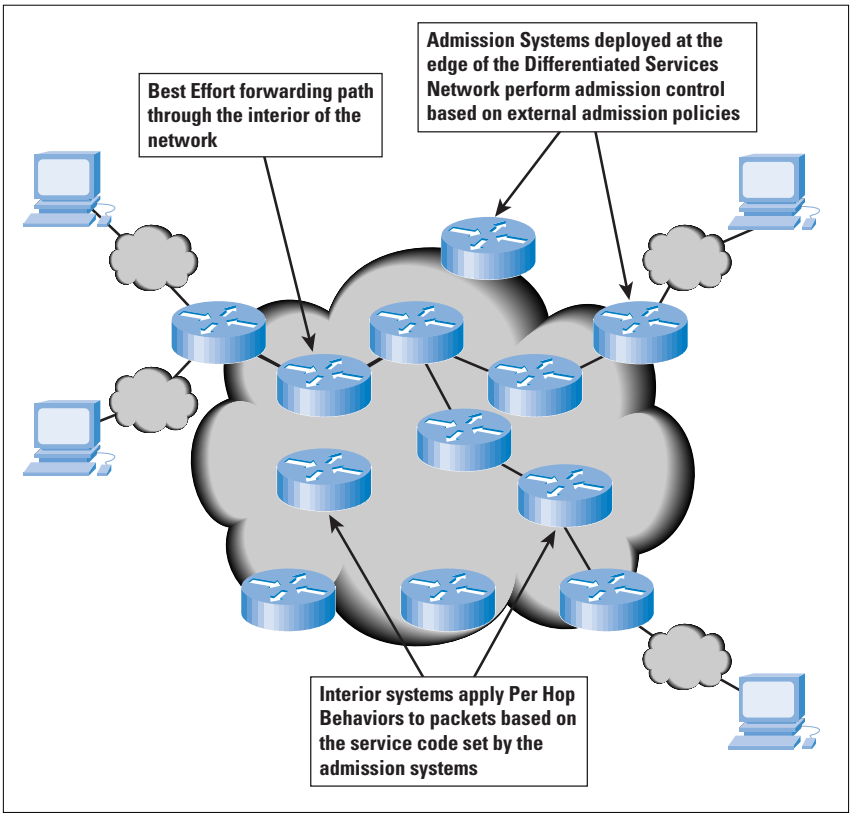

Figure 2: The Differentiated Services QoS Architecture

QoS Deployment

Neither approach alone is adequate to meet the QoS requirements. The Integrated Services approach alone imposes an excessive load in the core of large networks through the imposition of a per-application path state. The Differentiated Services approach does provide superior scaling properties through the use of aggregated service elements, but includes no concept of control signaling to inform the traffic conditioning elements of the current state of the network, or the current per-application requirements.

The underlying question then becomes: Is a combination of these two approaches sufficient to allow QoS to be widely deployed on the Internet?

At this stage the response does appear to be a "No." Perhaps this strong negative response should be further qualified. The existing tools are insufficient to support widespread use of QoS-based services on the multiprovider public Internet. The qualification is that within the enterprise network environment there are much stronger drivers for QoS mechanisms and much greater levels of administrative control over the overall network architecture, while within the multiprovider public Internet, these drivers are not apparent. The enterprise approach may also have some parallels within a single IP carrier's network, or even across some forms of bilateral agreements between carriers. However, such approaches are not anticipated to be a widespread feature of the public Internet service environment.

Let's look more closely at the public Internet and QoS to see why there is a mismatch between the two. The major stumbling blocks in attempting to address how QoS could be deployed in the public Internet are both engineering and economic in nature.

From an engineering perspective, we need to remember that in order to actually deliver any reasonable assurance of a quality-differentiated service, the service-quality mechanism chosen must be deployed across all networks along the end-to-end paths of the quality-service traffic. In a heterogeneous multiprovider environment such as the public Internet, this outcome is very unlikely. Within the tens of thousands of component service providers that make up the global Internet, such uniformity of action is highly improbable. The IPv6 transition structure correctly identifies the first step as isolated "islands" of IPv6 functionality, interconnected by some form of IPv6 "bridges." While the potential scenario of initial QoS deployment may be similar, in terms of isolated islands of deployment of QoS services, there is a much stricter requirement for the "bridges" across the non-QoS-aware parts of the network; namely, that they do not distort the service outcomes. In effect, this scenario requires a QoS response from a non-QoS system (see Figure 3).

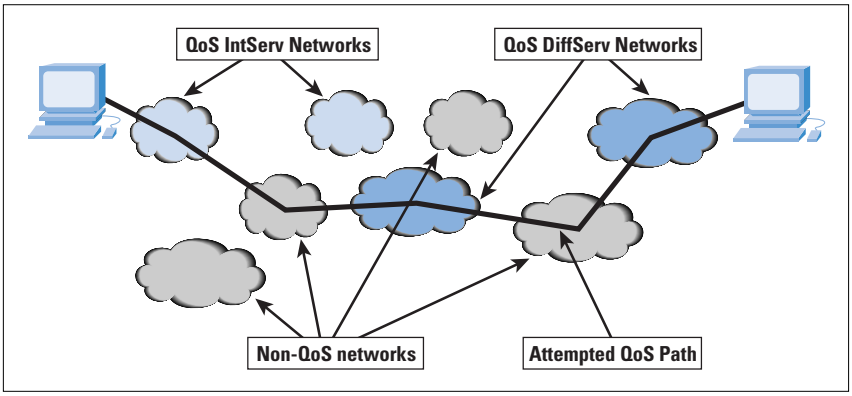

Figure 3: Attempted End-to-End QoS across the Public Internet

The engineering issues are deeper than simply the considerations of transition within a potential deployment scenario. The issues include:

- The need for QoS-enabled applications that can predict their service requirements in advance, and be able to signal these requirements into the network.
- In the case of the differentiated service approach of admission controls, there is a requirement for the interior of the network to be able to signal current load conditions to the network admission systems. This system also requires that the admission control points be able to use admission-decision support systems in order to include consideration of the service load, the current network load, and the policy parameters of the network that may allow some level of preemption of various admission decisions in order to meet high-priority service requirements.
- The signaling and negotiation aspect of QoS extends into the interdomain space, where two or more service providers need to negotiate mutually acceptable service profiles, and associated service access. This extends beyond the addition of bilateral agreements and encompasses the requirement to add QoS attributes to interdomain routing protocols. The tools and operating techniques required to support this functionality remain poorly defined.
- Measurement of service performance remains an area in which existing measurement tools are lacking. While it is possible to instrument every active device within a network into a network management system, such an element-by-element view does not readily translate to the end-to-end view of application service performance.

From an economic perspective, we must remember that no current Internet retail tariff includes a concept of end-to-end tariffed transactions. All tariffs are access based, because application transactions are not readily visible to the Internet network. In addition, no technically stable or financially stable structure of interprovider interconnection financial settlements exists today. The financial model of the Internet from an economic viewpoint is very polarized, with only customer and zero-dollar peer arrangements dominating the interprovider space. However, end-to-end QoS transactions demand a different economic model.

The initiator of the end-to-end QoS transaction has the discretion of choosing whether to request an end-to-end service profile. If such a profile is requested, the initiator should pay the initiating provider a retail tariff to cover the entire end-to-end cost of the transaction, and the initiating provider must then indicate a willingness to financially settle with transit peer networks in order for these transit peers to devote additional resources to service the traffic associated with this transaction, and so forth through the entire path of transit providers. The arbitrary nature of the Internet transits, the dynamic nature of routing, and the lack of transaction setups in any scalable form of QoS mechanisms make this entire scenario highly improbable within our current understanding of interprovider policy-management mechanisms.

The relatively loosely coordinated structure of the public Internet will have to change from the state we have today if we want to use QoS-based services. The changes include:

- A common selection of a set of QoS mechanisms to deploy,
- Ubiquitous deployment of these mechanisms across both service provider and client networks,
- The adoption of a uniform set of retail tariffs for QoS services,
- The definition and common acceptance of multi-party QoS-related financial settlements that support fair and equitable cost distribution among multiple providers, and
- The definition of commonly accepted service performance metrics and related measurement methodologies to allow end-to-end and network-by-network service outcomes to be objectively assessed.

This is a significant agenda for the industry at large to undertake, and more so in an environment that features diversity and vigorous competition between various public Internet service providers.

An additional factor is also working against QoS deployment in the public Internet space. The increasing availability of very-high-speed transmission systems is bringing network carriage capacity down to the level of an abundant commodity across large parts of the Internet world. As the unit costs of network capacity decline in the face of increasing levels of availability of transmission systems, the market niche that QoS could occupy in managing a scarce resource is shrinking. The driver for QoS deployment is not that the best-effort service is not good enough. The problem that QoS is attempting to address is one of allocation of network capacity at those points in time when the network is under heavy load, or, in other words, taking on the task of allocating capacity when there is not enough network capacity to meet every demand. When a network is under load, the QoS response is to place additional control functionality in both applications and in the network to manage this allocation function. Obviously such an activity imposes additional costs on the network operators and the network client. Such additional costs have not created any additional network capacity.

The total sum of demand remains in excess of capacity after the deployment of QoS mechanisms. The alternative approach is to incur additional cost by augmenting the capacity of the network. This approach minimizes the impact of load on the network causing disruption to individual transactions. Again this approach imposes additional costs onto the network, but in an environment of abundant transmission capacity, it may often be the more cost-effective approach.

Where does this leave QoS and the public Internet? There is no doubt that QoS is a very stimulating area of research, with much to offer the enterprise network environment, but in asking for QoS to be deployed within the existing incarnation of the public multiprovider Internet, we may be simply asking for too much at this point in time. More effort is required to turn a QoS Internet into a reliable production platform.

This RFC describes the components of the Integrated Services architecture, a proposed extension to the Internet architecture, and protocols to support real-time traffic flows through service-quality commitments.

[6] Blake, S., Black, D., Carlson, M., Davies, E., Wang, Z., and Weiss, W., "An Architecture for Differentiated Services," RFC 2475, Proposed Standard, December 1998.

The architecture description for the Differentiated Services enhancements to the Internet Protocol. This architecture achieves scalability by aggregating traffic classification state, which is conveyed by means of IP-layer packet marking using the Differentiated Services (DS) field. Packets are classified and marked to receive a particular per-hop forwarding behavior on nodes along their path. Sophisticated classification, marking, policing, and shaping operations need to be implemented only at network boundaries or hosts. Network resources are allocated to traffic streams by service-provisioning policies that govern how traffic is marked and conditioned upon entry to a differentiated services-capable network, and how that traffic is forwarded within that network.

http://staff.washington.edu/gray/papers/eqos22.html

A detailed view of an approach to supporting QoS in an enterprise environment. The paper is an excellent example of the procedural steps involved in network engineering, detailing the intended environment, the available tools and the desired outcomes, and then examining the viability of a number of QoS solutions.

[8] Huston, G., "Next Steps for the IP QoS Architecture." Available at:
www.ietf.org/internet-drafts/draft-iab-qos-00.txt

While there has been significant progress in the definition of IP QoS architecture, there are a number of aspects of QoS that appear to need further elaboration as they relate to translating a set of tools into a coherent platform for end-to-end service delivery. This document highlights the outstanding issues relating to the deployment and use of QoS mechanisms within the Internet, noting those areas where further standards work may be required. This draft is a work item of the Internet Architecture Board Working Group of the IETF.

GEOFF HUSTON holds a B.Sc. and a M.Sc. from the Australian National University. He has been closely involved with the development of the Internet for the past decade, particularly within Australia, where he was responsible for the initial build of the Internet within the Australian academic and research sector. Huston is currently the Chief Technologist in the Internet area for Telstra. He is also an active member of the IETF, and is the chair of the Internet Society Board of Trustees. He is author of *The ISP Survival Guide,* ISBN 0-471-31499-4, *Internet Performance Survival Guide: QoS Strategies for Multiservice Networks,* ISBN 0471-378089 and coauthor of *Quality of Service: Delivering QoS on the Internet and in Corporate Networks,* ISBN 0-471-24358-2, a collaboration with Paul Ferguson. All three books are published by John Wiley & Sons. E-mail: **gih@telstra.net**

Book Review

Removing the Spam

Removing the Spam: Email Processing and Filtering, Geoff Mulligan, ISBN 0-201-37957-0, Addison-Wesley, 1999.
http://cseng.aw.com/bookdetail.qry?ISBN=0-201-37957-0&ptype=0

Do not be fooled by the title of this book. You might purchase this book, part of the Addison-Wesley Networking Basics Series, thinking you are just getting information dealing with unsolicited commercial e-mail (commonly called, to Hormel's displeasure, "spam"). The title is probably the work of a marketeer who thought "spam" in the title would *sell!* The subtitle really describes the meat of the matter. This short, but thorough, book is about e-mail processing and filtering—dealing with spam, yes, but so much more.

A collection of essential information for the Internet e-mail "gatekeeper," *Removing the Spam* is really geared for the gatekeeper using a UNIX-based system, so NT system administrators be forewarned. Being an e-mail gatekeeper on the Internet involves keeping the e-mail flowing, making sure the automated processes in place do the job, supporting e-mail "mailing lists," and providing the services and features your users want or need for e-mail processing.

Commercial products support some of the many requirements, but the best software for most of these functions is freely available on the Internet. Geoff provides answers to the requirements using the most popular and commonly used solutions: *Sendmail* for mail delivery, *procmail* for e-mail filtering, and *majordomo* and *smartlist* for mailing-list management.

The book, however, tries to do a bit too much. Geoff indicates that the intended audience is not only the system administrator, but also the e-mail end users wanting to filter their own personal e-mail as well as those who want to run their own mailing list. Because of this broad audience, there are times when the book delves too long in the basics, giving the impression of topics added to lengthen the book. The overview of IP protocols, the brief history of the Internet, suggestions for users dealing with spammers, and mailing-list etiquette are examples that come to mind. Nevertheless, the other topics covered are "net essentials," and worth skimming over the already known.

The book clearly defines spam and its evils, and presents the tools and techniques available for removing, or at least minimizing, the spam. It is probably too ambitious when covering e-mail forgery and tracing e-mail spam, but leaves no essential unmentioned.

Sendmail coverage is good, dealing with installation as well as configuration, highlighting antispam features, and how to use them. Though not covering as much detail as other books that focus on Sendmail, the important elements of building and modifying are handled, as well as Sendmail's use of data bases, including the infamous "Realtime Blackhole List" (`http://maps.vix.com/rbl/`).

The e-mail gatekeeper, as well as end users of e-mail, can use procmail to preprocess e-mail before final delivery. Procmail is powerful and flexible, and, so, can be difficult to configure properly. Configuration files examples with explanations allow even the procmail-savvy reader to learn and try something new.

The mailing list section again instructs both system administrator and user. Information about subscribing, unsubscribing, and getting information from the mailing list software is useful for the user. The administrator will appreciate the examples of getting, installing, configuring, and running majordomo and smartlist. Geoff gives suggestions about when a manual versus automated solution is best.

About the Author

I knew Geoff back in our Digital Equipment Corporation days when he worked in the Network Systems Lab. My group ran one of the corporate Internet gateways, modeled after the one at NSL. Further, the group I ran also productized and delivered what is arguably the first commercial Internet firewall, based on a design from the team at NSL. All this to say, Geoff certainly has the background to write about these topics. Since those days, Geoff has been busy with other Internet endeavors, such as starting USA.NET and creating the NetAddress product (permanent, follow-you-anywhere e-mail addresses) and helping develop the Sun Microsystems Sunscreen Firewall. He also founded Geocast Network Systems. In various roles, in differing capacities, Geoff has had to wrestle with the matters covered in his book. What he writes is based on experience learned in the danger zone of the Internet gateway.

Organization

The book is divided into four chapters. The first chapter, the introduction really, is strangely entitled "The Dawn of Electronic Mail." This is also the "roughest" chapter. It is difficult to understand why some topics are covered in the order that they are here (and why some are covered at all—the aforementioned "list etiquette" and "Size and Growth of the Internet," for example). It introduces (needlessly, I think) The Internet Protocols, but then reviews the basics of understanding e-mail systems. It introduces spam, along with antispam resources, and the topics in the rest of the book to be covered in detail: e-mail processing, filtering, and e-mail lists.

Chapter 2 is entitled "Sendmail" and covers obtaining, installing, configuring, and running Sendmail on a UNIX machine. It gives the commands to build and install Sendmail and your Sendmail configuration file. This coverage is not detailed enough for *every* situation, but gives the most common configuration information, which should satisfy most readers' needs. Included are instructions for using Sendmail to help stop (or avert) spam at the mail gateway.

Chapter 3 unravels the mysteries behind procmail configuration for e-mail filtering. This chapter covers getting the software, installing it, and using procmail—the latter for system administrators and users alike. There are example "ready-to-run filters" included. Caveat: Some of the scripts have inherent errors. No doubt these errors are unfortunate publication glitches, but they do detract from the usefulness of this chapter. Geoff has compiled an errata list with corrected scripts. This can be found at: **`http://www.hz.com/spam/eratta`**

Chapter 4 covers mailing lists, specifically discussing administering them "by hand" (just using Sendmail) or "automatically" (majordomo and smartlist). Again, examples are given with step-by-step commands.

Closing Thoughts

Production errors aside (the serious ones in the procmail chapter and others that are just nits to pick—the "P" in ARPA stands for "Projects," not "Project"), this book is useful as an introduction as well as a reminder of things forgotten. I can recommend this book to the novice or seasoned e-mail gatekeeper, and I will recommend it to the students in my Sendmail courses.

—Frederick M. Avolio, Avolio Consulting

Would You Like to Review a Book for IPJ?

We receive numerous books on computer networking from all the major publishers. If you've got a specific book you are interested in reviewing, please contact us and we will make sure a copy is mailed to you. The book is yours to keep if you send us a review. We accept reviews of new titles, as well as some of the "networking classics." Contact us at **`ipj@cisco.com`** for more information.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

Fragments

ICANN Launches Membership Web Site for Individual Internet Users

The *Internet Corporation for Assigned Names and Numbers* (ICANN) recently announced the launch of its At Large Membership Web site. After considerable public input, the ICANN Board has developed this program as a new way for Internet users from all over the globe to participate directly in the ICANN process. Individuals can register to become ICANN members at **http://members.icann.org**

The At Large Membership of ICANN will give individual members of Internet communities worldwide a voice in the selection of Directors to the ICANN Board. By becoming an ICANN member, individuals will have an opportunity to become part of the ICANN "bottom-up" approach to making policy concerning Internet names and addresses. The basic requirements for applying to become an ICANN At Large member are: The completion of an online membership application, a working Internet e-mail address, and a single physical residence verified by a postal mail address. Thanks to a grant from the Markle Foundation, the initial launch of ICANN's At Large Membership program has been funded without the need for membership dues.

The ICANN Board will consider and adopt further policy about composition and structure of the At Large Membership, and establish rules for the nomination and election of candidates for the At Large Council. It is hoped that the target goal of 5,000 members can be reached in the next few weeks in order to move forward with the At Large Elections later this year.

ICANN is a non-profit, international corporation formed to oversee a select set of Internet technical management functions currently managed by the U.S. Government, or by its contractors and volunteers. Specifically, ICANN is assuming responsibility for coordinating the management of the *Domain Name System* (DNS), the allocation of IP address space, the assignment of protocol parameters, and the management of the root server system.

Online Registration for INET 2000 Now Open

INET 2000, the annual conference of the Internet Society (ISOC) will be held in Yokohama, Japan, July 18–21. You can register for this event by visiting ISOC's Web site at:
http://www.isoc.org/inet2000/register.shtml

Denial of Service Attacks

In early February, several high-profile Internet Web sites were severely disrupted by a number of so-called *Distributed Denial of Service* (DDoS) attacks. We plan to publish an article on this topic in the future. Meanwhile, we recommend you visit the Denial of Service Resource Page at **http://www.denialinfo.com/**

From The Editor

Two protocols used in the Internet are so important that they deserve special attention: the *Internet Protocol* (IP) from which this journal takes its name, and the *Transmission Control Protocol* (TCP). IP is fundamental to Internet addressing and routing, while TCP provides a reliable transport service that is used by most Internet applications, including interactive Telnet, file transfer, electronic mail, and Web page access via HTTP. Because of the critical importance of TCP to the operation of the Internet, it has received much attention in the research community over the years. As a result, numerous improvements to implementations of TCP have been developed and deployed. In this issue, Geoff Huston takes a detailed look at TCP from a performance perspective and describes several enhancements to the original protocol. In a second article, Geoff will look at the challenges facing TCP in a rapidly growing and changing Internet, and describe work to further augment TCP.

Electronic mail is by far the most used of all Internet applications. The fundamental protocols for delivery and retrieval of e-mail have not changed much since the early days of the ARPANET, but as with TCP, many enhancements have been added to accommodate new uses of e-mail. Today, Internet e-mail supports international character sets, includes the ability to send file attachments, and allows roaming e-mail clients to authenticate themselves to servers. All of this has been made possible by continued development in the *Internet Engineering Task Force* (IETF). In our second article, Paul Hoffman of the Internet Mail Consortium gives an overview of Internet mail standards.

This is the second anniversary issue of *The Internet Protocol Journal* (IPJ). By now more than 10,000 people from virtually every country in the world have subscribed to the paper edition of IPJ. In order to serve our readers better, we are developing an online subscription system, which will be deployed in July 2000. With this new system you will be able to modify your mailing address as well as select your preferred delivery method for the journal. You can choose to receive IPJ on paper, or be notified via e-mail when a new issue becomes available on line. More information about this new system can be found on our Web site at **www.cisco.com/ipj**. We would love to hear your feedback on this system and any other aspect of IPJ. Please send your comments to **ipj@cisco.com**

TCP Performance

by Geoff Huston, Telstra

The *Transmission Control Protocol* (TCP) and the *User Datagram Protocol* (UDP) are both IP transport-layer protocols. UDP is a lightweight protocol that allows applications to make direct use of the unreliable datagram service provided by the underlying IP service. UDP is commonly used to support applications that use simple query/response transactions, or applications that support real-time communications. TCP provides a reliable data-transfer service, and is used for both bulk data transfer and interactive data applications. TCP is the major transport protocol in use in most IP networks, and supports the transfer of over 90 percent of all traffic across the public Internet today. Given this major role for TCP, the performance of this protocol forms a significant part of the total picture of service performance for IP networks. In this article we examine TCP in further detail, looking at what makes a TCP session perform reliably and well. This article draws on material published in the *Internet Performance Survival Guide*[1].

Overview of TCP

TCP is the embodiment of reliable end-to-end transmission functionality in the overall Internet architecture. All the functionality required to take a simple base of IP datagram delivery and build upon this a control model that implements reliability, sequencing, flow control, and data streaming is embedded within TCP[2].

TCP provides a communication channel between processes on each host system. The channel is reliable, full-duplex, and streaming. To achieve this functionality, the TCP drivers break up the session data stream into discrete segments, and attach a TCP header to each segment. An IP header is attached to this TCP packet, and the composite packet is then passed to the network for delivery. This TCP header has numerous fields that are used to support the intended TCP functionality. TCP has the following functional characteristics:

- *Unicast protocol:* TCP is based on a unicast network model, and supports data exchange between precisely two parties. It does not support broadcast or multicast network models.
- *Connection state:* Rather than impose a state within the network to support the connection, TCP uses synchronized state between the two endpoints. This synchronized state is set up as part of an initial connection process, so TCP can be regarded as a connection-oriented protocol. Much of the protocol design is intended to ensure that each local state transition is communicated to, and acknowledged by, the remote party.
- *Reliable:* Reliability implies that the stream of octets passed to the TCP driver at one end of the connection will be transmitted across the network so that the stream is presented to the remote process as the same sequence of octets, in the same order as that generated by the sender.

This implies that the protocol detects when segments of the data stream have been discarded by the network, reordered, duplicated, or corrupted. Where necessary, the sender will retransmit damaged segments so as to allow the receiver to reconstruct the original data stream. This implies that a TCP sender must maintain a local copy of all transmitted data until it receives an indication that the receiver has completed an accurate transfer of the data.

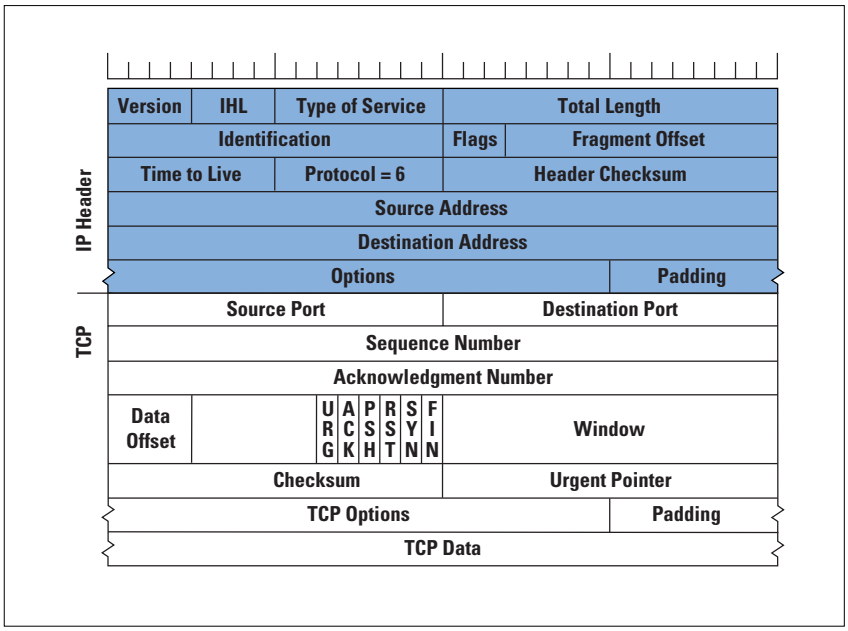
- *Full duplex:* TCP is a full-duplex protocol; it allows both parties to send and receive data within the context of the single TCP con–nection.
- *Streaming:* Although TCP uses a packet structure for network transmission, TCP is a true streaming protocol, and application-level network operations are not transparent. Some protocols explicitly encapsulate each application transaction; for every *write,* there must be a matching *read*. In this manner, the application-derived segmentation of the data stream into a logical record structure is preserved across the network. TCP does not preserve such an implicit structure imposed on the data stream, so that there is no pairing between *write* and *read* operations within the network protocol. For example, a TCP application may *write* three data blocks in sequence into the network connection, which may be collected by the remote reader in a single *read* operation. The size of the data blocks (segments) used in a TCP session is negotiated at the start of the session. The sender attempts to use the largest segment size it can for the data transfer, within the constraints of the maximum segment size of the receiver, the maximum segment size of the configured sender, and the maximum supportable non-fragmented packet size of the network path (path *Maximum Transmission Unit* [MTU]). The path MTU is refreshed periodically to adjust to any changes that may occur within the network while the TCP connection is active.
- *Rate adaptation:* TCP is also a rate-adaptive protocol, in that the rate of data transfer is intended to adapt to the prevailing load conditions within the network and adapt to the processing capacity of the receiver. There is no predetermined TCP data-transfer rate; if the network and the receiver both have additional available capacity, a TCP sender will attempt to inject more data into the network to take up this available space. Conversely, if there is congestion, a TCP sender will reduce its sending rate to allow the network to recover. This adaptation function attempts to achieve the highest possible data-transfer rate without triggering consistent data loss.

The TCP Protocol Header

The TCP header structure, shown in Figure 1, uses a pair of 16-bit source and destination *Port* addresses. The next field is a 32-bit *sequence number,* which identifies the sequence number of the first data octet in this packet. The sequence number does not start at an initial value of 1 for each new TCP connection; the selection of an initial value is critical, because the initial value is intended to prevent delayed data

from an old connection from being incorrectly interpreted as being valid within a current connection. The sequence number is necessary to ensure that arriving packets can be ordered in the sender's original order. This field is also used within the flow-control structure to allow the association of a data packet with its corresponding acknowledgement, allowing a sender to estimate the current round-trip time across the network.

Figure 1: The TCP/IP Datagram



The *acknowledgment sequence number* is used to inform the remote end of the data that has been successfully received. The acknowledgment sequence number is actually one greater than that of the last octet correctly received at the local end of the connection. The *data offset* field indicates the number of four-octet words within the TCP header. Six single *bit flags* are used to indicate various conditions. URG is used to indicate whether the *urgent pointer* is valid. ACK is used to indicate whether the *acknowledgment* field is valid. PSH is set when the sender wants the remote application to *push* this data to the remote application. RST is used to *reset* the connection. SYN (for *synchronize)* is used within the connection startup phase, and FIN (for *finish*) is used to close the connection in an orderly fashion. The *window* field is a 16-bit count of available buffer space. It is added to the acknowledgment sequence number to indicate the highest sequence number the receiver can accept. The TCP *checksum* is applied to a synthesized header that includes the source and destination addresses from the outer IP datagram. The final field in the TCP header is the *urgent pointer*, which, when added to the sequence number, indicates the sequence number of the final octet of urgent data if the urgent flag is set.

Many options can be carried in a TCP header. Those relevant to TCP performance include:

- *Maximum-receive-segment-size option:* This option is used when the connection is being opened. It is intended to inform the remote end of the maximum segment size, measured in octets, that the sender is willing to receive on the TCP connection. This option is used only in the initial SYN packet (the initial packet exchange that opens a TCP connection). It sets both the maximum receive segment size and the maximum size of the advertised TCP window, passed to the remote end of the connection. In a robust implementation of TCP, this option should be used with path MTU discovery to establish a segment size that can be passed across the connection without fragmentation, an essential attribute of a high-performance data flow.
- *Window-scale option:* This option is intended to address the issue of the maximum window size in the face of paths that exhibit a high-delay bandwidth product. This option allows the window size advertisement to be right-shifted by the amount specified (in binary arithmetic, a right-shift corresponds to a multiplication by 2). Without this option, the maximum window size that can be advertised is 65,535 bytes (the maximum value obtainable in a 16-bit field). The limit of TCP transfer speed is effectively one window size in transit between the sender and the receiver. For high-speed, long-delay networks, this performance limitation is a significant factor, because it limits the transfer rate to at most 65,535 bytes per round-trip interval, regardless of available network capacity. Use of the window-scale option allows the TCP sender to effectively adapt to high-bandwidth, high-delay network paths, by allowing more data to be held in flight. The maximum window size with this option is 2^{30} bytes. This option is negotiated at the start of the TCP connection, and can be sent in a packet only with the SYN flag. Note that while an MTU discovery process allows optimal setting of the maximum-receive-segment-size option, no corresponding bandwidth delay product discovery allows the reliable automated setting of the window-scale option[3].
- *SACK-permitted option and SACK option:* This option alters the acknowledgment behavior of TCP. SACK is an acronym for *selective acknowledgment*. The SACK-permitted option is offered to the remote end during TCP setup as an option to an opening SYN packet. The SACK option permits selective acknowledgment of permitted data. The default TCP acknowledgment behavior is to acknowledge the highest sequence number of in-order bytes. This default behavior is prone to cause unnecessary retransmission of data, which can exacerbate a congestion condition that may have been the cause of the original packet loss. The SACK option allows the receiver to modify the acknowledgment field to describe noncontinuous blocks of received data, so that the sender can retransmit only what is missing at the receiver's end[4].

Any robust high-performance implementation of TCP should negotiate these parameters at the start of the TCP session, ensuring the following: that the session is using the largest possible IP packet size that can be carried without fragmentation, that the window sizes used in the transfer are adequate for the bandwidth-delay product of the network path, and that selective acknowledgment can be used for rapid recovery from line-error conditions or from short periods of marginally degraded network performance.

TCP Operation

The first phase of a TCP session is establishment of the connection. This requires a *three-way handshake*, ensuring that both sides of the connection have an unambiguous understanding of the sequence number space of the remote side for this session. The operation of the connection is as follows:

- The local system sends the remote end an initial sequence number to the remote port, using a SYN packet.
- The remote system responds with an ACK of the initial sequence number and the initial sequence number of the remote end in a response SYN packet.
- The local end responds with an ACK of this remote sequence number.

The connection is opened.

The operation of this algorithm is shown in Figure 2. The performance implication of this protocol exchange is that it takes one and a half *round-trip times* (RTTs) for the two systems to synchronize state before any data can be sent.

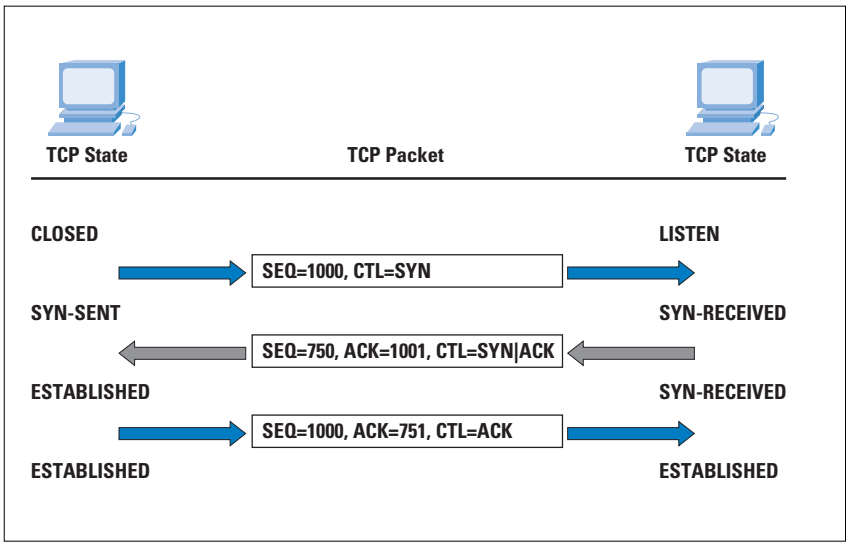


Figure 2: TCP Connection Handshake

After the connection has been established, the TCP protocol manages the reliable exchange of data between the two systems. The algorithms that determine the various retransmission timers have been redefined numerous times. TCP is a *sliding-window* protocol, and the general principle of flow control is based on the management of the advertised window size and the management of retransmission timeouts, attempting to optimize protocol performance within the observed delay and loss parameters of the connection. Tuning a TCP protocol stack for optimal performance over a very low-delay, high-bandwidth LAN requires different settings to obtain optimal performance over a dialup Internet connection, which in turn is different for the requirements of a high-speed wide-area network. Although TCP attempts to discover the delay bandwidth product of the connection, and attempts to automatically optimize its flow rates within the estimated parameters of the network path, some estimates will not be accurate, and the corresponding efforts by TCP to optimize behavior may not be completely successful.

Another critical aspect is that TCP is an adaptive flow-control protocol. TCP uses a basic flow-control algorithm of increasing the data-flow rate until the network signals that some form of saturation level has been reached (normally indicated by data loss). When the sender receives an indication of data loss, the TCP flow rate is reduced; when reliable transmission is reestablished, the flow rate slowly increases again.

If no reliable flow is reestablished, the flow rate backs further off to an initial probe of a single packet, and the entire adaptive flow-control process starts again.

This process has numerous results relevant to service quality. First, TCP behaves *adaptively*, rather than *predictively*. The flow-control algorithms are intended to increase the data-flow rate to fill all available network path capacity, but they are also intended to quickly back off if the available capacity changes because of interaction with other traffic, or if a dynamic change occurs in the end-to-end network path. For example, a single TCP flow across an otherwise idle network attempts to fill the network path with data, optimizing the flow rate within the available network capacity. If a second TCP flow opens up across the same path, the two flow-control algorithms will interact so that both flows will stabilize to use approximately half of the available capacity per flow. The objective of the TCP algorithms is to adapt so that the network is fully used whenever one or more data flows are present. In design, tension always exists between the efficiency of network use and the enforcement of predictable session performance. With TCP, you give up predictable throughput but gain a highly utilized, efficient network.

Protocol Performance

In this section we examine the transfer of data using the TCP protocol, focusing on the relationship between the protocol and performance. TCP is generally used within two distinct application areas: short-delay short data packets sent on demand, to support interactive applications such as *Telnet*, or *rlogin*, and large packet data streams supporting reliable volume data transfers, such as mail transfers, Web-page transfers, and *File Transfer Protocol* (FTP). Different protocol mechanisms come into play to support interactive applications, as distinct from short- and long-held volume transactions.

Interactive TCP

Interactive protocols are typically directed at supporting single-character interactions, where each character is carried in a single packet, as is its echo. The protocol interaction to support this is indicated in Figure 3. These 2 bytes of data generate four TCP/IP packets, or 160 bytes of protocol overhead. TCP makes some small improvement in this exchange through the use of *piggybacking*, where an ACK is carried in the same packet as the data, and *delayed acknowledgment*, where an ACK is delayed up to 200 ms before sending, to give the server application the opportunity to generate data that the ACK can piggyback. The resultant protocol exchange is indicated in Figure 4.

Figure 3: Interactive Exchange

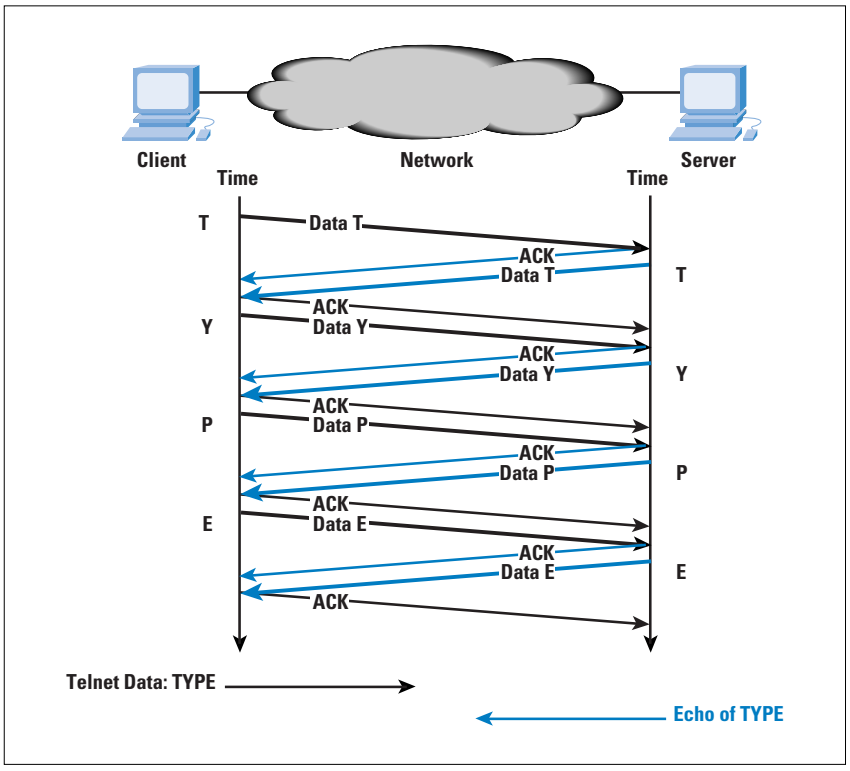

Figure 4:
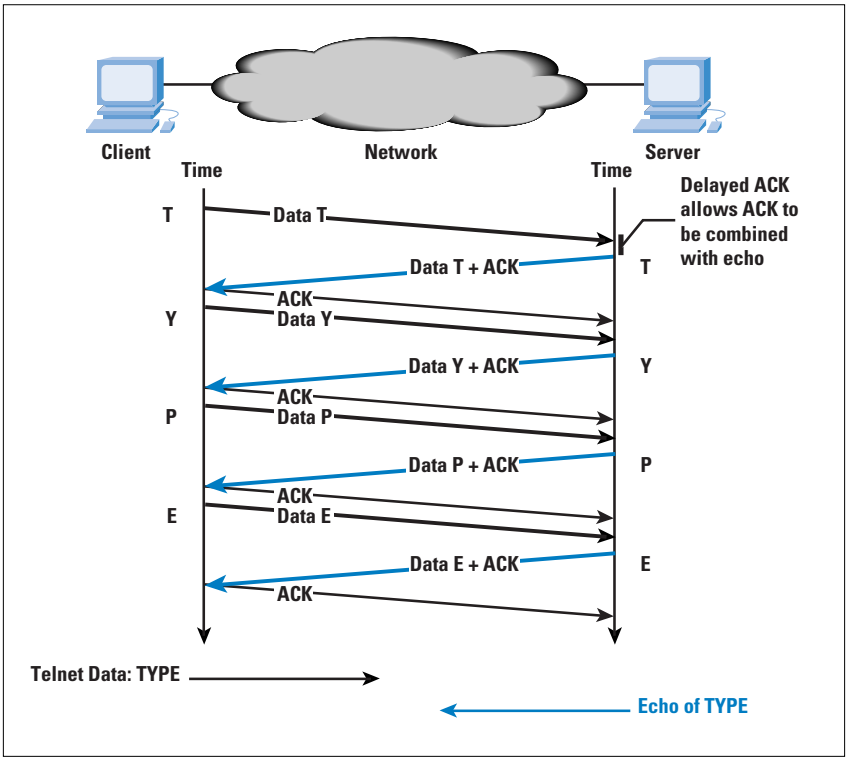
Interactive Exchange
with Delayed ACK



For short-delay LANs, this protocol exchange offers acceptable performance. This protocol exchange for a single data character and its echo occurs within about 16 ms on an Ethernet LAN, corresponding to an interactive rate of 60 characters per second. When the network delay is increased in a WAN, these small packets can be a source of congestion load. The TCP mechanism to address this small-packet congestion was described by John Nagle in RFC 896[5]. Commonly referred to as the *Nagle Algorithm*, this mechanism inhibits a sender from transmitting any additional small segments while the TCP connection has outstanding unacknowledged small segments. On a LAN, this modification to the algorithm has a negligible effect; in contrast, on a WAN, it has a dramatic effect in reducing the number of small packets in direct correlation to the network path congestion level (as shown in Figures 5 and 6). The cost is an increase in session jitter by up to a round-trip time interval. Applications that are jitter-sensitive typically disable this control algorithm.

TCP is not a highly efficient protocol for the transmission of interactive traffic. The typical carriage efficiency of the protocol across a LAN is 2 bytes of payload and 120 bytes of protocol overhead. Across a WAN, the Nagle algorithm may improve this carriage efficiency slightly by increasing the number of bytes of payload for each payload transaction, although it will do so at the expense of increased session jitter.

Figure 5: WAN Interactive Exchange

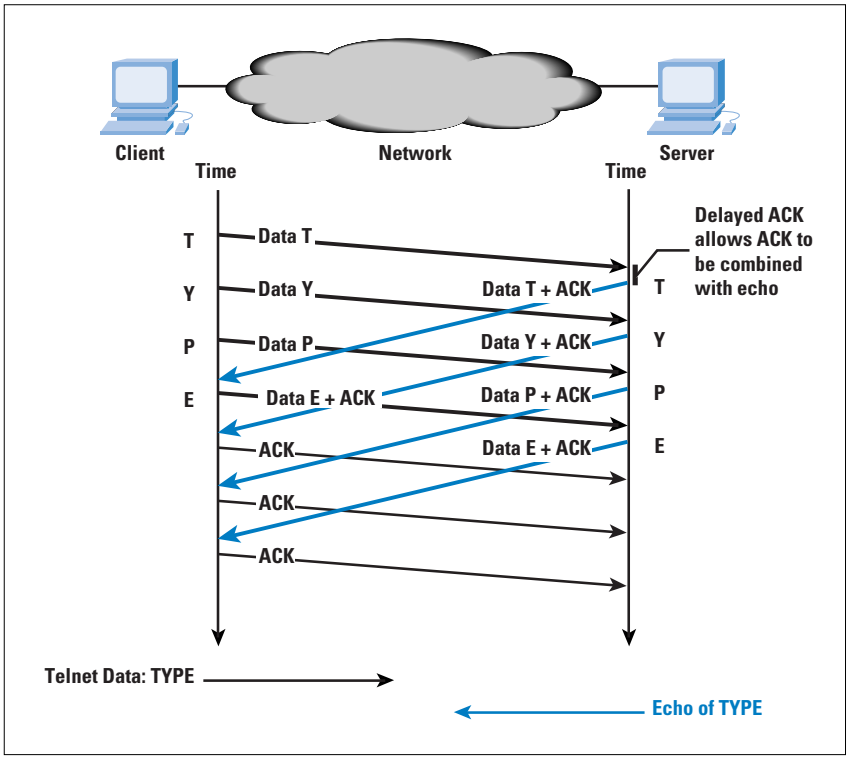


Figure 6: WAN Interactive Exchange with Nagle Algorithm

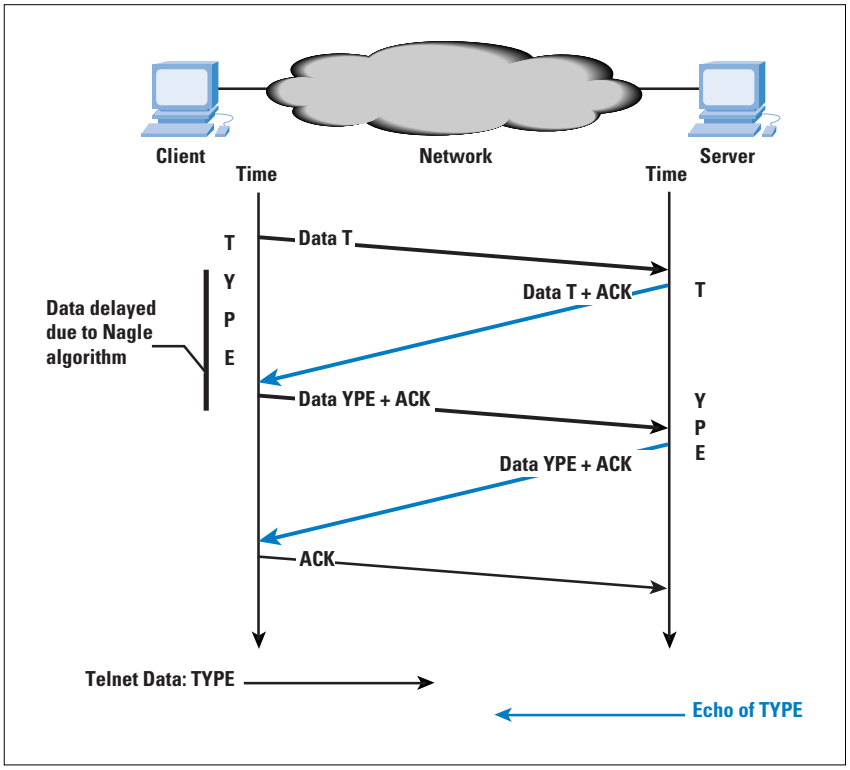


TCP Volume Transfer

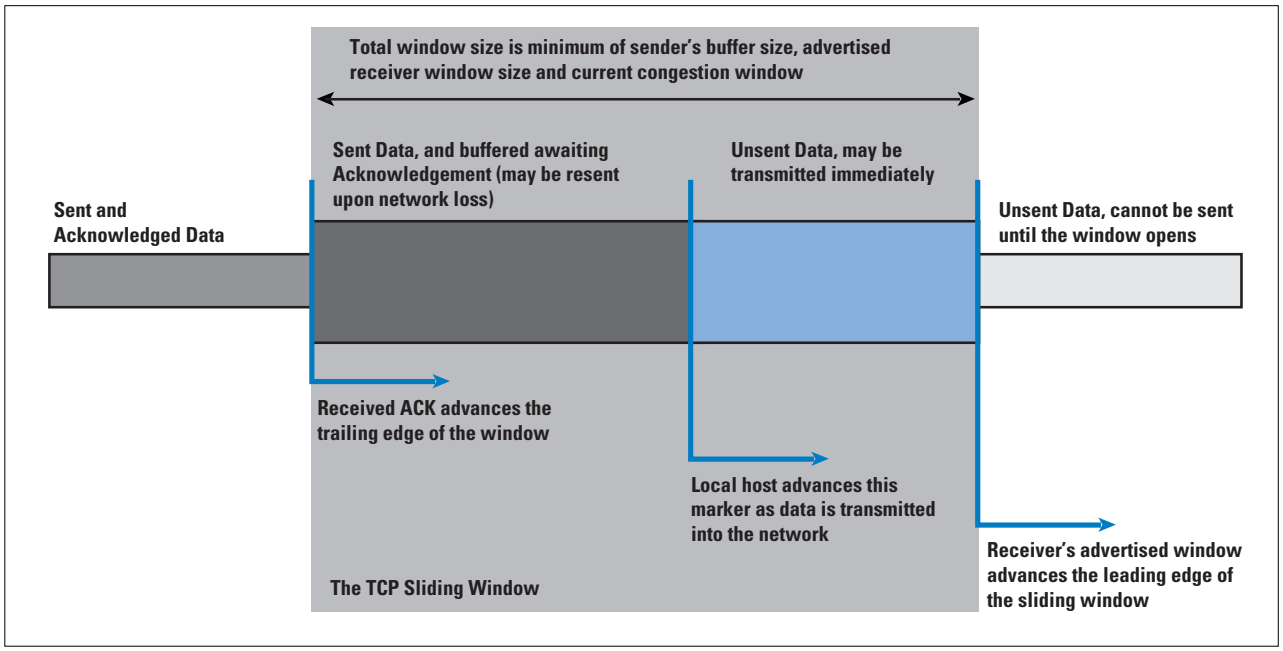
The objective for this application is to maximize the efficiency of the data transfer, implying that TCP should endeavor to locate the point of dynamic equilibrium of maximum network efficiency, where the sending data rate is maximized just prior to the onset of sustained packet loss.

Further increasing the sending rate from such a point will run the risk of generating a congestion condition within the network, with rapidly increasing packet-loss levels. This, in turn, will force the TCP protocol to retransmit the lost data, resulting in reduced data-transfer efficiency. On the other hand, attempting to completely eliminate packet-loss rates implies that the sender must reduce the sending rate of data into the network so as not to create transient congestion conditions along the path to the receiver. Such an action will, in all probability, leave the network with idle capacity, resulting in inefficient use of available network resources.

The notion of a point of equilibrium is an important one. The objective of TCP is to coordinate the actions of the sender, the network, and the receiver so that the network path has sufficient data such that the network is not idle, but it is not so overloaded that a congestion backlog builds up and data loss occurs. Maintaining this point of equilibrium requires the sender and receiver to be synchronized so that the sender passes a packet into the network at precisely the same time as the receiver removes a packet from the network. If the sender attempts to exceed this equilibrium rate, network congestion will occur. If the sender attempts to reduce its rate, the efficiency of the network will drop.

TCP uses a sliding-window protocol to support bulk data transfer (Figure 7). The receiver advertises to the sender the available buffer space at the receiver. The sender can transmit up to this amount of data before having to await a further buffer update from the receiver. The sender should have no more than this amount of data in transit in the network. The sender must also buffer sent data until it has been ACKed by the receiver. The send window is the minimum of the sender's buffer size and the advertised receiver window. Each time an ACK is received, the trailing edge of the send window is advanced. The minimum of the sender's buffer and the advertised receiver's window is used to calculate a new leading edge. If this send window encompasses unsent data, this data can be sent immediately.

Figure 7: TCP Sliding Window



The size of TCP buffers in each host is a critical limitation to performance in WANs. The protocol is capable of transferring one send window of data per round-trip interval. For example, with a send window of 4096 bytes and a transmission path with an RTT of 600 ms, a TCP session is capable of sustaining a maximum transfer rate of 48 Kbps, regardless of the bandwidth of the network path. Maximum efficiency of the transfer is obtained only if the sender is capable of completely filling the network path with data. Because the sender will have an amount of data in forward transit and an equivalent amount of data awaiting reception of an ACK signal, both the sender's buffer and the receiver's advertised window should be no smaller than the *Delay-Bandwidth Product* of the network path. That is:

$$\textit{Window size} \geq \textit{Bandwidth (bytes/sec)} \times \textit{Round-trip time (sec)}$$

The 16-bit field within the TCP header can contain values up to 65,535, imposing an upper limit on the available window size of 65,535 bytes. This imposes an upper limit on TCP performance of some 64 KB per RTT, even when both end systems have arbitrarily large send and receive buffers. This limit can be modified by the use of a window-scale option, described in RFC 1323, effectively increasing the size of the window to a 30-bit field, but transmitting only the most significant 16 bits of the value. This allows the sender and receiver to use buffer sizes that can operate efficiently at speeds that encompass most of the current very-high-speed network transmission technologies across distances of the scale of the terrestrial intercontinental cable systems.

Although the maximum window size and the RTT together determine the maximum achievable data-transfer rate, there is an additional element of flow control required for TCP. If a TCP session commenced by injecting a full window of data into the network, then there is a strong probability that much of the initial burst of data would be lost because of transient congestion, particularly if a large window is being used. Instead, TCP adopts a more conservative approach by starting with a modest amount of data that has a high probability of successful transmission, and then probing the network with increasing amounts of data for as long as the network does not show signs of congestion. When congestion is experienced, the sending rate is dropped and the probing for additional capacity is resumed.

The dynamic operation of the window is a critical component of TCP performance for volume transfer. The mechanics of the protocol involve an additional overriding modifier of the sender's window, the *congestion window,* referred to as *cwnd*. The objective of the window-management algorithm is to start transmitting at a rate that has a very low probability of packet loss, then to increase the rate (by increasing the *cwnd* size) until the sender receives an indication, through the detection of packet loss, that the rate has exceeded the available capacity of the network. The sender then immediately halves its sending rate by reducing the value of *cwnd,* and resumes a gradual increase of the sending rate. The goal is to continually modify the sending rate such that it oscillates around the true value of available network capacity. This oscillation enables a dynamic adjustment that automatically senses any increase or decrease in available capacity through the lifetime of the data flow.

The intended outcome is that of a dynamically adjusting cooperative data flow, where a combination of such flows behaves fairly, in that each flow obtains essentially a fair share of the network, and so that close to maximal use of available network resources is made. This flow-control functionality is achieved through a combination of *cwnd* value management and packet-loss and retransmission algorithms. TCP flow control has three major parts: the flow-control modes of *Slow Start* and *Congestion Avoidance,* and the response to packet loss that determines how TCP switches between these two modes of operation.

TCP Slow Start

The starting value of the *cwnd* window (the *Initial Window,* or IW) is set to that of the *Sender Maximum Segment Size* (SMSS) value. This SMSS value is based on the receiver's maximum segment size, obtained during the SYN handshake, the discovered path MTU (if used), the MTU of the sending interface, or, in the absence of other information, 536 bytes. The sender then enters a flow-control mode termed *Slow Start*.

The sender sends a single data segment, and because the window is now full, it then awaits the corresponding ACK. When the ACK is received, the sender increases its window by increasing the value of *cwnd* by the value of SMSS. This then allows the sender to transmit two segments; at that point, the congestion window is again full, and the sender must await the corresponding ACKs for these segments. This algorithm continues by increasing the value of *cwnd* (and, correspondingly, opening the size of the congestion window) by one SMSS for every ACK received that acknowledges new data.

If the receiver is sending an ACK for every packet, the effect of this algorithm is that the data rate of the sender doubles every round-trip time interval. If the receiver supports delayed ACKs, the rate of increase will be slightly lower, but nevertheless the rate will increase by a minimum of one SMSS each round-trip time. Obviously, this cannot be sustained indefinitely. Either the value of *cwnd* will exceed the advertised receive window or the sender's window, or the capacity of the network will be exceeded, in which case packets will be lost.

There is another limit to the slow-start rate increase, maintained in a variable termed *ssthresh*, or *Slow-Start Threshold*. If the value of *cwnd* increases past the value of *ssthresh,* the TCP flow-control mode is changed from Slow Start to congestion avoidance. Initially the value of *ssthresh* is set to the receiver's maximum window size. However, when congestion is noted, *ssthresh* is set to half the current window size, providing TCP with a memory of the point where the onset of network congestion may be anticipated in future.

One aspect to highlight concerns the interaction of the slow-start algorithm with high-capacity long-delay networks, the so-called *Long Fat Networks* (or LFNs, pronounced "elephants"). The behavior of the slow-start algorithm is to send a single packet, await an ACK, then send two packets, and await the corresponding ACKs, and so on. The TCP activity on LFNs tends to cluster at each epoch of the round-trip time, with a quiet period that follows after the available window of data has been transmitted. The received ACKs arrive back at the sender with an inter-ACK spacing that is equivalent to the data rate of the bottleneck point on the network path. During Slow Start, the sender transmits at a rate equal to twice this bottleneck rate. The rate adaptation function that must occur within the network takes place in the router at the entrance to the bottleneck point. The sender's packets arrive at this router at twice the rate of egress from the router, and the router stores the overflow within its internal buffer. When this buffer overflows, packets will be dropped, and the slow-start phase is over. The important conclusion is that the sender will stop increasing its data rate when there is buffer exhaustion, a condition that may not be the same as reaching the true available data rate. If the router has a buffer capacity considerably less than the delay-bandwidth product of the egress circuit, the two values are certainly not the same.

In this case, the TCP slow-start algorithm will finish with a sending rate that is well below the actual available capacity. The efficient operation of TCP, particularly in LFNs, is critically reliant on adequately large buffers within the network routers.

Another aspect of Slow Start is the choice of a single segment as the initial sending window. Experimentation indicates that an initial value of up to four segments can allow for a more efficient session startup, particularly for those short-duration TCP sessions so prevalent with Web fetches[6]. Observation of Web traffic indicates an average Web data transfer of 17 segments. A slow start from one segment will take five RTT intervals to transfer this data, while using an initial value of four will reduce the transfer time to three RTT intervals. However, four segments may be too many when using low-speed links with limited buffers, so a more robust approach is to use an initial value of no more than two segments to commence Slow Start[7].

Packet Loss

Slow Start attempts to start a TCP session at a rate the network can support and then continually increase the rate. How does TCP know when to stop this increase? This slow-start rate increase stops when the congestion window exceeds the receiver's advertised window, when the rate exceeds the remembered value of the onset of congestion as recorded in *ssthresh,* or when the rate is greater than the network can sustain. Addressing the last condition, how does a TCP sender know that it is sending at a rate greater than the network can sustain? The answer is that this is shown by data packets being dropped by the network. In this case, TCP has to undertake many functions:

- The packet loss has to be detected by the sender.
- The missing data has to be retransmitted.
- The sending data rate should be adjusted to reduce the probability of further packet loss.

TCP can detect packet loss in two ways. First, if a single packet is lost within a sequence of packets, the successful delivery packets following the lost packet will cause the receiver to generate a *duplicate* ACK for each successive packet The reception of these duplicate ACKs is a signal of such packet loss. Second, if a packet is lost at the end of a sequence of sent packets, there are no following packets to generate duplicate ACKs. In this case, there are no corresponding ACKs for this packet, and the sender's retransmit timer will expire and the sender will assume packet loss.

A single duplicate ACK is not a reliable signal of packet loss. When a TCP receiver gets a data packet with an out-of-order TCP sequence value, the receiver must generate an immediate ACK of the highest in-order data byte received. This will be a duplicate of an earlier transmitted ACK. Where a single packet is lost from a sequence of packets, all subsequent packets will generate a duplicate ACK packet.

On the other hand, where a packet is rerouted with an additional incremental delay, the reordering of the packet stream at the receiver's end will generate a small number of duplicate ACKs, followed by an ACK of the entire data sequence, after the errant packet is received. The sender distinguishes between these cases by using three duplicate ACK packets as a signal of packet loss.

The third duplicate ACK triggers the sender to immediately send the segment referenced by the duplicate ACK value (*fast retransmit*) and commence a sequence termed *Fast Recovery*. In fast recovery, the value of *ssthresh* is set to half the current send window size (the send window is the amount of unacknowledged data outstanding). The congestion window, *cwnd,* is set three segments greater than *ssthresh* to allow for three segments already buffered at the receiver. If this allows additional data to be sent, then this is done. Each additional duplicate ACK inflates *cwnd* by a further segment size, allowing more data to be sent. When an ACK arrives that encompasses new data, the value of *cwnd* is set back to *ssthresh,* and TCP enters congestion-avoidance mode. Fast Recovery is intended to rapidly repair single packet loss, allowing the sender to continue to maintain the ACK-clocked data rate for new data while the packet loss repair is being undertaken. This is because there is still a sequence of ACKs arriving at the sender, so that the network is continuing to pass timing signals to the sender indicating the rate at which packets are arriving at the receiver. Only when the repair has been completed does the sender drop its window to the *ssthresh* value as part of the transition to congestion-avoidance mode[8].

The other signal of packet loss is a complete cessation of any ACK packets arriving to the sender. The sender cannot wait indefinitely for a delayed ACK, but must make the assumption at some point in time that the next unacknowledged data segment must be retransmitted. This is managed by the sender maintaining a *Retransmission Timer*. The maintenance of this timer has performance and efficiency implications. If the timer triggers too early, the sender will push duplicate data into the network unnecessarily. If the timer triggers too slowly, the sender will remain idle for too long, unnecessarily slowing down the flow of data. The TCP sender uses a timer to measure the elapsed time between sending a data segment and receiving the corresponding acknowledgment. Individual measurements of this time interval will exhibit significant variance, and implementations of TCP use a smoothing function when updating the retransmission timer of the flow with each measurement. The commonly used algorithm was originally described by Van Jacobson[9], modified so that the retransmission timer is set to the smoothed round-trip-time value, plus four times a smoothed mean deviation factor[10].

When the retransmission timer expires, the actions are similar to that of duplicate ACK packets, in that the sender must reduce its sending rate in response to congestion. The threshold value, *ssthresh,* is set to half of the current value of outstanding unacknowledged data, as in the duplicate ACK case. However, the sender cannot make any valid assumptions about the current state of the network, given that no useful information has been provided to the sender for more than one RTT interval. In this case, the sender closes the congestion window back to one segment, and restarts the flow in slow start-mode by sending a single segment. The difference from the initial slow start is that, in this case, the *ssthresh* value is set so that the sender will probe the congestion area more slowly using a linear sending rate increase when the congestion window reaches the remembered *ssthresh* value.

Congestion Avoidance

Compared to Slow Start, congestion avoidance is a more tentative probing of the network to discover the point of threshold of packet loss. Where Slow Start uses an exponential increase in the sending rate to find a first-level approximation of the loss threshold, congestion avoidance uses a linear growth function.

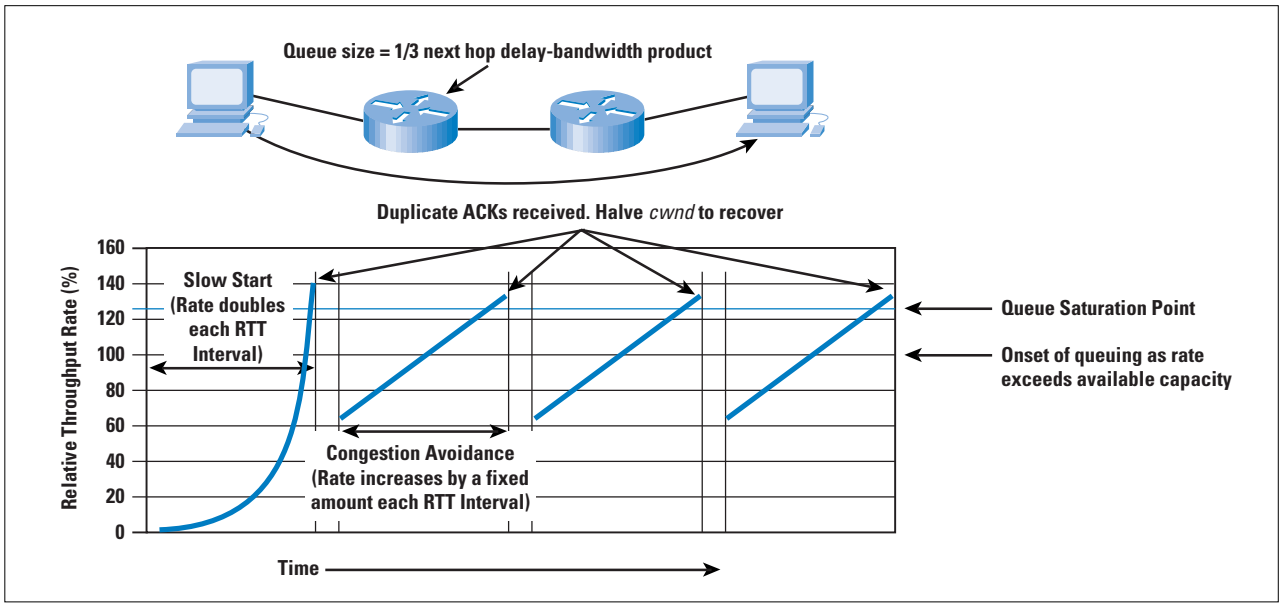
When the value of *cwnd* is greater than *ssthresh*, the sender increments the value of *cwnd* by the value *SMSS* × *SMSS/cwnd,* in response to each received nonduplicate ACK[7], ensuring that the congestion window opens by one segment within each RTT time interval.

The congestion window continues to open in this fashion until packet loss occurs. If the packet loss is isolated to a single packet within a packet sequence, the resultant duplicate ACKs will trigger the sender to halve the sending rate and continue a linear growth of the congestion window from this new point, as described above in fast recovery.

The behavior of *cwnd* in an idealized configuration is shown in Figure 8, along with the corresponding data-flow rates. The overall characteristics of the TCP algorithm are an initial relatively fast scan of the network capacity to establish the approximate bounds of maximal efficiency, followed by a cyclic mode of adaptive behavior that reacts quickly to congestion, and then slowly increases the sending rate across the area of maximal transfer efficiency.

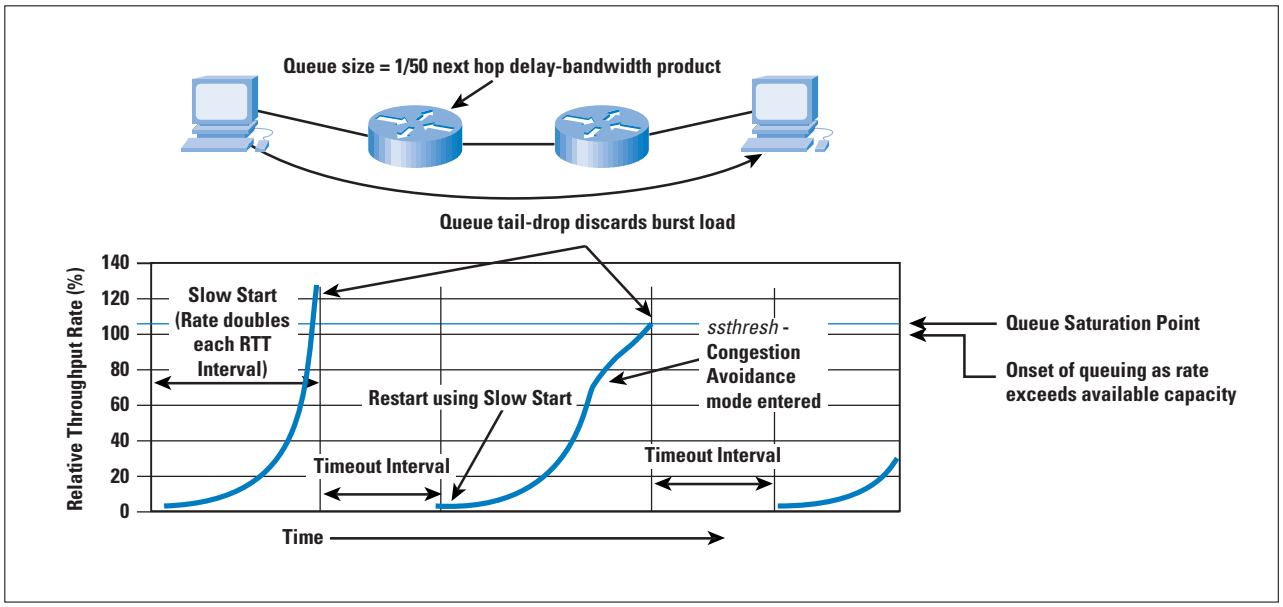
Packet loss, as signaled by the triggering of the retransmission timer, causes the sender to recommence slow-start mode, following a timeout interval. The corresponding data-flow rates are indicated in Figure 9.

Figure 8: Simulation of Single TCP Transfer



The inefficiency of this mode of performance is caused by the complete cessation of any form of flow signaling from the receiver to the sender. In the absence of any information, the sender can only assume that the network is heavily congested, and so must restart its probing of the network capacity with an initial congestion window of a single segment. This leads to the performance observation that any form of packet-drop management that tends to discard the trailing end of a sequence of data packets may cause significant TCP performance degradation, because such drop behavior forces the TCP session to continually time out and restart the flow from a single segment again.

Figure 9: Simulation of TCP Transfer with Tail Drop Queue

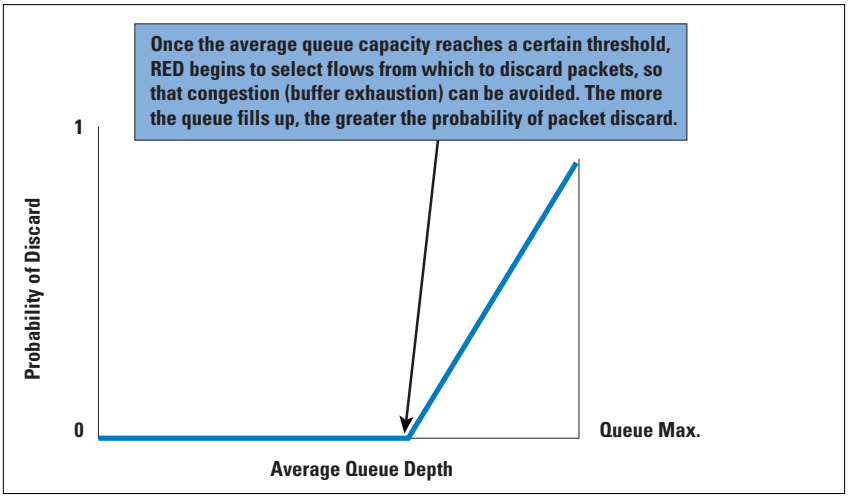


Assisting TCP Performance within the Network—RED and ECN

Although TCP is an end-to-end protocol, it is possible for the network to assist TCP in optimizing performance. One approach is to alter the queue behaviour of the network through the use of *Random Early Detection* (RED). RED permits a network router to discard a packet even when there is additional space in the queue. Although this may sound inefficient, the interaction between this early packet-drop behaviour and TCP is very effective.

RED uses a the weighted average queue length as the probability factor for packet drop. As the average queue length increases, the probability of a packet being dropped, rather than being queued, increases. As the queue length decreases, so does the packet-drop probability. (See Figure 10). Small packet bursts can pass through a RED filter relatively intact, while larger packet bursts will experience increasingly higher packet-discard rates. Sustained load will further increase the packet-discard rates. This implies that the TCP sessions with the largest open windows will have a higher probability of experiencing packet drop, causing a back-off in the window size.

Figure 10: RED Behavior



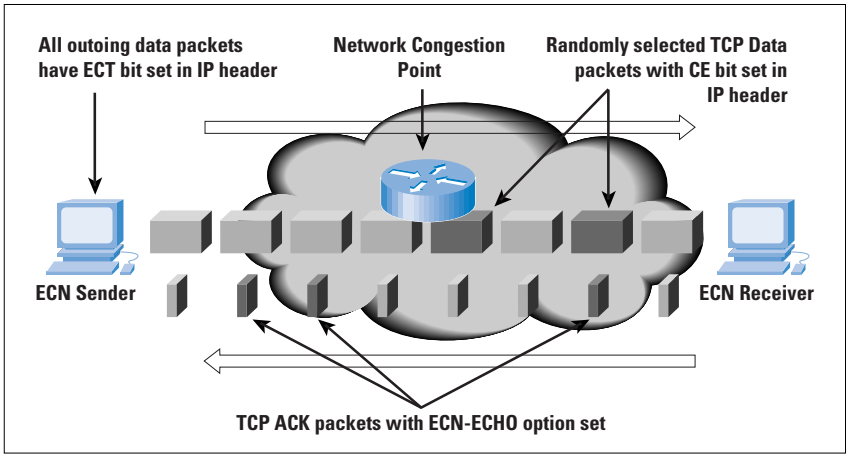
A major goal of RED is to avoid a situation in which all TCP flows experience congestion at the same time, all then back off and resume at the same rate, and tend to synchronize their behaviour[11,12]. With RED, the larger bursting flows experience a higher probability of packet drop, while flows with smaller burst rates can continue without undue impact. RED is also intended to reduce the incidence of complete loss of ACK signals, leading to timeout and session restart in slow-start mode. The intent is to signal the heaviest bursting TCP sessions the likelihood of pending queue saturation and tail drop before the onset of such a tail-drop congestion condition, allowing the TCP session to undertake a fast retransmit recovery under conditions of congestion avoidance. Another objective of RED is to allow the queue to operate efficiently, with the queue depth ranging across the entire queue size within a timescale of queue depth oscillation the same order as the average RTT of the traffic flows.

Behind RED is the observation that TCP sets very few assumptions about the networks over which it must operate, and that it cannot count on any consistent performance feedback signal being generated by the network. As a minimal approach, TCP uses packet loss as its performance signal, interpreting small-scale packet-loss events as peak load congestion events and extended packet loss events as a sign of more critical congestion load. RED attempts to increase the number of small-scale congestion signals, and in so doing avoid long-period sustained congestion conditions.

It is not necessary for RED to discard the randomly selected packet. The intent of RED is to signal the sender that there is the potential for queue exhaustion, and that the sender should adapt to this condition. An alternative mechanism is for the router experiencing the load to mark packets with an explicit *Congestion Experienced* (CE) bit flag, on the assumption that the sender will see and react to this flag setting in a manner comparable to its response to single packet drop[13] [14]. This mechanism, *Explicit Congestion Notification* (ECN), uses a 2-bit scheme, claiming bits 6 and 7 of the IP Version 4 *Type-of-Service* (ToS) field (or the two *Currently Unused* [CU] bits of the IP *Differentiated Services* field). Bit 6 is set by the sender to indicate that it is an ECN-capable transport system (the ECT bit). Bit 7 is the CE bit, and is set by a router when the average queue length exceeds configured threshold levels.

The ECN algorithm is that an active router will perform RED, as described. After a packet has been selected, the router may mark the CE bit of the packet if the ECT bit is set; otherwise, it will discard the selected packet. (See Figure 11).

Figure 11: Operation of Explicit Congestion Notification



The TCP interaction is slightly more involved. The initial TCP SYN handshake includes the addition of ECN-echo capability and *Congestion Window Reduced* (CWR) capability flags to allow each system to negotiate with its peer as to whether it will properly handle packets with the CE bit set during the data transfer. The sender sets the ECT bit in all packets sent. If the sender receives a TCP packet with the ECN-echo flag set in the TCP header, the sender will adjust its congestion window as if it had undergone fast recovery from a single lost packet.

The next sent packet will set the TCP CWR flag, to indicate to the receiver that it has reacted to the congestion. The additional caveat is that the sender will react in this way at most once every RTT interval. Further, TCP packets with the ECN-echo flag set will have no further effect on the sender within the same RTT interval. The receiver will set the ECN-echo flag in all packets when it receives a packet with the CE bit set. This will continue until it receives a packet with the CWR bit set, indicating that the sender has reacted to the congestion. The ECT flag is set only in packets that contain a data payload. TCP ACK packets that contain no data payload should be sent with the ECT bit clear.

The connection does not have to await the reception of three duplicate ACKs to detect the congestion condition. Instead, the receiver is notified of the incipient congestion condition through the explicit setting of a notification bit, which is in turn echoed back to the sender in the corresponding ACK. Simulations of ECN using a RED marking function indicate slightly superior throughput in comparison to configuring RED as a packet-discard function.

However, widespread deployment of ECN is not considered likely in the near future, at least in the context of Version 4 of IP. At this stage, there has been no explicit standardization of the field within the IPv4 header to carry this information, and the deployment base of IP is now so wide that any modifications to the semantics of fields in the IPv4 header would need to be very carefully considered to ensure that the changed field interpretation did not exercise some malformed behavior in older versions of the TCP stack or in older router software implementations.

ECN provides some level of performance improvement over a packet-drop RED scheme. With large bulk data transfers, the improvement is moderate, based on the difference between the packet retransmission and congestion-window adjustment of RED and the congestion-window adjustment of ECN. The most notable improvements indicated in ECN simulation experiments occur with short TCP transactions (commonly seen in Web transactions), where a RED packet drop of the initial data packet may cause a six-second retransmit delay. Comparatively, the ECN approach allows the transfer to proceed without this lengthy delay.

The major issue with ECN is the need to change the operation of both the routers and the TCP software stacks to accommodate the operation of ECN. While the ECN proposal is carefully constructed to allow an essentially uncoordinated introduction into the Internet without negative side effects, the effectiveness of ECN in improving overall network throughput will be apparent only after this approach has been widely adopted. As the Internet grows, its inertial mass generates a natural resistance to further technological change; therefore, it may be some years before ECN is widely adopted in both host software and Internet routing systems. RED, on the other hand, has had a more rapid introduction to the Internet, because it requires only a local modification to router behavior, and relies on existing TCP behavior to react to the packet drop.

Tuning TCP

How can the host optimize its TCP stack for optimum performance? Many recommendations can be considered. The following suggestions are a combination of those measures that have been well studied and are known to improve TCP performance, and those that appear to be highly productive areas of further research and investigation[1].

- *Use a good TCP protocol stack:* Many of the performance pathologies that exist in the network today are not necessarily the by-product of oversubscribed networks and consequent congestion. Many of these performance pathologies exist because of poor implementations of TCP flow-control algorithms; inadequate buffers within the receiver; poor (or no) use of path-MTU discovery; no support for fast-retransmit flow recovery, no use of window scaling and SACK, imprecise use of protocol-required timers, and very coarse-grained timers. It is unclear whether network ingress-imposed Quality-of-Service (QoS) structures will adequately compensate for such implementation deficiencies. The conclusion is that attempting to address the symptoms is not the same as curing the disease. A good protocol stack can produce even better results in the right environment.
- *Implement a TCP Selective Acknowledgment (SACK) mechanism:* SACK, combined with a selective repeat-transmission policy, can help overcome the limitation that traditional TCP experiences when a sender can learn only about a single lost packet per RTT.
- *Implement larger buffers with TCP window-scaling options:* The TCP flow algorithm attempts to work at a data rate that is the minimum of the delay-bandwidth product of the end-to-end network path and the available buffer space of the sender. Larger buffers at the sender and the receiver assist the sender in adapting more efficiently to a wider diversity of network paths by permitting a larger volume of traffic to be placed in flight across the end-to-end path.
- *Support TCP ECN negotiation:* ECN enables the host to be explicitly informed of conditions relating to the onset of congestion without having to infer such a condition from the reserve stream of ACK packets from the receiver. The host can react to such a condition promptly and effectively with a data flow-control response without having to invoke packet retransmission.
- *Use a higher initial TCP slow-start rate than the current 1 MSS (Maximum Segment Size) per RTT.* A size that seems feasible is an initial burst of 2 MSS segments. The assumption is that there will be adequate queuing capability to manage this initial packet burst; the provision to back off the send window to 1 MSS segment should remain intact to allow stable operation if the initial choice was too large for the path. A robust initial choice is two segments, although simulations have indicated that four initial segments is also highly effective in many situations.

- *Use a host platform that has sufficient processor and memory capacity to drive the network.* The highest-quality service network and optimally provisioned access circuits cannot compensate for a host system that does not have sufficient capacity to drive the service load. This is a condition that can be observed in large or very popular public Web servers, where the peak application load on the server drives the platform into a state of memory and processor exhaustion, even though the network itself has adequate resources to manage the traffic load.

All these actions have one thing in common: They can be deployed incrementally at the edge of the network and can be deployed individually. This allows end systems to obtain superior performance even in the absence of the network provider tuning the network's service response with various internal QoS mechanisms.

Conclusion

TCP is not a predictive protocol. It is an adaptive protocol that attempts to operate the network at the point of greatest efficiency. Tuning TCP is not a case of making TCP pass more packets into the network. Tuning TCP involves recognizing how TCP senses current network load conditions, working through the inevitable compromise between making TCP highly sensitive to transient network conditions, and making TCP resilient to what can be regarded as noise signals.

If the performance of end-to-end TCP is the perceived problem, the most effective answer is not necessarily to add QoS service differentiation into the network. Often, the greatest performance improvement can be made by upgrading the way that hosts and the network interact through the appropriate configuration of the host TCP stacks.

In the next article on this topic, we will examine how TCP is facing new challenges with increasing use of wireless, short-lived connections, and bandwidth-limited mobile devices, as well as the continuing effort for improved TCP performance. We'll look at a number of proposals to change the standard actions of TCP to meet these various requirements and how they would interact with the existing TCP protocol.

Overview of Internet Mail Standards

by Paul Hoffman, Internet Mail Consortium

People who are new to the Internet often think it is equivalent to "the Web" since that's what they have heard about most in the media. After a few weeks of using their new Internet account, they tend to say the Internet is "e-mail and the Web," in that order.

Business users have an even higher regard for e-mail. According to the American Management Association, most business people say that e-mail has surpassed the telephone in importance for business communication. While many companies believe that their Web site will be very important in a few years, their e-mail system is already extremely critical to them today.

Because mail is one of the oldest services on the Internet, the protocols used to move mail around are more stable and mature than those used for newer services. The flip side of this is that some of the protocols that are used to move the billions of pieces of mail a day are somewhat arcane and even quaint. The *Internet Engineering Task Force* (IETF) motto "if it isn't broken, don't fix it!" has prevented people from redesigning Internet mail. Instead, numerous extensions and enhancements have been added to the original set of mail standards, as we shall see later.

Historically, there have been many other mail systems, such as BITNET, Fidonet, MAPI, cc:Mail, and so on. Of course, users of these systems still exist, and there is quite an active market for systems that act as gateways between Internet mail and other systems. However, this article only covers the tried-and-true Internet mail system.

The Internet Mail Model

Many Internet protocols are simple client/server systems with a single message payload format. Mostly due to history, Internet mail doesn't have this luxury. Figure 1 shows the main protocols and formats used to move Internet mail.

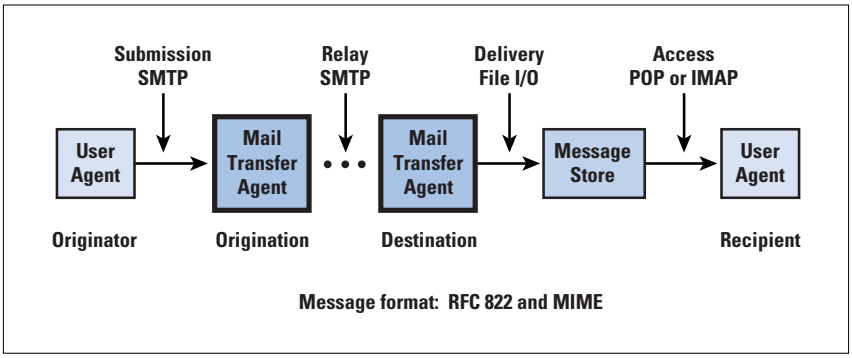

Figure 1: Internet Mail Architecture

A typical mail transaction goes from left to right in the figure. A *Mail User Agent* (MUA), which is most often run by a human but could be controlled by a program, submits a message using the *Simple Mail Transfer Protocol* (SMTP) to the initiating host. That host looks up the IP address associated with the destination host computer and sends the message to the destination host using SMTP. The destination host receives the message and writes it into the local message store (which almost always is a file or database on a hard drive).

The recipient MUA checks the mail store periodically and, if there is mail, retrieves it. Again, the recipient is often a human but might be an automated program such as an order entry system that is controlled by e-mail. The protocols that checks for and retrieves mail are usually the *Post Office Protocol* (POP) or *Internet Message Access Protocol* (IMAP), but it could also be any number of proprietary systems.

E-mail messages have a format that is quite easy to understand, so much so that many other protocols have adopted very similar formats. The message consists of ASCII text *headers* followed by one ASCII (or possibly binary) message *body*. The header format is defined in RFC 822[1], thus the headers are called "RFC 822 headers" or just "822 headers." A simple message body is a single string of text; a complex body uses the *Multipurpose Internet Mail Extensions* (MIME) message format.

Moving Between Hosts: SMTP

Early host-to-host mail delivery was done using file transfer protocols. Since such methods offer little flexibility and requires knowledge of user names and file structures of the remote system, a more general purpose delivery mechanism evolved. The resulting protocol, SMTP was defined in 1982 and has proven to work effectively in the face of orders of magnitude increase in the size of the network.

Even though SMTP moves mail between two host computers, it is a client/server protocol. The host that initiates the contact always acts as a *client,* and the host that was contacted is the *server*. (There are a few rarely-used exceptions to this rule.) The client has a variety of text-based commands that it can give, and the server replies with short responses. The server in the relationship never gives commands on its own, so it is up to the client to ask enough questions, and to carefully watch the server's responses, to know how best to interact with the server.

When a host wants to send mail somewhere on the Internet, it determines where the mail should go and initiates contact with the target server. Thus, the sender is always the SMTP client, and the hosts that are listening for SMTP traffic are always servers. In reality, most SMTP server software can act both as clients and servers; MUAs almost always only participate in SMTP as clients.

The sending host uses the *Domain Name System* (DNS) to determine the IP address of the target host, contacts that host using TCP port 25, and uses SMTP to deliver the message. Sometimes, as we shall see later, this IP lookup involves a level of indirection,—the target host may use a different host to receive mail on its behalf.

SMTP client commands consist of a keyword, possibly followed by command arguments. The server's response always starts with a three-digit number that is a status indicator, which is possibly followed by additional information.

Most SMTP interactions follow a typical set of steps, shown in Figure 2. The initiator who has mail to send (the client) is on the left and the host that is receiving the mail (the server) is on the right. The client first opens a TCP connection on port 25 on the the server. Next, the client and server exchange greetings (the HELO command and response). The client then prepares the server to receive the message by telling the server who the message is from and who it is to; the server gives a positive acknowledgment to each of these commands. The client then asks if the server is ready for the body of the message and, when the server says yes, sends the message as a stream of lines that is followed by a single period on a line by itself. After the server says that it has received the message fully, the client says good-bye and closes the connection.

Figure 2: A Typical SMTP Exchange

Client Action	*Server Response*
<connects to the server using TCP>	
	`220 example.com WhizzyMail server version 2.32`
`HELO somecompany.com`	
	`250-example.com says howdy`
`MAIL FROM:<chrisj@somecompany.com>`	
	`250 OK`
	`354 Start mail input; end with <CRLF>.<CRLF>`

`Text of message...`
`...more text of message...`
`.`	

	`250 OK`
`QUIT`	
	`221 example.com Service finished`
<disconnects from the server>	

Submission and Relay

After a message is created, the creator uses SMTP to submit the message to one of two places: a local mail-forwarding host (such as the mail server at the sender's *Internet Service Provider* (ISP) or corporate IS services) or the mail server that the DNS says is definitive for the recipient. The former is typically used by Internet users who do not have persistent network connections; the latter is more common on systems with network connections that are always available.

Messages may be forwarded hop-by-hop from the sending host, via intermediary hosts, to the recipient. This is called "relaying." In many cases, a message will go through more than two relays, for instance when the recipient's network is configured to accept all incoming messages on one machine that later relays messages to individual departmental hosts. Note that submission and relay uses the same SMTP commands described above (a recent change to this scheme is described near the end of this article).

The last host in the chain makes the message available to the recipient. This is done by moving the message to the message store, which usually means "write the message out on disk." There are, of course, many ways to write something on disk; some hosts write out each message as a separate file, some concatenate the message at the end of a file, while others write the message into a database.

Mail Addresses and MX Records

The initiating host's first job is to determine where a message is supposed to go, that is, how to contact the recipient's host. SMTP is a hop-by-hop protocol, meaning that a sending host does not know the true destination host for a message: it only knows the designated recipient host. Of course, this might be the recipient's final host, or it might be a host that will pass the message along further.

The domain name in mail addresses do not necessarily correspond to hosts on the Internet. For example, there is no host whose domain name is **`imc.org`**. When determining where to send a message, the initiating host first looks in the DNS for a *Mail Exchange* (MX) record that matches the domain name in the recipient's mail address. If there is no MX record, the initiating host looks for a DNS A record that matches the domain name. If there is no MX record or A record, the message cannot be delivered.

Many people find MX records to be somewhat tricky. Part of the confusion comes from the fact that an SMTP host is supposed to look up MX records before they look for A records; there are very few protocols that don't rely on A records. Another confusing aspect is that MX records may have wildcards in them. For instance, if a message is being sent to **`someone@eng.example.com`**, there may be no MX record for **`eng.example.com`**, but there may be one for **`*.example.com`**. Wildcard MX records tell the sending host that any message for a domain name that matches the wildcard specification should be sent to the named host.

Modern Mail Extensions

All protocols must evolve, and SMTP has improved over the years. Early mail implementors realized that the initial set of SMTP commands would have to expand. Since the SMTP client gives all commands in an exchange, the client determines which SMTP commands a server will be able to handle. The *SMTP Service Extension*s (ESMTP), defined in RFC 1869[2], is a small change to SMTP that allows an SMTP server to list the commands it knows at the beginning of an SMTP session.

The bootstrapping process for ESMTP is quite simple. Instead of starting with the "HELO" command, an ESMTP server starts with the "EHLO" command. If the SMTP host indicates that it has no idea what "EHLO" means, the client knows that the server doesn't understand ESMTP, and therefore doesn't understand any SMTP extensions. On the other hand, if the server does understand the "EHLO" greeting, the host responds with the entire list of SMTP extensions that the client is allowed to use during the session.

There have been over a dozen extensions to SMTP that are on standards track in the IETF, and many more have been proposed. However, most modern SMTP servers have only implemented a few of these.

Probably the most publicized SMTP extension in the past few years has been the *SMTP Service Extension for Authentication* (AUTH) for authenticating the SMTP client to the server. The AUTH extension, described in RFC 2554[3], allows roaming users to submit mail from outside their local networks without forcing the servers to accept mail from just anyone. This new method, which is now starting to appear in both mail clients and servers, will reduce the hassle faced by many roaming users as they move from ISP to ISP.

Another significant SMTP extension that has become widely implemented is *Delivery Status Notifications*, or DSNs defined in RFC 1891[4]. These are similar to return receipts in postal mail, but with some significant differences. DSNs are issued by SMTP servers, not end users. Thus, the meaning of a DSN is interpreted as "the message was received by this SMTP host," not "the message was received by the intended recipient."

Retrieving Mail

After the final SMTP server has received a message and written it into the message store, the recipient needs to be able to access the message. In the early days of Internet mail, the message store was nothing more than a text file on disk, and mail was read by reading the text file. In fact, many people still read their mail this way, albeit using somewhat more modern tools.

If the recipient is not directly logged into the host computer that has the message store, reading the disk file can be difficult. To alleviate this problem, the *Post Office Protocol* (POP), described in RFC 1939[5] introduced a client/server model for an MUA to get mail from the message store and store it on the local computer. The vast majority of mail users today use POP to retrieve their mail.

POP looks like many Internet protocols. The client connects to the server, logs in using a user name and password, checks if it has any messages waiting for it, then asks for the messages one by one. The client has the option of leaving messages that it has read on the server or deleting them after they have been retrieved.

Modern Mail Access with IMAP

Although POP works well for many people, it has its drawbacks. The mail client cannot preview a message to see whether or not it wants to download it. The client has only one mailbox which has no hierarchical structure. In most POP systems, leaving all your mail on the server makes retrieving new mail quite slow. To get around these problems, the mail community developed the *Internet Message Access Protocol* (IMAP), described in RFC 2060[6].

IMAP is significantly more powerful than POP. IMAP clients give the user much more control over their mail, such as letting them keep some of their mail locally while leaving other mail on the server. IMAP even allows for mailboxes that are shared among users, such as group announcements lists. It also gives mail administrators many more opportunities to support novice users by keeping their mail in a central location. Most modern mail clients support IMAP, and IMAP servers are available from many vendors.

It should be noted that, although IMAP is considered much more useful than POP and is widely available, it has had very little adoption in the ISP market (it has been accepted much more readily in the enterprise mail market). The reasons for this are not clear. Many ISPs say they do not want to incur the costs and responsibilities of storing users' mail, even if this gives them greater ability to administer the mail. It is not clear what, if anything, will shift ISPs away from POP to IMAP.

Access Through Web Browsers

The ubiquity of the Web has introduced a new method for getting mail that has become surprisingly popular: the use of the *HyperText Transfer Protocol* (HTTP). Web access to e-mail lets users read their mail without a POP or IMAP client. Of course, this offers many fewer features than POP or IMAP; for instance, you can't easily store messages after reading them and getting file attachments in your mail takes many more steps. However, the big advantage of this method is that Web browsers are almost everywhere these days, and there are many situations where you don't care about being able to store your mail on your local computer.

Giving users Web browser access to their mail quickly became a commodity market. Now, almost every portal offers such services. In fact, many corporations and ISP also offer this service because it is a fairly easy add-on to POP and IMAP servers. As more and more users want to access their e-mail from small devices such as cellular phones, it is likely that these devices will include Web-like mail interfaces.

Client Extensions

Both POP and IMAP are extensible, and developers have proposed many extensions for both protocols, although most work is being done on IMAP. Because of the slow adoption of IMAP by ISPs (who could make its advantages much more visible), it's not clear when these will appear in clients and servers, even though many of them add interesting functionality that is wanted by both users and administrators.

There are many client extensions that don't rely on either POP or IMAP, however. One of the most popular is *Message Disposition Notifications* (MDNs), which are quite similar to postal return receipts. Unlike DSNs, which say that a particular message got to one of the servers in an SMTP chain, MDNs are truly end-to-end, and are returned by recipients when they open their mail.

Some people find MDNs intrusive ("why should he know when I read this?"), and they aren't particularly reliable because not all mail clients (most notably Web browser readers) support them. However, they are a good example of what end users are seeing in terms of extensions that add desired functions to the Internet mail system.

The Format of Mail Messages

SMTP, POP, and (to a great extent) IMAP ignore the contents of a message. SMTP uses its own control information to find the recipient of a message; POP and IMAP retrieve messages based on user account names, which may or may not correspond to the address in a message. In users minds, however, the contents of the messages they read are almost always much more important than the way that the message got to them.

Mail messages consist of two parts: the *headers* and the *body*. The headers come first, followed by a blank line, followed by the body, as shown in Figure 3. The basic structure of messages has remained unchanged since it was defined in RFC 822. Originally, the headers were designed to look like inter-office memos, and also to contain control and debugging information; today, some parts of the headers are considered to be as important as the body of the message.

Message Headers

Because they were designed to be functional, message headers have a very straight-forward design. Each header has a single token, followed by a colon, followed by the parameters and options of the header. Headers usually consist of a single line, but you can create multi-line headers by starting the continuation lines with blanks.

There are dozens of common headers, and dozens more that are rarely used. Almost all mail users are familiar with "To:", "From:", "Subject:", and "Date:", and they may have seen additional common headers such as "Cc:" and "Received:". Depending on the interface of the MUA, users typically see some of these headers after they have retrieved a message with POP or IMAP but before they have "opened" the message to see the message body.

Basic and Advanced Message Bodies

Originally, the body of mail messages consisted of plain ASCII text. This was sufficient for the inventors of e-mail, who spoke mostly English and had access to other information transfer mechanisms such as FTP to move binary data around. Of course, such restrictions would not last.

Probably the biggest advance in Internet mail in the past ten years is in the format of mail messages, not in their transport. In the early 1990s, Internet mail went from being text-only to allowing the transfer of non-text messages and parts of messages. MIME, described in RFCs 2045–2047[7, 8, 9], revolutionized the usefulness of Internet mail by allowing senders to include files with messages, to use styled text, to give their messages useful structure, and to provide the first interoperable support for international e-mail.

Unfortunately, the term "attachments" became associated with MIME even though it is much more powerful than just allowing files to be attached to a message. The majority of MIME-enabled messages today don't contain any attachments: instead, they use MIME's capability of labeling the type of a single message body part. MIME labeling can tell the receiving client the format of the message (for instance, an HTML message) and, if it is a text message, the type of characters in the message.

Another great feature of MIME is that it allows messages to have structure. For instance, Figure 4 shows a message with two representations of the same information: text and HTML. A mail client that cannot display HTML can skip that part of the message and just display the plain text. This allows message content to gradually migrate towards new technology. In the near future, it is likely that similar logic will be used for messages that contain XML, HTML, and plain text.

```

Because of the capability to structure messages, MIME can be used for multimedia and unified messaging. A single mail message can contain one or more movies, sound files, text files in a variety of formats, binary files such as word processing documents, calendar events, fax images, and so on. The MIME structure tells the recipient software which parts of the message contain particular types of data, as well the relationship between the parts (such as "this part contains three different alternative sound formats").

With the explosion of the popularity of the Web, users have come to expect that the content they read will look like Web pages. Most users don't understand that a "Web page" that "contains" graphics in fact isn't a single entity but is really a page of HTML that has links to other pages that contain individual images. They expect to be able to receive mail messages that look just like the things they see on the Web. The MHTML protocol (described in RFC 2557[10]) describes how to structure MIME messages that contain both HTML parts and images so that they appear together in mail clients exactly like they appear in Web browsers.

MIME enables a plethora of other uses for e-mail. For example, secure e-mail using S/MIME and PGP uses MIME to structure the messages so that the cryptographic control information is separate from the message itself. For instance, in a digitally-signed message, the signature information (which is unreadable to the human recipient) is in a different part of the structure than the human-readable content. You can even have layers of encryption and signatures, all structured through MIME.

Internationalization of E-mail

You can use character sets other than ASCII in both the headers and body of Internet e-mail messages. Using different character sets in text bodies requires the use of the "charset" parameter in the "Content-type:" header, as described in RFC 2046[8]. You can also use character sets in message headers with the methods described in RFC 2047[9].

The Future of E-mail

E-mail is incredibly popular with Internet users, but it is far from finished. The next billion new e-mail users will most likely be much less technically savvy than today's Internet users, and they will come to the Internet with very different expectations. In order to give these users a more pleasant experience, the Internet mail industry will have to add many new features and make mail clients easier.

The number of ISPs is also increasing, although not as fast as the number of Internet users. Since e-mail is such an integral part of the service that an ISP offers, mail server software will also have to become easier to administer. Internet mail server vendors are working on such enhancements as a way of gaining a competitive advantage.

The most major change that users will see in the next few years are more highly enabled MUAs. These clients will be all-in-one messaging centers that will handle faxes, voice messages, paging, calendar and event management, and probably some sort of instant messaging. In this way, traditional mail will be only one part of what the user sees when they go to their messaging client.

The importance of Internet fax should not be underestimated. The recent standards for Internet fax, defined in RFCs 2301–2306[11, 12, 13, 14, 15, 16] specify how faxes go through Internet mail. Although there have been a raft of proprietary real-time fax proposals, fax vendors have rallied around faxes in e-mail as an easy way to transition from fax over phone lines. Comparing the high cost of sending international faxes to the near-zero cost of sending e-mail, many companies are quickly moving towards the new standards.

Other mail-enabled services are becoming standardized as well. For example, calendaring over Internet mail is nearing completion. This will allow users to coordinate schedules for meetings, even with people who are not online. E-mail fall-back for phone conversations that were not completed is also being researched.

The e-mail world five and ten years from now will not necessarily look completely different from the way it looks today. Certainly, there will be many more enriched text and multimedia messages being composed by end users. Mailing lists will grow and the mail on them will be more like Web pages than today's text messages. Many people predict that the face of e-mail will change radically if e-mail becomes the "universal inbox" for voicemail, faxes, and other types of communication. Many companies are discovering that regular newsletters sent through e-mail are more effective than expecting users to come to a web site regularly, and it is likely that there will be an increase in the number of publications that are delivered as e-mail.[18]

There is still plenty of room for additions to Internet mail that resemble today's non-Internet services. For instance, users are already clamoring for features such as true message tracking, which is currently available from many package delivery services. Better security is clearly desired, although there seems to be major impediments caused by the need for trusted certificates before we can see wide deployment of secure mail. More problematic features such as message rescinding also have been proposed.

Forces outside the Internet mail world will also change how Internet mail works. For instance, the rapid increase in wireless users will change the way that large messages are handled by message stores. As more users start reading their mail from more than one system, IMAP may become more popular. At the same time, users will expect to be able to move their configuration information with them from machine to machine, probably using protocols such as the *Application Configuration Access Protocol* (ACAP) defined in RFC 2244[17].

There are plenty of opportunities in the Internet mail market. The only significant dark cloud is the possibility that increasing unsolicited e-mail—so called "spam"—might scare away users. To date, the technical solutions for battling spam have been limited, and they probably won't scale well if the amount of spam increases by an order of magnitude. On the bright side, it appears that most legitimate marketers have been scared away from spam and are focusing on opt-in e-mail marketing. This could be a boon for ISPs who specialize in bringing interested e-mail users and potential advertisers together.[19]

In such an environment, mail with rich media and lots of convenience could become the place where many users want to spend much of their time. To get there, we need to build on today's well-established mail protocols and to be creative in the kinds of features we add to both the transport and display of e-mail. Fortunately, we don't need to do much with SMTP, IMAP, and MIME in order to bring these new capabilities to the burgeoning numbers of new users waiting to get on the Internet.

Book Review

Introduction to Data Communications and Networking

Introduction to Data Communications and Networking, Behrouz Farouzan, ISBN 0-256-23044-7, WCB/McGraw-Hill, 1998.

As personal computers have proliferated the landscape over the years, they have become the domain of an increasing number of nontechnical end users. Two things assisted in this transformation. The realization of their value as a productivity tool became apparent, as well as their ability to become more user friendly to the masses. Networks, and networking, have followed a similar path. The investment in creating a networked environment in the past may have been a burden—in both time and added complexity—to all but the largest corporations. However, as the world becomes more "wired," the presence of networks has become commonplace in nearly every work environment, not to mention the movement into private residences. The need to become familiar with concepts and terms as they relate to data communications and networks has become an important part of the technological landscape. *Introduction to Data Communications and Networking* assists the novice in grasping these concepts, as well as serving as a refresher to the more experienced audience.

Organization

The preface explains the ways this book can be useful. The textbook portion is helpful. Multiple choice as well as discussion questions are provided within each chapter, although all the answers are not. In addition, some of the questions asked do not always seem to be posed in the context of the chapter just covered. However, it does turn out to be a rather small inconvenience. The requisite appendices are included as well—such as ASCII and EBCDIC codes, and various representations of numbers. However, two areas that usually receive only fleeting recognition—Fourier analysis and Huffman coding—are covered. Not being an engineer, I'm not sure that I now understand these concepts, but at least now I know why.

Although the areas covered in this book are covered in many introductory network books, this one takes nothing for granted. A good portion of the more experienced readers will know that Layers 2–6 of the OSI model have headers, only Layer 2 will include a trailer. Details such as these are easily forgotten. Introducing concepts in meaningful, practical ways is another positive attribute of this book. One great example is how the author describes the difference between analog and digital. Hands of a traditional, or analog, clock do not jump from minute to minute or hour to hour. The notion of time advancing seems to be a smooth transition, much like an analog signal is a continuous wave form that changes smoothly over time. Digital (as in the case of a digital clock), on the other hand, indicates discrete units of time—usually whole hours and minutes—and can have only limited numbers of defined values. In Chapter 4, analog and digital signals are detailed and explained with clarity and excellent examples are given as well.

In fact, the only subject matter I had difficulty deciphering concerned material presented in Chapter 5. The concepts of polar, unipolar, and bipolar encoding seemed straightforward enough, but digital-to-analog and analog-to-analog encoding will definitely have to be revisited. Amplitude and phase shifting keys may or may not be revisited. In fact, it was at this point that I realized that the material was moving to a different, more difficult, level.

Although the preface states that the first eight chapters are essential for readers being introduced to networking concepts, I found that chapters 5–8 went into a level of depth that would be particularly daunting for an introductory discussion.

Summary

I don't remember exactly how I was introduced to this book—whether I read about it in a journal or it was recommended by a friend—but the book got favorable reviews wherever I inquired about it. It is a practical addition to your bookshelf, regardless of your level of comfort with networks and voice/data communications.

The book is relevant and practical for the professional who has been working in the field for a few years. It is also useful as a textbook for use in the classroom. However, I do not believe that all the information can be adequately covered in a semester, as the author suggests. I believe one of the reasons I enjoyed this book was because of the way it explained ideas and concepts that were never used in any class I had ever taken. I recall promises of receiving a good, comprehensive background in these areas, yet years later I continue to struggle with some of the same concepts I've encountered in classes before. I found myself continually searching for a source that would provide me the information in a comprehensive, understandable fashion. I believe I have finally found it.

Would You Like to Review a Book for IPJ?

We receive numerous books on computer networking from all the major publishers. If you've got a specific book you are interested in reviewing, please contact us and we will make sure a copy is mailed to you. The book is yours to keep if you send us a review. We accept reviews of new titles, as well as some of the "networking classics." Contact us at **ipj@cisco.com** for more information.

Fragments

New Top-Level Domains Are Coming

For several years, there have been proposals to introduce new *generic top-level domains* (gTLDs) into the Internet *Domain Name System* (DNS). Although the introduction of gTLDs raises several issues that are of concern to various members of the Internet community, significant progress has been made recently toward achieving a consensus solution. The *Internet Corporation for Assigned Names and Numbers* (ICANN) Board of Directors is expected to consider adopting a policy to introduce new gTLDs at its meeting in July 2000. The *Names Council* has recommended to the ICANN Board that: "...a limited number of new top-level domains be introduced initially and that the future introduction of additional top-level domains be done only after careful evaluation of the initial introduction."

ICANN Announces CPR Institute as New Dispute Resolution Provider

ICANN recently announced that the *CPR Institute for Dispute Resolution* has been designated an approved provider under their *Uniform Dispute Resolution Policy* (UDRP) for domain name disputes. CPR, an alliance of 500 general counsel of global corporations and partners of major law firms, is the fourth dispute resolution provider to be designated by ICANN to handle domain disputes, joining the *National Arbitration Forum,* the *Disputes.org/eResolution Consortium,* and the *World Intellectual Property Organization.* The UDRP establishes a streamlined, economical process administered by neutral arbitration companies to provide a quick and cheap alternative to litigation. The procedure applies to cases that meet all three of the following criteria: The domain name must be identical or confusingly similar to a name in which the complaining party has trademark rights (either through a registered trademark or a common-law trademark); The domain name holder must have no legitimate right or interest in the name; The domain name must have been registered and used in bad faith.

In its first few months of operation, the UDRP has proven to be a very popular means of quickly resolving trademark/domain name disputes. To date, 691 proceedings have been commenced under the policy involving 1022 domain names. Of those proceedings, 348 have already been resolved. For additional information on UDRP, see **`http://www.icann.org/udrp/udrp.htm`**

From The Editor

In our last issue, Geoff Huston described the basic design and operation of the *Transmission Control Protocol* (TCP). He outlined how numerous enhancements to TCP implementations have been developed over time to improve its performance, particularly in the face of congested networks. The Internet is a rapidly changing environment in which both the applications and the underlying transmission systems are undergoing an evolution, if not a revolution. Some of these changes, such as the introduction of wireless devices, affect the way TCP works, because the protocol makes many implicit assumptions about the network over which it operates. In this issue, Geoff looks at the future for TCP and describes techniques for adopting TCP to today's Internet.

Security continues to be a major concern for everyone involved in the design and operation of networks. Widely publicized "hacker attacks," "denial-of-service attacks," and outright online fraud has brought the topic into sharp focus in the last few years. Because security was not part of the original design of the Internet, numerous solutions at every level of the protocol stack have been proposed and implemented over the last three decades. Today's network manager is, therefore, faced with a *system* of security components that must be carefully configured and monitored in order to provide sufficient security without preventing users from getting their work done. In our second article, Chris Lonvick explores a model for evaluating and securing a network.

The online subscription system for this journal is now up and running at **www.cisco.com/ipj** In addition to offering a subscription form, the system allows you to select delivery options, update your mailing and e-mail address, and much more. The Future for TCP

by Geoff Huston, Telstra

The previous article, "TCP Performance," examined the operation of the *Transmission Control Protocol* (TCP) protocol[1]. The article examined the role of TCP in providing a reliable end-to-end data transfer function, and described how TCP incorporates numerous control functions that are intended to make efficient use of the underlying IP network through a host-based congestion control function. Congestion control is an important component of TCP implementations, and today TCP congestion control plays an important role in the overall stability of the Internet.

Today's Internet spans a very broad base of uses, and ensuring that TCP provides a highly robust, efficient, and reliable service platform for such a diversity of use is a continuing task. The Web has introduced a component of short duration reliable transfers into the public Internet traffic profile. These short sessions are often referred to as "TCP mice" because of the short duration and large number of such TCP sessions. Complementing these short sessions is the increasing size of large transfers as *File Transfer Protocol* (FTP) data sets become larger in response to increasing capacity within the public Internet network[4]. In addition, there is an increasing diversity of media used within the Internet, both in terms of higher-speed systems and in the use of wireless systems for Internet access. In this article we will extend our examination of TCP by looking at how TCP is being used and adapted to match this changing environment.

A Review of TCP Performance

Within any packet-switched network, when demand exceeds available capacity, the packet switch will use a queue to hold the excess packets. When this queue fills, the packet switch must drop packets. Any reliable data protocol that operates across such a network must recognize this possibility and take corrective action. TCP is no exception to this constraint. TCP uses data sequence numbering to identify packets, and explicit acknowledgements (ACKs) to allow the sender and receiver to be aware of reliable packet transfer. This form of reliable protocol design is termed "end-to-end" control, because interior switches do not attempt to correct packet drops. Instead, this function is performed through the TCP protocol exchange between sender and receiver. TCP uses cumulative ACKs rather than per-packet ACKs, where an ACK referencing a particular point within the data stream implicitly acknowledges all data with a sequence value less than the ACKed sequence.

TCP also uses ACKs to clock the data flow. ACKs arriving back at the sender arrive at intervals approximately equal to the intervals at which the data packets arrived at the sender. If TCP uses these ACKs to trigger sending further data packets into the network, then the packets will be entered into the network at the same rate as they are arriving at their destination. This mode of operation is termed "ACK clocking."

TCP recovers from packet loss using two mechanisms. The most basic operation is the use of packet timeouts by the sender. If an ACK for a packet fails to arrive within the timeout value, the sender will retransmit the oldest unacknowledged packet. In such a case, TCP assumes that the loss was caused by a network congestion condition, and the sender will enter "Slow Start" mode. This condition causes significant delays within the data transfer, because the sender will be idle during the timeout interval and upon restarting will recommence with a single packet exchange, gradually recovering the data rate that was active prior to the packet loss. Many networks exhibit transient congestion conditions, where a data stream may experience loss of a single packet within a packet train. To address this, TCP introduced the mechanism of "fast recovery." This mechanism is triggered by a sequence of three duplicate ACKS received by the data sender. These duplicate ACKs are generated by the packets that trail the lost packet, where the sender ACKs each of these packets with the ACK sequence value of the lost packet. In this mode the sender immediately retransmits the lost packet and then halves its sending rate, continuing to send additional data as permitted by the current TCP sending window. In this mode of operation, "congestion-avoidance" TCP increases its sending window at a linear rate of one segment per *Round-Trip Time* (RTT). This mode of operation is referred to as *Additive Increase, Multiplicative Decrease* (AIMD), where the protocol reacts sharply to signs of network congestion, and gradually increases its sending rate in order to equilibrate with concurrent TCP sessions.

TCP Design Assumptions

It is difficult to design any transport protocol without making some number of assumptions about the environment in which the protocol is to be used, and TCP certainly has some inherent assumptions hidden within its design. The most important set of assumptions that lie behind the design of TCP are as follows:

- *A network of wires, not wireless:* As we continually learn, wireless is different. Wireless systems typically have higher *bit error rates* (BERs) than wire-based carriage systems. Mobile wireless systems also include factors of signal fade, base-station handover, and variable levels of load. TCP was designed with wire-based carriage in mind, and the design of the protocol makes numerous assumptions that are typical of such of an environment. TCP makes the assumption that packet loss is the result of network congestion, rather than bit-level corruption. TCP also assumes some level of stability in the RTT, because TCP uses a method of damping down the changes in the RTT estimate.
- *A best-path route-selection protocol:* TCP assumes that there is a single best metric path to any destination because TCP assumes that packet reordering occurs on a relatively minor scale, if at all. This implies that all packets in a connection must follow the same path within the network or, if there is any form of load balancing, the order of packets within each flow is preserved by some network-level mechanism.

- *A network with fixed bandwidth circuits, not varying bandwidth:* TCP assumes that available bandwidth is constant, and will not vary over short time intervals. TCP uses an end-to-end control loop to control the sending rate, and it takes many RTT intervals to adjust to varying network conditions. Rapidly changing bandwidth forces TCP to make very conservative assumptions about available network capacity.
- *A switched network with first-in, first-out (FIFO) buffers:* TCP also makes some assumptions about the architecture of the switching elements within the network. In particular, TCP assumes that the switching elements use simple FIFO queues to resolve contention within the switches. TCP makes some assumption about the size of the buffer as well as its queuing behavior, and TCP works most efficiently when the buffer associated with a network interface is of the same order of size as the delay bandwidth product of the associated link.
- *The duration of TCP sessions:* TCP also makes some assumptions about the nature of the application. In particular, it assumes that the TCP session will last for some number of round-trip times, so that the overhead of the initial protocol handshake is not detrimental to the efficiency of the application. TCP also takes numerous RTT intervals to establish the characteristics of the connection in terms of the true RTT interval of the connection as well as the available capacity. The introduction of short-duration sessions, such as found in transaction applications and short Web transfers, is a new factor that impacts the efficiency of TCP.
- *Large payloads and adequate bandwidth:* TCP assumes that the overhead of a minimum of 40 bytes of protocol per TCP packet (20 bytes of IP header and 20 bytes of TCP header) is an acceptable overhead when compared to the available bandwidth and the average payload size. When applied to low-bandwidth links, this is no longer the case, and the protocol overheads may make the resultant communications system too inefficient to be useful.
- *Interaction with other TCP sessions:* TCP assumes that other TCP sessions will also be active within the network, and that each TCP session should operate cooperatively to share available bandwidth in order to maximize network efficiency. TCP may not interact well with other forms of flow-control protocols, and this could result in unpredictable outcomes in terms of sharing of the network resource between the active flows as well as poor overall network efficiency.

If these assumptions are challenged, the associated cost is that of TCP efficiency. If the objective is to extend TCP to environments where these assumptions are no longer valid, while preserving the integrity of the TCP transfer and maintaining a high level of efficiency, then the TCP operation itself may have to be altered.

There are two basic ways of altering TCP operation: by altering the actions of the end host by making changes to the TCP protocol, or by altering the characteristics of the network, making them more "friendly" to TCP. We will look at the potential for both responses in examining various scenarios for adapting TCP to suit these changing environments.

Some caution should be noted about making changes to the TCP protocol. The major constraint is that any changes that are contemplated to TCP should be backward compatible with existing TCP behavior. This constraint requires a modified TCP protocol to attempt to negotiate the use of a specific protocol extension, and the knowledge that a basic common mode of protocol operation may be required if the negotiation fails. The second constraint is that TCP does assume that it is interacting with other TCP sessions within the network, and the outcome of fair sharing of the network between concurrent sessions depends on some commonality of the protocol used by these sessions. Major changes to the protocol behavior can lead to unpredictable outcomes in terms of sharing of the network resource between "unmodified" and "modified" TCP sessions, and unpredictable outcomes in terms of efficiency of the use of the network. For this reason there is some understandable reluctance to undertake modifications of TCP that radically alter TCP startup behavior or behavior in the face of network congestion.

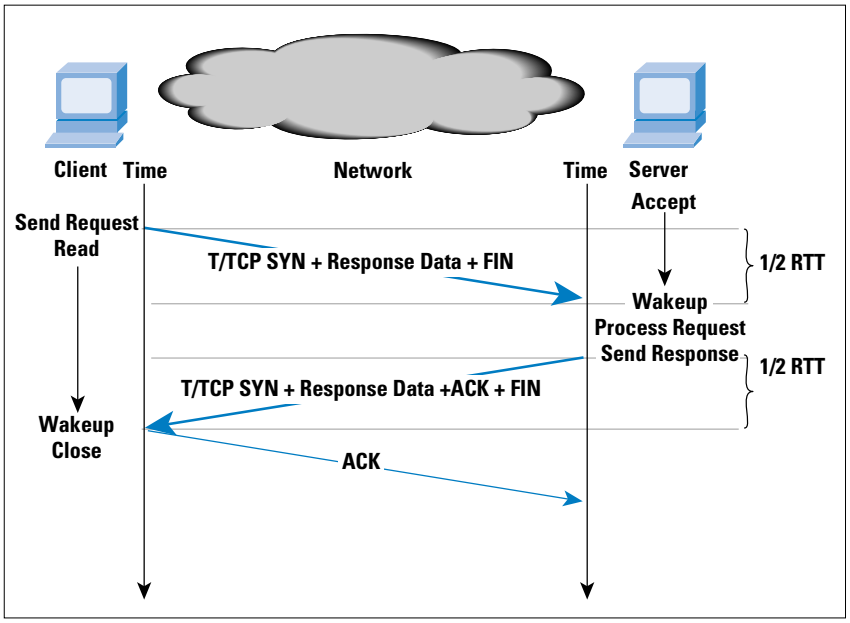
Short-Duration Sessions—TCP for Transactions

For network applications that generate small transactions, the application designer is faced with a dilemma. The application may be able to use the *User Datagram Protocol* (UDP), in which case the sender must send the query and await the response. This operation is highly efficient, because the total elapsed time for the client is a single RTT. However, this speed is gained at the cost of reliability. A missing response is ambiguous, in that it is impossible for the initiator to tell whether the query was lost or the response was lost. If multiple queries are generated, it is not necessarily true that they will arrive at the remote server in the same order as they were generated. Alternatively, the application can use TCP, which will ensure reliability of the transaction. However, TCP uses a three-way handshake to complete the opening of the connection, and uses acknowledged FIN signals for each side to close its end of the connection after it has completed sending data. Under the control of TCP, the sender will retransmit the query until it receives an acknowledgment that the query has arrived at the remote server. Similarly, the remote host will retransmit the response until the server receives an indication that the response has been successfully delivered. The cost of this reliability is application efficiency, because the minimum time to conduct the TCP transaction for the client is two RTT intervals.

TCP for Transactions (commonly referred to as T/TCP[5]) attempts to improve the performance of small transactions while preserving the reliability of TCP. T/TCP places the query data and the closing FIN in the initial SYN packet. This can interpreted as attempting to open a session, pass data, and close the sender's side of the session within a single packet. If the server accepts this format, the server responds with a single packet, which contains its SYN response, an ACK of the query data, the server's data in response, and the closing FIN. All that is required to complete the transaction is for the query system to ACK the server's data and FIN (Figure 1). If the server does not accept this format, the client can back off to a conventional TCP handshake followed by a data exchange.

For the client, the time to undertake this T/TCP transaction is one RTT interval, a period equal to the UDP-supported transaction, while still allowing for the two systems to use TCP to negotiate a reliable exchange of data as a backup.

Figure 1: T/TCP Operation



T/TCP requires changes to the protocol stack of both the sender and the receiver in order to operate correctly. The design of the protocol explicitly allows the session initiator to back off to use TCP if the receiver cannot correctly respond to the initial T/TCP packet.

T/TCP is not in common use in the Internet today, because while it improves the efficiency of simple transactions, the limited handshake makes it more vulnerable from a security perspective, and concerns over this vulnerability have been a prohibitive factor in its adoption. This is illustrative of the nature of the trade-offs that occur within protocol design, where optimizing one characteristic of a protocol may be at the expense of other aspects of the protocol.

Long Delay—TCP for Satellite Paths

Satellite-based services pose a set of unique issues to the network designer. Most notably, these issues include delay, bit errors, and bandwidth.

When using a satellite path, there is an inherent delay in the delivery of a packet due to signal propagation times related to the altitude of communications satellites. Geo-stationary orbit spacecraft are located at an altitude of some 36,000 km, and the propagation time for a signal to pass from an earth station directly below the satellite to the satellite and back is 239.6 ms. If the earth station is located at the edge of the satellite view area, this propagation time extends to 279.0 ms. In terms of a round trip that uses the satellite path in both directions, the RTT of a satellite hop is between 480 and 560 ms.

The strength of a radio signal falls in proportion to the square of the distance traveled. For a satellite link, the signal propagation distance is large, so the signal becomes weak before reaching its destination, resulting in a poor signal-to-noise ratio. Typical BERs for a satellite link today are on the order of 1 error per 10 million bits (1×10^{-7}). *Forward error correction* (FEC) coding can be added to satellite services to reduce this error rate, at the cost of some reduction in available bandwidth and an increase in latency due to the coding delay.

There is also a limited amount of bandwidth available to satellite systems. Typical carrier frequencies for commercial satellite services are 6/4 GHz (C-band) and 14/12 GHz (Ku band). Satellite transponder bandwidth is typically 36 MHz[6].

When used in a data carriage role for IP traffic, satellite channels pose several challenges for TCP.

The delay-bandwidth product of a transmission path defines the amount of data TCP should have within the transmission path at any one time, in order to fully utilize the available channel capacity. The delay used in this equation is the RTT and the bandwidth is the capacity of the bottleneck link in the network path. Because the delay in satellite environments is large, a TCP flow may need to keep a large amount of data within the transmission path. For example, a typical path that includes a satellite hop may have a RTT of some 700 ms. If the bottleneck bandwidth is 2 Mbps, then a sender will need to buffer 180 kB of data to fully utilize the available bandwidth with a single traffic flow. For this to be effective, the sender and receiver will need to agree on the use of TCP Window Scaling to extend the available window size beyond the protocol default limit of 64 kB. A sender using an 8 kB buffer would be able to achieve a maximum transfer rate of 91 kbps, irrespective of the available bandwidth on the satellite path.

Even with advanced FEC techniques, satellite channels exhibit a higher BER than typical terrestrial networks. TCP interprets packet drop as a signal of network congestion, and reduces its window size in an attempt to alleviate the situation. In the absence of certain knowledge about whether a packet was dropped because of congestion or corruption, TCP must assume the drop was caused by congestion in order to avoid congestion collapse[7, 8]. Therefore, packets dropped because of corruption cause TCP to reduce the size of its sending window, even though these packet drops do not signal congestion in the network. To mitigate this, some care must be taken with the satellite hop *Maximum Transmission Unit* (MTU) size, to reduce the probability of packet corruption. This is an area of compromise, in that the consequence is the potential for a high level of IP packet fragmentation on the satellite feeder router. In addition, the sender needs to use the TCP fast retransmit and fast recovery algorithms[9] in order to recover from the packet loss in a rapid, but stable fashion. In addition, the sender needs to use larger sending windows to operate the path more efficiently, with a consequent risk of multiple packet drops per RTT window. For this reason the use of *Selective Acknowledgements* (SACKs) is necessary in order to recover from multiple packet drops in a single RTT interval.

The long delay causes TCP to react slowly to the prevailing conditions within the network. The slow start of TCP commences with a single packet exchange, and it takes some number of RTT intervals for the sender's rate to reach the same order of size as the delay bandwidth product of the long delay path. For short-duration TCP transactions, such as much of the current Web traffic, this is a potential source of inefficiency. For example, if a transaction requires the transfer of ten packets, the slow-start algorithm will send a single packet in the first RTT interval, two in the second interval, four in the third, and the remaining three packets in the fourth RTT interval. Irrespective of the available bandwidth of the path, the transaction will take a minimum of four RTT intervals. This theoretical model is further exacerbated by delayed ACKs [RFC 1122], where a receiver will not immediately ACK a packet, but will await the expiration of the 500ms ACK timer, or a second full-sized packet. During slow start, where a sender sends an initial packet, and then awaits an ACK, the receiver will delay the ACK until the expiration of the delayed ACK timer, adding up to 500ms additional delay in the first data exchange. The second part of the delayed ACK algorithm is that it will only ACK every second full-sized data packet, slowing down the window inflation rate of slow start. Also, if congestion occurs on the forward data path, the TCP sender will not be aware of the condition until it receives duplicate ACKs from the receiver. A congestion condition may take many RTT intervals to clear, and in the case of a satellite path, transient congestions may take tens of seconds to be resolved.

The TCP mechanisms that assist in mitigating some of the more serious effects of satellite systems include *Path MTU Discovery*[10], *Fast Retransmit* and *Fast Recovery*, window scaling options, in order to extend the sender's buffer beyond 65,535 bytes[11], and the companion mechanisms of *Protection Against Wrapped Sequence Space* (PAWS) and *Round-Trip Time Measurements* (RTTM) and SACKs[12]. A summary of TCP options is shown in Figure 2.

Figure 2: TCP Options for Satellite Paths (after RFC 2488)

Mechanism	Use	Location
Path-MTU Discovery	Recommended	Sender
FEC	Recommended	Link
TCP		
Slow Start	Required	Sender
Congestion Avoidance	Required	Sender
Fast Retransmit	Recommended	Sender
Fast Recovery	Recommended	Sender
Window Scaling	Recommended	Sender and Receiver
PAWS	Recommended	Sender and Receiver
RTTM	Recommended	Sender and Receiver
SACK	Recommended	Sender and Receiver

Further refinements to the TCP stack have been considered in relation to satellite performance[13].

The options considered include the use of T/TCP as a means of reducing the overhead of the initial TCP three-way handshake. This is effective for short transactions where the data to be transferred can be held in a single packet, or in a small number of packets.

The use of delayed acknowledgements also is an issue for long-delay network paths, particularly if the sender is using slow start with an initial window of a single segment. In this case, the receiver will not immediately acknowledge the initial packet, but will wait up to one-half second for the delayed ACK timer to trigger. Altering the initial window size to two segments allows the receiver to trigger an ACK on reception of the second packet, bypassing the delayed ACK timer. However, even this change to TCP does not completely address the performance issue relating to delayed ACKs on long delay paths for TCP slow start. The delayed ACK algorithm triggers an ACK on every second full-sized packet. Because the sender's congestion window is opened on receipt of ACKs, this causes the slow-start window to open more slowly than if the receiver generated an ACK every packet. One variant of TCP congestion control allows the TCP sender to count the number of bytes acknowledged in an ACK message to control the expansion of the congestion window, making the algorithm less sensitive to delayed ACKs[9]. Although this approach has some merit for long delay paths, this is a case where the correction is potentially as bad as the original problem. The byte counting mode of congestion control allows a sender to sharply increase its sending rate, causing potential instabilities within the network and impacting concurrent TCP sessions.

One approach to address this is to place a limit on the size of the window expansion, where each increment of the congestion window is limited to the minimum of one or two segment sizes and the size of the data spanned by the ACK. If the limit is set to a single segment size, the window expansion will be in general slightly more conservative to the current TCP ACK-based expansion mechanism. If this upper limit is set to two segments, the congestion window expansion will account for the delayed ACKs, expand at a rate equal to one segment for every successfully transmitted segment during slow start, and expand the window by one segment size each RTT during congestion avoidance. Because a TCP receiver will ACK a large span of data following recovery, this byte counting is bounded to a single segment per ACK in the slow-start phase following a transmission timeout. Another approach that has been explored is for the receiver to disable delayed ACKs until the sender has completed the slow-start phase. Although such an approach shows promising results under simulated conditions, the practical difficulty is that it is difficult for the receiver to remotely determine the current TCP sending state, and the receiver cannot reliably tell if the sender is in slow start, congestion avoidance, or in some form of recovery mode. Explicit signaling of the sender's state as a TCP flag is an option, but the one-half RTT delay in the signaling from the sender to the receiver may prove to be an issue here. This area of congestion control for TCP remains a topic of study.

All of these approaches can mitigate only the worst of the effects of the long delay paths. TCP, as an adaptive reliable protocol that uses end-to-end flow control, can undertake only incremental adjustments in its flow rates in intervals of round-trip times. When the round-trip times extend, then TCP is slower to speed up from an initial start, slower to recover from packet loss, and slower to react to network congestion.

Tuning TCP—ACK Manipulation

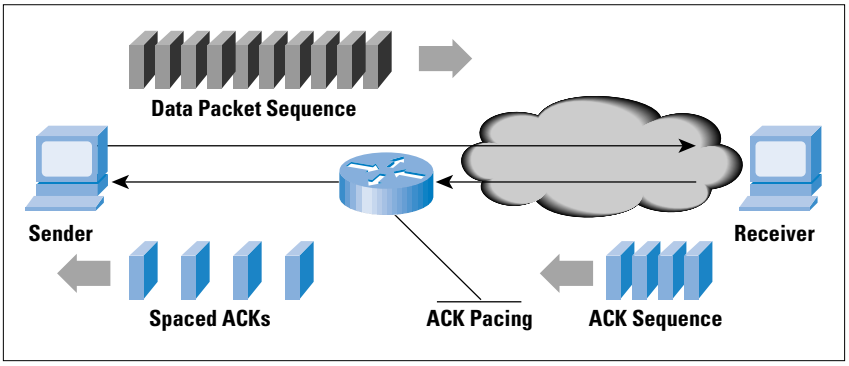
The previous article of TCP Performance discussed numerous network responses to congestion using *Random Early Detection* (RED) for active queue control and *Explicit Congestion Notification* (ECN) as an alternative to RED packet drop. It is feasible for a network control point to impose a finer level of control on a TCP flow by using an approach of direct manipulation of the TCP packets.

The approaches described above to mitigate some of the side effects of satellite paths all share in the side effect of having some latency associated with the congestion response. The sender must await the reception of trailing packets by the receiver, and then await the reception of the matching ACK packets from the data receiver back to the sender to learn of the fate of the original data packet. This may take up to one RTT interval to complete. An alternative approach to congestion management responses is to manipulate the ACK packets to modify the sender's behavior.

The prerequisite to perform this manipulation is that the traffic path be symmetric, so that the congestion point can identify ACK packets traveling in the opposite direction. If this is the case, a couple of control alternatives can mitigate the onset of congestion:

- *ACK Pacing:* Each burst of data packets will generate a corresponding burst of ACK packets. The spacing of these ACK packets determines the burst rate of the next sending packet sequence. For long-delay systems, the size of such bursts becomes a limiting factor. TCP slow start generates packet bursts at twice the bottleneck data rate, so that the bottleneck feeder router may have to absorb one-half of every packet burst within its internal queues. If these queues are not dimensioned to the delay bandwidth product of the next hop, these queues become the limiting factor, rather than the path bandwidth itself. If you can slow down the TCP burst rate, the pressure on the feeder queue is alleviated. One approach to slow down the burst rate is to impose a delay on successive ACKs at a network control point (Figure 3). This measure will reduce the burst rate, but not impact the overall TCP throughput. ACK pacing is most effective on long delay paths, and it is intended to spread out the burst load, reducing the pressure on the bottleneck queue and increasing the actual data throughput.

Figure 3: ACK Pacing



- *Window Manipulation:* Each ACK packet carries a receiver window size. This advertised window determines the maximum burst size available to the sender. Manipulating this window size downward allows a control point to control the maximal TCP sending rate. This manipulation can be done as part of a traffic-shaping control point, enforcing bandwidth limitations on a flow or set of flows.

Both of these mechanisms make some sweeping assumptions about the network control point that must be carefully understood. The major assumption is that these mechanisms assume symmetry of data flows at the network control point, where the data and the associated ACKs flow through this control point (but in opposite directions, of course). Both mechanisms also assume that the control point can cache per-flow state information, so that the current flow RTT and the current transfer rate and receiver window size are available to the service controller.

ACK pacing also implicitly assumes that a single ACK timing response is active at any time along a network path. A sequence of ACK delay actions may cause the sender's timers to trigger, and the sender to close down the transfer and reenter slow-start mode. These environmental conditions are more common at the edge of the network, and such mechanisms are often part of a traffic control system for Web-hosting platforms or similar network service delivery platforms. As a network control tool, ACK manipulation makes too many assumptions, and the per-flow congestion state information represents a significant overhead for large network systems. In general, such manipulations are more appropriate as an edge traffic filter, rather than as an effective congestion management response. For this reason, the more indirect approach of selective data packet discard is more effective as a congestion management measure.

Assisting Short-Duration TCP Sessions—Limited Transmit

One of the challenges to the original set of TCP assumptions is that of short-duration TCP sessions. The Web has introduced a large number of short-duration sessions, and the issue with these sessions is that they use small initial windows. If congestion loss occurs within this early period of TCP slow start, there are not enough packets in the network to generate the three duplicate ACKs required to initiate fast retransmit and fast recovery. Instead the TCP sender must await the expiry of the *retransmission timeout* (RTO), a timer that uses a minimum value of one second. For short-duration TCP sessions that may last six or seven RTT intervals of a small number of milliseconds, the incremental penalty of single packet loss is then extremely severe. A study of this problem indicates that approximately 56 percent of retransmissions are sent following an RTO timeout[25].

One potential mitigation to this is a mechanism termed "Limited Transmit." With this mechanism, a duplicate ACK may trigger an immediate transmission of a segment of new data. Two conditions are applied to this; the receiver's advertised window allows the transmission of this segment, and the amount of outstanding data would remain less than the congestion window plus the duplicate ACK threshold used to trigger Fast Retransmit. This second condition implies that the sender can send only two segments beyond the congestion window, and will do so only in response to the receiver lifting a segment off the network. The basic principle of this strategy is to continue the signaling between the sender and receiver in the face of packet loss, increasing the probability that the sender will recover from packet loss using duplicate ACKs and fast recovery, and reducing the probability of the one-second (or longer) RTO timeout as being the recovery trigger. The limited transmit also reduces the potential for the recovery actions to burst into the network at a level that may cause further packet loss.

Low Bandwidth and High Error Rates—TCP for Wireless Systems

One of the more challenging environments for a the Internet Protocol, and TCP in particular, is that of mobile wireless.

One approach to supporting the wireless environment is that of the so-called "walled garden." Here the protocols in use within the wireless environment are specifically adapted to the wireless world. The transport protocols can account for the low bandwidth, the longer latency, the BERs, and the variability within all three of these metrics. In this model, Internet applications interact with an application gateway to reach the wireless world, and the application gateway uses a wireless transport protocol and potentially a modified version of the application data to interact with the mobile wireless device. The most common approach is extension of the World Wide Web client into the mobile wireless device, using some form of proxy server at the boundary of the wireless network and the Internet. This is the approach adopted by the *Wireless Access Protocol Forum* (WAP)[14].

An alternative approach lies in extending not only the World Wide Web to a mobile handset, but also allowing mobile devices to access a complete range of Internet-based services as the functional objective. In this approach, the intent is to allow the mobile wireless device to function as any other Internet-connected device, and there is a consequent requirement for some form of end-to-end direct IP continuity, and an associated requirement for end-to-end TCP functionality, where the TCP path straddles both wired and wireless segments. Ensuring the efficient operation of TCP in this environment is an integral part of the development of such an environment. Given that TCP must now work within a broader environment, it is no longer a case of adjusting TCP to match the requirements of the wireless environment, but one of attempting to provide seamless interworking between the wired and wireless worlds (Figure 4).

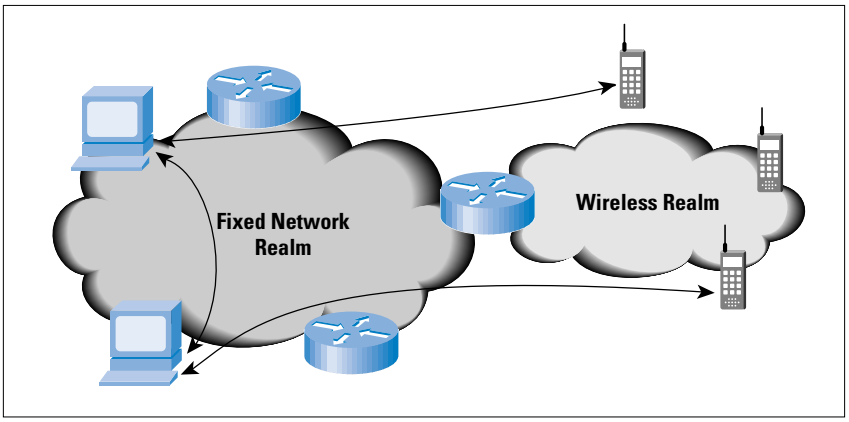


Figure 4: Linking the Wired and Wireless Worlds

The wireless environment challenges many of the basic assumptions of TCP noted above. Wireless has significant levels of bit error rates, often with bursting of very high error rates. Wireless links that use forward error correcting codes have higher latency. If the link level protocol includes automatic retransmission of corrupted data, this latency will have high variability. Wireless links may also use adaptive coding techniques that adjust to the prevailing signal to noise ratio of the link, in which case the link will have varying bandwidth. If the wireless device is a hand-held mobile device, it may also be memory constrained. And finally, such an environment is typically used to support short duration TCP sessions.

The major factor for mobile wireless is the BER, where frame loss of up to 1 percent is not uncommon, and errors occur in bursts, rather than as evenly spaced bit errors in the packet stream. In the case of TCP, such error conditions force the TCP sender to initially attempt fast retransmit of the missing segments, and when this does not correct the condition, the sender will have an ACK timeout occur, causing the sender to collapse its sending window and recommence from the point of packet loss in slow-start mode. The heart of this problem is that assumption on the part of TCP that packet loss is a symptom of network congestion rather than packet corruption. It is possible to use a model of TCP AIMD performance to determine the effects of this loss rate on TCP performance. If, for example the link has a 1-percent average packet loss rate, a *Maximum Segment Size* (MSS) size of 1000 bytes, and a 120ms RTT, then the AIMD models predict a best-case performance of 666Kbps throughput, and a more realistic target of 402Kbps throughput[15]. (See the appendix on page 24 for details of these models.) TCP is very sensitive to packet loss levels, and sustainable performance rapidly drops when packet drop levels exceed 1 percent.

Link-level solutions to the high BER are available to designers, and FEC codes and *automatic retransmission systems* (ARQ) can be used on the wireless link. FEC introduces a relatively constant coding delay and a bandwidth overhead into the path, but cannot correct all forms of bit error corruption. ARQ uses a "stop and resend" control mechanism similar to TCP itself. The consequent behavior is one of individual packets experiencing extended latency as the ARQ mechanisms retransmit link-level fragments to correct the data corruption, because the packet flow may halt for an entire link RTT interval for the link-level error to be signaled and the corrupted level 2 data to be retransmitted. The issue here is that TCP may integrate these extended latencies into its RTT estimate, making TCP assume a far higher latency on the path than is the case, or, more likely, it may trigger a retransmission at the same time as the level 2 ARQ is already retransmitting the same data. An alternative Layer 2 approach to bit-level corruption is to deliver those level 2 frames that were successfully transmitted, while resending any frames that were corrupted in transmission.

The problem for TCP here is that the level 2 drivers are adding packet reordering to the extended latency, and from TCP perspective the delivery of the out-of-order packets will generate duplicate ACKs that may trigger a simultaneous TCP fast retransmit.

Perversely, some approaches have advocated TCP delaying its duplicate ACK response in such situations[13]. To quote from RFC 2488, "The interaction between link-level retransmission and transport-level retransmission is not well understood."[6]

If ARQ is not the best possible answer to addressing packet loss in mobile wireless systems, then what can be done at the TCP level to address this? TCP can take numerous basic steps to alleviate the worst aspects of packet corruption on TCP performance. These include the use of Fast Retransmit and Fast Recovery to allow a single packet loss to be repaired moderately quickly. This mechanism triggers only after three duplicate ACKs, so the associated action is to ensure that the TCP sender and receiver can advertise buffers of greater than four times the MSS. SACKs allow a sender to repair multiple segment losses per window within a single RTT, and where large windows are operated over long delay paths, SACK is undoubtedly useful.

However, useful as these mechanisms may be, they are probably inadequate to allow TCP to function efficiently over all forms of wireless systems. Particularly in the case of mobile wireless systems, packet corruption is sufficiently common that, for TCP to work efficiently, some form of explicit addressing of network packet corruption appears to be necessary.

One approach is to decouple TCP congestion control mechanisms from data recovery actions. The intent is to allow new data to be sent during recovery to sustain TCP ACK clocking. This approach is termed *Forward Acknowledgements with Rate Halving* (FACK)[13], where one packet is sent for every two ACKs received while TCP is recovering from lost packets. This algorithm effectively reduces the sending rate by one-half within one RTT interval, but does not freeze the sender to wait the draining on one-half of the congestion window's amount of data from the network before proceeding to sending further data, nor does it permit the sender to burst retransmissions into the network. This is particularly effective for long-delay networks, where the fast recovery algorithm causes the sender to cease sending for up to one RTT interval, thereby losing the accuracy of the implicit ACK clock for the session. FACK allows the sender to continue to send packets into the network during this period, in an effort to allow the sender to maintain an accurate view of the ACK clock. FACK also provides an ability to set the number of SACK blocks that specify a missing segment before resending the segment, allowing the sender greater levels of control over sensitivity to packet reordering. The changes to TCP to support FACK are a change in the sender's TCP to use the FACK algorithm for recovery, and, for optimal performance, use of SACK options by the receiver.

In looking for alternative responses to packet corruption, it is noted that TCP segments that are corrupted are often detected at the link level, and are discarded by the link-level drivers. This discard cannot be used to generate an error message to the packet sender, given that the IP header of the packet may itself be corrupted, nor can the discard signal be reliably passed to the receiver, for the same reason. However, despite this unreliability of information, this signaling from the link level to the transport level is precisely the objective here, because, at the TCP protocol level, the sender needs to be aware that the packet loss was not due to network congestion, and that there is no need to take corrective action in terms of TCP congestion behavior.

One approach to provide this signaling from the data link level to the transport level calls for the link-level device to forward a "corruption experienced" *Internet Control Message Protocol* (ICMP) packet when discarding a corrupted packet[13]. This approach has the ICMP packet being sent in the forward direction to the receiver, who then has the task of converting this message and the associated lost packet information into a signal to the sender that the duplicate ACKs are the result of corruption, not network congestion. This signal from the receiver to the sender can be embedded in a TCP header option. The sending TCP session will maintain a corruption experienced state for two RTT intervals, retransmitting the lost packets without halving the congestion window size.

As we have noticed, corruption may have occurred in the packet header, and the sender's address may not be reliable. This approach addresses this by having the router keep a cache of recent packet destinations, and when the IP header information is unreliable because of a failed IP header checksum, the router will forward the ICMP message to all destinations in the cache. The potential weakness in this approach is that if network congestion occurs at the same time as packet corruption, the sender will not react to the congestion, and will continue to send into the congestion for a further two RTT intervals. This approach is not without some deployment concerns. It calls for modification to the wireless routers and to the receiver's link-level drivers to generate the ICMP corruption experienced messages, modification to the receiver's IP stack in order to take signals from the IP ICMP processor and from the link-level driver and convert them to TCP corruption loss signals within the TCP header of the duplicate ACKs, and modifications to the TCP processor at the sender to undertake corruption-experienced packet loss recovery. Even with these caveats in mind, this approach of explicit corruption signaling is a very promising approach to addressing performance issues with TCP over wireless.

Of course high levels of bit errors is not the only problem facing TCP over wireless systems. Mobile wireless systems are typically small handsets or personal digital assistants, and the application transactions are often modified to reduce the amount of data transferred, given that a limited amount of data can be displayed on the device.

In this case, the ratio between payload and IP and TCP headers starts to become an issue, and some consideration of header compression is necessary. Header compression techniques typically take the form of stripping out those fields of the header that do not vary on a packet-by-packet basis, or that vary by amounts that can be derived from other parts of the header, and then transmitting the delta values of those fields that are varying[16, 17].

Although such header compression schemes can be highly efficient in operation, the limitation of such schemes is that the receiver needs to have successfully received and decompressed the previous packet before the receiver can decompress the next packet in the TCP stream. In the face of high levels of bit error corruption, such systems do introduce additional latencies into the data transfer, and multiple packet drops are difficult to detect and signal via SACK in this case.

A more subtle aspect of mobile wireless is that of temporary link outages. For example, a mobile user may enter an area of no signal coverage for a period of time, and attempt to resume the data stream when signal is obtained again. In the same way that there is no accepted way of a link-level driver informing TCP of packet loss due to corruption, there is no way a link-level driver can inform TCP of a link-level outage. In the face of such link-level outages, TCP will assume network-level congestion, and in the absence of duplicate ACKs, TCP retransmission timers will trigger. TCP will then attempt to restart the session in slow-start mode, commencing with the first dropped packet. Each attempt to send the packet will result in TCP extending its retransmission timer using an exponential backoff on each attempt, so that successive probes are less and less frequent. Because the link level cannot inform the sender on the resumption of the link, TCP may wait some considerable time before responding to link restoration. The intention is for the link level to be able to inform the TCP for resumption of the connection following a link outage. One approach is for the link level to retain a packet from each TCP stream that attempted to use the link. When the link becomes operational again, the link-level driver immediately transmits these packets on the link. The result is that the receiver will then generate a response that will then trigger the sender into transmission within a RTT interval. Only a single packet per active TCP stream is necessary to trigger this response, so that the link level does not need to hold an extensive buffer of undeliverable packets during a link outage. Of course if the routing level repaired the link outage in the meantime, the delivery of an out-of-order TCP packet would normally be discarded by the sender.

The bottom line here is the question: Is TCP suitable for the mobile wireless environment? The answer appears to be that TCP can be made to work as efficiently as any other transport protocol for the mobile wireless environment.

However, this does imply that some changes in the operation of TCP need to be undertaken, specifically relating to the signaling of link-level states into the TCP session and use of advanced congestion control and corruption signaling within the TCP session. Although it is difficult to conceive of a change to every deployed TCP stack within the deployed Internet to achieve this added functionality, there does exist a middle ground between the "walled garden" approach and open IP. In this middle ground, the wireless systems would have access to "middleware," such as Web proxies and mail agents. These proxies would use a set of TCP options when communicating with mobile wireless clients that would make the application operate as efficiently as possible, while still permitting the mobile device transparent access to the Internet for other transactions.

Unbundling TCP—Stream Control Transmission Protocol

There are occasions where the application finds the control functions of TCP too limiting. In the case of handling *Public Switched Telephone Network* (PSTN) signaling across an Internet network, the application requirements are somewhat different from those of TCP delivered service. PSTN signaling reliable delivery is important, but the individual transactions within the application are included within each packet, so the concept of preservation of strict order of delivery is unnecessary. Relaxation of this requirement of strict order of packet delivery allows the transport protocol to function more efficiently, because there is no head-of-line blocking at the receiver when awaiting retransmission of lost packets. TCP also assumes the transfer of a stream of data, so that applications that wish to add some form of record delineation to the data stream have to add their own structure to the data stream. In addition, the limited scope of TCP sockets complicates the support of a high-availability application that may use multihomed hosts, and TCP itself is vulnerable to many attacks, such as SYN attacks. The intention of the *Stream Control Transmission Protocol* (SCTP) is to address these application requirements[16].

The first major difference between SCTP and TCP occurs during initialization, where the SCTP endpoints exchange a list of SCTP endpoint addresses (IP addresses and port numbers) that are to be associated with the SCTP session. Any pair of these source and destination addresses can be used within the SCTP session.

The startup of SCTP is also altered into a four-way handshake, where the initiator sends a tag value to the other end, which then responds with a copy of this tag and a tag of its own. At this stage the recipient does not allocate any resources for the connection, making the initialization sequence more robust in the face of TCP SYN-styled attacks. The initiator can then respond to this with an echo of the recipient's tag (COOKIE-ECHO), and can also attach data to the response, allowing data to be transferred as early as possible in the handshake process.

After the recipient ACKs this message, the SCTP session is now established. The closing of an SCTP session is also different from TCP. In TCP, one side can close its sending function via a FIN TCP packet, and continue to receive packets, operating in a "half-open" state. In SCTP, a close from one side will cause the other end to drain its send queues and also shut down.

SCTP also functions in a form of transport-level multiplexing, where numerous logical streams can be supported across a single transport-level association. Although message order within an individual stream is preserved by SCTP, retransmission within one stream does not impact the operation of any other stream that is supported across the same SCTP transport association. Each stream has an explicit identification and a per-stream sequence identification to support this function. SCTP also provides for nonsequenced message delivery, where a message within a stream is marked for immediate delivery, irrespective of the relative order of the message within a stream (Figure 5).

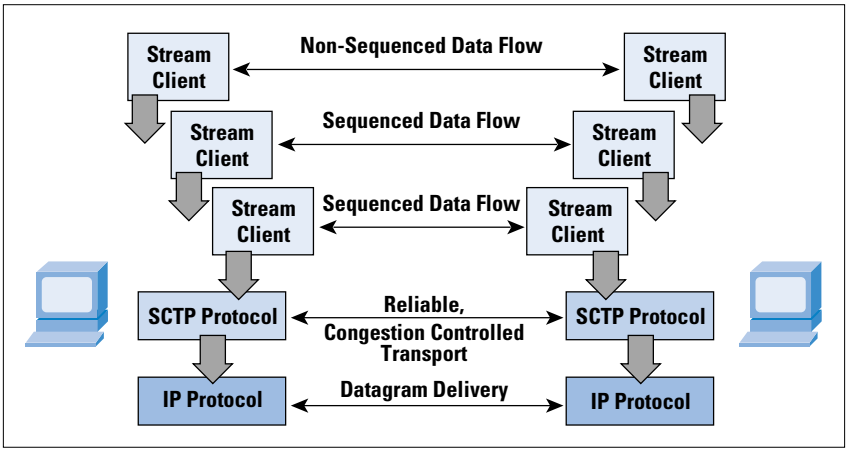

Figure 5: The SCTP Transport Service Model

SCTP explicitly uncouples transport-level reliability and congestion control from per-stream sequenced delivery through the use of a separate transport-level interaction. The transport-level data and ACKs and the corresponding transport-level congestion window controls operate using a transport-level sequence space. This sequence space counts transport-level messages, not byte offsets within the message, so that no explicit window scaling option is necessary for SCTP. The congestion control functions reference those of TCP with fast retransmit and fast recovery, with an explicit specification of the SACK protocol and specification of the maintenance of the transmission timers and congestion control. SCTP also requires the use of MTU path discovery, so that larger transactions will use SCTP-level segmentation, avoiding the IP retransmission problem with lost fragments of a fragmented IP packet. SCTP does use a modified retransmission mechanism to that of TCP. Like TCP, SCTP associates a retransmission timer with each message, and if the timer expires the message is retransmitted and SCTP collapses the congestion window to a single message size. The SCTP receiver will generate SACK reports for a minimum of every second received packet.

If a message is within a SACK gap, then after three further such SACK messages, the sender will immediately send the missing messages, and half its congestion window, analogous to the fast retransmit and fast recovery of TCP.

The use of multiple endpoint addresses assumes that each of the endpoint addresses is associated with the same end host, but with a potentially different network path between the two endpoints. SCTP refreshes path availability to each of the endpoint addresses with a periodic keepalive, so that in the event of primary path failure, SCTP can continue by using one of the secondary endpoint addresses.

One could describe SCTP as being overly inclusive in terms of its architecture, and there is certainly a lot of capability in the protocol that is not contained within TCP. The essential feature of the protocol is to use a single transport congestion state between two systems to allow a variety of applications to attach as stream clients. In itself, this is analogous to TCP multiplexing. It also implicitly assumes that every stream is provided the same service level by the network, an assumption shared by almost all transport multiplexing systems. The essential alteration with SCTP is the use of many transport modes: reliable sequenced message streams, reliable sequenced streams with interrupt message capability, and reliable nonsequenced streams. It remains to be seen whether the utility provided by this protocol will become widely deployed within the Internet environment, or whether it will act as a catalyst for further evolution of transport service protocols.

Sharing TCP information—Endpoint Congestion Management

The notion of sharing a single TCP congestion state across multiple reliable streams is one that may also be applied to a mix of reliable and nonreliable data streams that operate concurrently between a pair of endpoints. It is this form of the multiplexing service model that is explored by the congestion manager model. The Congestion Manager is an end-system module that allows a collection of concurrent streams from the host to a single destination to share a common congestion control function, and permits various forms of reliable and nonreliable streams to use the network in a way that cooperates with concurrent congestion controlled flows[19].

One of the major motivations for the congestion manager is the observation that the most critical part of network performance management is that of managing the interaction between congestion-controlled TCP streams and nonresponsive UDP data streams. In the extreme cases of this interaction, either traffic class can effectively deny service to the other by placing sufficient pressure on the network queuing resources that starve the other traffic class of any usable throughput. The observation made in the motivation for the congestion manager is that applications such as the Web typically open up a set of parallel connections to provide service, sending a mix of reliable flow-controlled data

along one connection and unreliable real-time streaming content along another. If the set of flows used a common congestion-control function at the sending host, the collection of flows would utilize the network resources in a manner analogous to a single TCP connection.

The manner of providing this common congestion control function is an advisory function to applications, as shown in Figure 6. One mechanism is that of a *callback,* where an application inserts a request to send a single message segment with the congestion manager. The Congestion Manager responds with invoking a callback to the requestor when the application may pass the data segment to the protocol driver. The other supported mechanism is that of *synchronous transmission,* where the Congestion Manager has a callback function that updates the application with a maximal available bit rate, the smoothed round-trip time estimate, and the smoothed linear deviation in the round-trip time estimate. In this mode the application can request further notification only when the network state changes by some threshold amount.

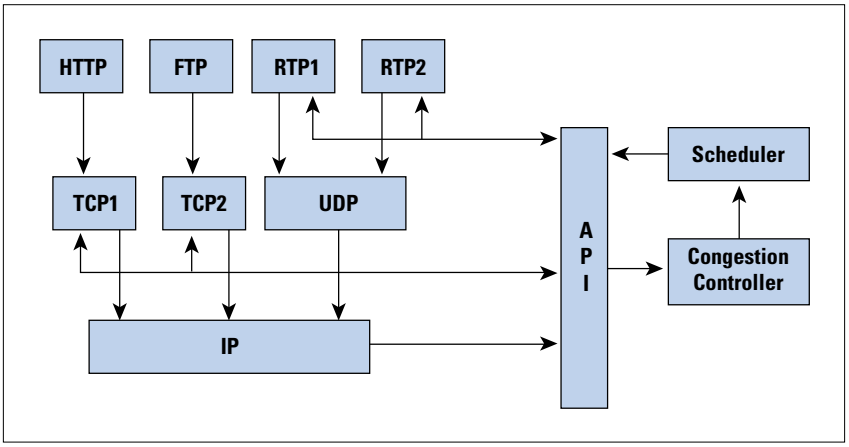

Figure 6: The CM Model, (after "The Congestion Manager"[19])

For the Congestion Manager to maintain a current picture of the congestion state of the path to the destination, each active stream needs to update the congestion manager as to the response from the remote host. It does this by informing the congestion manager of the number of bytes received, the number of bytes lost, and the RTT measurement, as measured at the application level. The application is also expected to provide an indication of the nature of the loss, as a timeout expiry, a transient network condition, or based on the reception of an ECN signal.

There has been little practical experience as yet with this model of shared congestion control within the Internet environment. There also remains a number of issues about how network performance information is passed back from the receiver to the sender in the absence of an active concurrent TCP session. The concurrent operation of a TCP session with a UDP streaming session to the same destination allows Congestion Manager to use the TCP congestion state to determine the sending capability of the streaming flow.

If the TCP session is idle, or if there is no TCP session, then the UDP streaming application will require some form of receiver feedback. The feedback will need to report on the span of data covered by the report, and the data loss rates and jitter levels, allowing the sender to assess the current quality and capacity of the network path.

This approach, and that of SCTP, are both illustrative of the approach of unbundling the elements of TCP and allowing applications to use combinations of these elements in ways that differ from the conventional monolithic transport-level protocol stack, with the intention of allowing the TCP congestion control behavior to be applied to a wider family of applications.

Better than TCP?

Recently, numerous "better-than-TCP" protocol stacks have appeared on the market, most commonly in conjunction with Web server systems, where the performance claim is that these protocol stacks can interoperate with standard TCP clients, but offer superior download performance to a standard TCP protocol implementation.

This level of performance is achieved by modifying the standard TCP flow control systems in a number of ways. The modified implementation may use a lower initial RTT estimate to provide a more aggressive startup rate, and a more finely grained RTT timer system to allow the sender to react more quickly to network state changes. Other modifications may include using a larger initial congestion window size or may use an even faster version of slow start, where the sending rate is tripled, or more, every round-trip time interval. The same technique of incremental modification can be applied to the congestion avoidance state, where the linear rate increase of one segment size per round-trip time interval can be increased to some multiple of the segment size, or use a time base other than the round-trip time for linear expansion of the congestion window. The backoff algorithm can also be altered such that the congestion window is reduced by less than half during congestion backoff. Resetting the TCP session to slow-start mode following the ACK timeout can also be avoided in such modified protocol implementations.

These techniques are all intended to force the sender to behave more aggressively in its transmission of packets into the network, thereby increasing the pressure on the network buffers. The network is not the only subject of this increased sending pressure; such modified protocol systems tend to impose a significant performance penalty on other concurrent TCP sessions that share the path with these modified protocol hosts. The aggressive behavior of the modified TCP systems in filling the network queues tends to cause the other concurrent standard TCP sessions to reduce their sending rate. This in turn opens additional space in the network for the modified TCP session to increase its transmission rate.

In an environment where the overall network resource-sharing algorithm is the outcome of dynamic equilibration between cooperative sending systems, such aggressive flow control modification can be considered to be extremely antisocial behavior at the network level. Paradoxically, such systems can also be less efficient than a standard TCP implementation. TCP server systems modified in this way tend to operate with higher levels of packet loss because their efforts to saturate the network with their own data packets make them less sensitive to the signals of network congestion.

Consequently, when delivering large volumes of traffic, or where there are moderately low levels of competitive pressure for network resources, the modified TCP stack may often perform less efficiently than a standard TCP implementation. Accordingly, these modified better-than-TCP implementations remain in the experimental domain. Within the production environment, their potential to impose undue performance penalties on concurrent TCP sessions and their potential to reduce overall network efficiency are reasonable indicators that such modified stacks should be used in private network environments, and with considerable care and discretion, if at all. Their utility in the public Internet is highly dubious.

TCP Evolution

The evolution of TCP is a careful balance between innovation and considered constraint. The evolution of TCP must avoid making radical changes that may stress the deployed network into congestion collapse, and also must avoid a congestion control "arms race" among competing protocols[20]. The Internet architecture to date has been able to achieve new benchmarks of network efficiency, and translate this carriage efficiency into ground-breaking benchmark prices for IP-based carriage services. Much of the credit for this must go to the operation of TCP, which manages to work at that point of delicate balance between self-optimization and cooperative behavior.

Widespread deployment of transport protocols that take a more aggressive position on self-optimization will ultimately lead to situations of congestion collapse, while widespread deployment of more conservative transport protocols may well lead to lower jitter and lower packet retransmission rates, but at a cost of considerably lower network efficiency.

The challenges faced with the evolution of TCP is to maintain a coherent control architecture that has consistent behavior within the network, consistent interaction with instances of data flows that use the same control architecture, and yet be adequately flexible to adapt to differing network characteristics and differing application profiles. It is highly likely that we will see continued innovation within Internet transport protocols, but the bounds of such effort are already well recognized.

We can now state relatively clearly what levels of innovation are tolerable within an Internet network model that achieves its efficiency not through enforcement of rigidly enforced rules of sharing of the network resource, but through a process of trust between competing user demands, where each demand is attempting to equilibrate its requirements against a finite network capacity. This is the essence of the TCP protocol.

Appendix: TCP Performance Models

This appendix is an extract from "Advice for Internet Subnet Designers," work in progress[15].

The performance of the TCP AIMD Congestion Avoidance algorithm has been extensively analyzed. The current best formula for the performance of the specific algorithms used by Reno TCP is given by Padhye et. al.[21], this formula is:

$$BW = \frac{MSS}{(RTT \times \sqrt{(1.33 \times \rho)}) + (RTO \times \rho \times [1 + 32 \times \rho^2] \times min(1, 3 \times \sqrt{0.75 \times \rho}))}$$

MSS is the segment size being used by the connection.
RTT is the end-to-end round-trip time of the TCP connection.
RTO is the packet timeout (based on RTT).
ρ is the packet loss rate for the path (that is, 0.01 if there is 1-percent packet loss)

This is currently considered to be the best approximate formula for Reno TCP performance. A further simplification to this formula is generally made by assuming that RTO is approximately 5 × RTT.

TCP is constantly being improved. A simpler formula, which gives an upper bound on the performance of any AIMD algorithm that is likely to be implemented in TCP in the future, was derived by Ott, et.al.[22, 23].

$$BW = 0.93 \times \frac{MSS\ 1}{RTT\sqrt{\rho}}$$

Assumptions of these formulae:

- Both of these formulae assume that the TCP Receiver Window is not limiting the performance of the connection in any way. Because the receiver window is entirely determined by end hosts, we assume that hosts will maximize the announced receiver window in order to maximize their network performance.
- Both of these formulae allow for bandwidth to become infinite if there is no loss. This is because an Internet path will drop packets at bottleneck queues if the load is too high. Thus, a completely lossless TCP/IP network can never occur (unless the network is being underutilized).
- The RTT used is the average RTT including queuing delays.

- The formulae are calculations for a single TCP connection. If a path carries many TCP connections, each will follow the formulae above independently.
- The formulae assume long-running TCP connections. For connections that are extremely short (<10 packets) and don't lose any packets, performance is driven by the TCP slow-start algorithm. For connections of medium length, where on average only a few segments are lost, single-connection performance will actually be slightly better than given by the formulae above.
- The difference between the simple and complex formulae above is that the complex formula includes the effects of TCP retransmission timeouts. For very low levels of packet loss (significantly less than 1 percent), timeouts are unlikely to occur, and the formulae lead to very similar results. At higher packet losses (1 percent and above), the complex formula gives a more accurate estimate of performance (which will always be significantly lower than the result from the simple formula).

Note that these formulae break down as ρ approaches 100 percent.

Addendum: An Update on Explicit Congestion Notification

The previous article on TCP performance noted that there was no explicit standardization of the IPv4 header field to carry the *Explicit Congestion Notification* (ECN) signals. As an update to the status of ECN, RFC 2481, the document that describes ECN, categorizes this proposal as an "Experimental" RFC document[27]. The Internet Standards process[28] describes this category as follows: "The 'Experimental' designation typically denotes a specification that is part of some research or development effort. Such a specification is published for the general information of the Internet technical community ..." ECN is the only experimental proposal to use these two bits of the IP header, and the use of the category "Experimental" reflects the current status of the proposal, in that the Internet Engineering Steering Group has, at the time of publication, yet to make a final decision to allocate these two bits of the IP header to ECN.

Some encouragement to use ECN is certainly timely. As RFC 2481 notes: "Given the current effort to implement RED, we believe this is the right time for router vendors to examine how to implement congestion avoidance mechanisms that do not depend on packet drops alone. With the increased deployment of applications and transports sensitive to the delay and loss of a single packet (e.g., realtime traffic, short web transfers), depending on packet loss as a normal congestion notification mechanism appears to be insufficient (or at the very least, non-optimal)."

Securing the Infrastructure

by Chris Lonvick, Cisco Systems

People are becoming much more reliant upon the proper operation of their networks. Consequently, the administrators of these networks are being tasked with providing an ever-increasing level of service. At this time of high reliance upon the network, methods and procedures need to be instilled into the network so the operators can maintain control of their network and they can know with some certainty the effect of each potential change. This may become increasingly difficult as network resiliency techniques are being proposed and deployed with the intent of automatically keeping these networks in top operation. Having a predictable network that is secured in a proper manner results in a network that is more suitable for the users and better meets the intended purpose of the network.

Most of the current network security models start with the physical perimeter of the network as its defining boundary. All things within this boundary are supposed to be protected from the perceived inimical forces that are outside of the perimeter. We are, however, finding that the perimeter of the network is no longer solidly defined. There are many exceptions to the "hard-shell perimeter" model—companies merge, remote sites are linked through *Virtual Private Networks* (Site-to-Site VPNs) across untrusted paths, access is granted in-bound for the network users through *Access Virtual Private Networks* (Access VPNs), and there are several other exceptions. For this article, let's consider a different model. This model has a boundary of the acceptable network users rather than any geographical or logical perimeter. It is important that these users are allowed access to the services provided by the network. It is equally important that the people who are not authorized to use the network must be prevented from consuming its resources and otherwise disrupting its services.

Other models tend to focus on the restrictions of the users to access devices to provide security to the network. This model, however, looks at the effect that the users and each of the devices have upon the state of the network. To conceptualize this model, visualize that the only time this network would be running at a "steady state" is when there is no user traffic, no administrative or management traffic, and no routing update changes. The insertion of any traffic, or the addition or removal of any device or link, would change the state of this network. Changes to the state of this network may come from any number of sources, but they can be seen as coming from four different, quantifiable areas.

- Operators may enable or disable lines and devices.
- A network device publishing a new route or a different metric to a destination may cause the remainder of the network devices to dynamically recompute paths to all other destinations.
- Servers may insert traffic.
- Users may insert traffic.

Of these, the last two should be the least disruptive to the network as long as the traffic amounts are within the predicted and acceptable ranges. Changes that are within the goals of the network—for example to provide a service to the users—are considered good, while changes that cause outages or other disruptions are to be avoided. As such, it is vital that the network administrators understand the potential impact and consequences of each possible change in their network.

In this model, then, the administrators must know and understand the influences that will change the state of the network. The desire to achieve this goal sometimes leads to improper restrictions placed upon the users. Consider one extreme case of this model where each change in the network must be stringently authorized and authenticated. As a narrow example, this would mean that even traffic that is fundamentally taken for granted as a proper process of the network would have to be authenticated and authorized. *Domain Name System* (DNS) transactions would show that this extreme case is impractical. Each DNS query would have to be associated with a user or authenticated process, and that user or process would have to be authorized to make each specific query. A vastly more practical case for real networks would be for the administrators to allow any DNS query from any device without authentication—as it is done in existing dynamic networks today. In the model, the normal DNS queries and responses would be an influence upon the state of the network. For this influence to change the network in a way that meets the goals of the network, the administrators would have to feel comfortable that the servers and the available bandwidth will adequately handle the amount of DNS traffic as well as all other traffic. On the other hand, the administrators do need to establish a strict set of rules for the influences that they consider sensitive or possibly disruptive to their network. Continuing this example, the administrators may want to place restrictions upon the devices and processes that can insert and update the DNS records. It would be rather inappropriate, and potentially devastating, if any unauthorized person or network device were allowed to overwrite any existing records. If anyone were allowed to perform any DNS update that he or she wished, chaos would soon result. There must be a center position for this example that allows the operators to maintain control but still permits the dynamic freedoms expected by the users. Specifically to address this, the DNS Extensions Working Group has proposed several Internet Drafts[1].

In the broader sense, this places a very heavy responsibility upon the people who are running the network. They must find some acceptable median between the desire to rigidly control all aspects of the network and the freedoms that are expected by the users, while at the same time satisfying the business requirements of their network. However, defining the freedoms and restrictions of the users is only one part of maintaining the network. The administrators and operators must have an understanding of the influences on the network as described in the model. In this, each aspect of the parts of the network must be under-

stood well enough to predict their behavior as they are normally used, and to limit the potential for disruption if they are used beyond their means. The one area that is vital to the proper working of the network is the infrastructure. This article explores some of the thoughts that may go into the process of securing the network infrastructure.

Table 1: Sources of Change to the Network

Sources of Change to the Network	Some Examples of How the Source Influences the Network	Examples of Device Types within the Network (The 4 Groups)	
Operators and their Devices	• Add/remove new lines and circuits • Install/remove network devices		
	• Login to the network devices to change their configuration • Poll network devices for their status	• Operations Consoles • Network Management Stations	Operators
Network Devices	• Dynamically route or switch traffic • Dynamically mark lines and circuits in or out of service and then use them accordingly • Authenticate users and permit their accesses accordingly • Dynamically assign addresses and register that information for retrieval by others	• Routers and Switches • Firewalls	Infrastructure Devices
		• Authentication Servers • DNS/DHCP Servers	
Servers	• Servers send content to User's workstations to fulfill their requests • Servers broadcast and multicast content to recipients	• Servers offering Content and Servers	Servers
Users and their Devices	• Client workstations request content from servers and upload content to servers • Client workstations utilize services that are offered within the network	• Client Workstations	Users
	• A user encourages many others to visit a particular web site which causes a stampede • A user tells others that a particular service is down or unavailable causing others to not attempt access		

Description of Problem

In this abstracted network model, four sources of change were noted. As shown in Table 1, these changes, or influences to the network, may come from the operators, the network devices, the servers, and the users of the network. Let's first look at the influences that each of these groups can effect upon the network by first categorizing the network devices. All the devices on the network may be somewhat separated into four groups that correspond to the four sources. These groups of network devices can be seen in the third column of the table.

- *Operators:* For the purpose of this article, let's describe the Operators as all the people who operate the network, including the network engineers, the installers, the people who monitor the net-

work, and all the other people who make it work. The first group then is made of the operators and the devices that these operators use to run the network, such as the network management stations and all other operations consoles. Operators periodically make changes for moves and additions for better network performance, or to overcome disruptions. They will also monitor the network through polling, receiving alerts, and sometimes directly interacting with the network devices. Generally the amount of traffic inserted into the network from their activities is minimal. Because they generally have physical access to all locations, they can insert or remove network devices. Operators can have influence over all aspects of the network at all layers—from the physical layer, all the way up the stack. Operators can influence the network either in band or out of band, and they should be the only people who directly access the network infrastructure devices such as the routers and DNS servers. Usually this access will be from the management platforms, but in many situations, operators require access from devices that would otherwise be classified as a user's workstation.

- *Infrastructure Devices:* The network infrastructure devices themselves have the ability to change the network as well. This is mostly done through the dynamic nature of the network. At some times the physical portions of the network might fail and cause outages. In some cases, such as self-healing ring topologies, physical-layer devices may heal the network. In other cases, such as when a router is taken out of the network for maintenance, the routing updates will heal the network to the best of their abilities. The network infrastructure devices can be somewhat separated into two categories. The first of these would be the infrastructure devices that have no direct interaction with the users of the network. This category would consist of the devices such as the routers, switches, access control devices, and perhaps even the physical-layer devices such as multiplexers and modems. The user machines and content servers normally would not form sessions or require any information from these devices. The second category would be the devices with which customers indirectly interact. These would be devices such as the DNS servers, *Dynamic Host Configuration Protocol* (DHCP) servers, *Network Time Protocol* (NTP) servers, authentication servers, and the like. The users and servers would form sessions with these supporting devices and would require information from them for the basic operation of the network. In some cases, such as with a DNS/DHCP server, the results of the indirect user interaction would even update the servers with information. This latter group may be called "supporting devices." These two categories can be taken together with all the wires, circuits, and lines to form the infrastructure of the network. Although the users do not actively see their presence, this infrastructure must be available and functioning before any user can actually do anything productive on the network.

- *Servers:* The servers in this group are those that contain content or services with which the users directly interact. These would be databases, Web servers, application servers, and the like. Like the operators group, this group is not considered to be part of the network infrastructure.
- *Users:* The users and their machines constitute the bulk of the network. The changes that the users make upon the network will probably come through transferring content or requesting and utilizing services. They can change the nature of the network by withdrawing from the network, or by causing others to withdraw from the network. In a nonmalicious way, the user base can degrade the state of the network by using it beyond its expected capacity. In certain situations, users with malicious intent may find exploitable network vulnerabilities. In most normal cases, however, the influence from the users upon the network will be through their interactions with the servers.

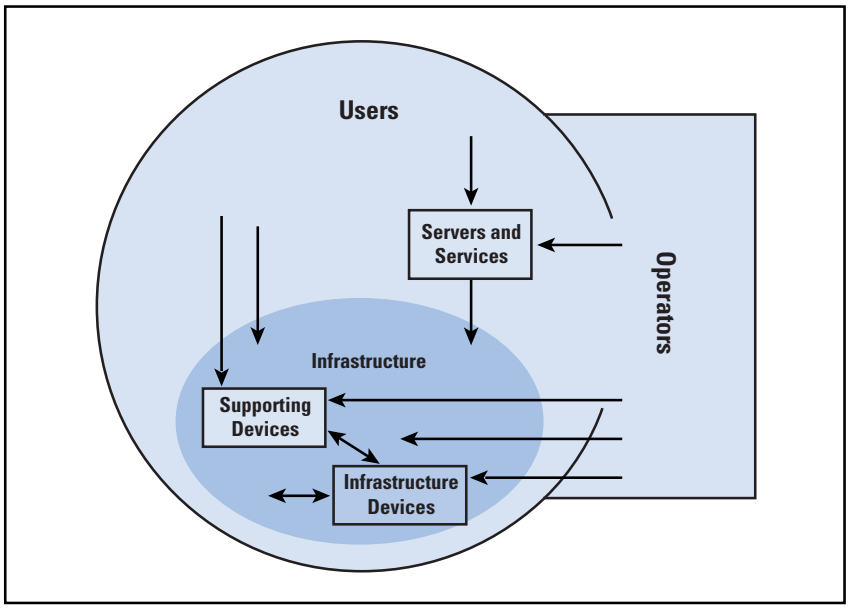
Each type of influence may also be considered to have a different weight. For example, the insertion of a new router into an existing network would be expected to have a larger effect upon the operations of the network than the change to the network caused by a user retrieving some information through a Web browser. To quantify some of the expected network changes, consider that there may be spheres and levels of influence. Any influence that may cause a change over the entire network may be considered to have a global sphere of influence. A router recently inserted into the network would start exchanging routing information with its neighbors. With no restrictions placed upon routing updates, this router could announce a new network, or it could announce the best path to an otherwise difficult-to-reach network. The remainder of the network would be affected, and all other routers would have to recalculate their paths. If the announcements were true, then the network would continue servicing the needs of the users. If the announcements were false, possibly because of an incorrect configuration, then the whole network could suffer. In this case, it is possible to limit the sphere of influence by restricting the acceptance of routing updates. In one method, all the routers could be restricted to disallow the acceptance of an announcement to the "default" network. Additionally, all the routers may be restricted to accept only announcements that are known to be within an acceptable address range. In another method, the routers could be grouped to accept announcements only from a select set of other routers. Additionally, some routing protocols have an option to include an authentication and integrity check through signing the updates. Any of these methods would help to reduce the sphere of influence and thus the potential for changes that could be made by the insertion of a router. There is, however, a cost associated with this; the operators would have to diligently enforce this control.

The level of influence can also be considered a factor in this model. The sphere of influence of a single transmission line can be defined to include any portion of the network that uses that line. If that line develops a fault, it may corrupt or discard packets and the associated network devices may automatically disable that line. If there is a backup line or an alternate path, then this change will be a small problem to the operations staff and its loss may go unnoticed by the users. That would be a low level of influence upon the network. On the other hand, if the line has an intermittent fault that can cause a route flap, or if the line has no backup, then major disruptions may occur. That would be considered a high level of influence.

If the goal of the network is to provide a service to its users, then its operators must try to quantify each of the influences. In a theoretically ideal network, the administrators would appropriately limit the sphere and would try to minimize the level for every influence. As was noted above, however, attempting to do this would require numerous operations tasks. Many of those may be unnecessary for their specific environment. For example, in a small business where there is a high degree of trust that no one has any malicious intent, controls would still be placed upon the influences that would most probably cause network problems through accidents. If the security policy allowed anyone to connect any device to the network, it may still be prudent to disallow the routers from receiving routing updates from any source other than the other routers.

A well-running network is the result of a well-controlled network. These networks must have a separation of authorized administration from other influences, and these other influences must be understood well enough to know how they will change the network. The following diagram shows the network and the groupings of influences upon it, and the table below that describes the elements of this model. This model does not show access paths, but rather the influences that each grouping of devices has upon the infrastructure and upon other devices. As can be seen, the users are pervasive throughout the network (because they are a principal reason for its existence), and they must have the access paths to contact the servers and necessary infrastructure devices. The users will influence the infrastructure as they insert traffic upon the lines, but they should have no direct influence upon the infrastructure devices such as the routers and digital access cross-connects. The operators do have influence upon the infrastructure devices and must have an access path to those devices. It would be most appropriate if the users were not allowed to usurp the access paths of the operators. However, because the two are sometimes nearly indistinguishable, the task of separating the administrative channels from the user channels becomes difficult.

Figure 1: The Network Security Model



The following table describes the elements in this model.

Table 2: Network Model Elements

Element	Description	Example
Operators	The devices and people who operate, manage and support the network	Monitoring and Management Workstations, Syslog servers
Infrastructure	This composite area denotes the entire infrastructure. This is broken out to show the actual infrastructure devices as well as the supporting devices.	• Infrastructure Devices: Routers and Switches • Supporting Devices: DNS and DHCP servers • All other infrastructure components: wires, circuits, DSU/CSUs, SONET equipment, repeaters, etc.
Servers and Services	The devices that host content and services for the users	Web servers, file servers
Users	All of the users of the network and their workstations	Alice, Bob, Carol, Dan and their workstations
Arrows	Define which element influences or changes which other element	Users insert traffic into the network and thus influence the Servers and Services. Operators may also influence each of the components of the Infrastructure

Know Your Business

All well-running networks must have a *security policy* defined. This must reflect the goals of the network and must also be acceptable to the users and administrators. There are good examples of policies as well as methods that can be used to generate them. RFC 2196[2] contains several thoughts about constructing a policy and SANS[3] offers courses on this. While defining a network security policy, it will be advantageous to list the most likely disruptive influences to the network. This is commonly called *The Threat Model*. All potentially disruptive factors should be considered when forming the threat model, and they must be addressed when writing the security policy. It may, however, be beyond the capabilities of the operations staff to negate all of them. It may also be prohibitively expensive to try. In those cases, the writers of the policy should acknowledge the factors that won't be negated, but they should still find ways to minimize them. For example, in an Enterprise network the operators are somewhat likely to require access to routers and switches from any physical location in the network. In Service Provider networks, there may be less of a chance of that because the operators traditionally reside with the network management devices. In both cases, it would not be considered good for the network if a user could gain control of a router. The security policy for an Enterprise network may explain that network access to routers will be opened and available for any other device within the network. This will allow any operator to access the routers from any location. On the other hand, the security policy for a Service Provider network may state that access to the routers will be opened only for specific address ranges. Implementing this will prevent users, who reside within the address spaces assigned to the users, from accessing the infrastructure devices while allowing the operators, who reside within their own address space, to access the routers. In both cases, however, strong authentication will probably be required to additionally limit access to only authorized people.

Within the business of the network, operators must have the ability to control the infrastructure devices. Traditionally, the ways to interact with a device have been called "interfaces." A terminal with keyboard attached to the console port of a router is an interface just as is a Web browser accessing the router via the *Hypertext Transfer Protocol* (HTTP) through the network. Also, the path between the controlling device and the infrastructure device has traditionally been called a "channel." The wire connecting the terminal to the router is a channel just as is the TCP session that transports the HTTP in the prior example. The channels between the operators and the infrastructure devices must be secured, as well as the channels between the infrastructure devices. The first step in obtaining this goal is to identify all of the interfaces needed by the operations staff to access each of the remote devices. Along with this, they also need to identify each of the interfaces needed for the proper functioning of the network. The following lists are some of the possible network-available interfaces to some of the infrastructure devices in a dynamic network. This is somewhat broken down

into the interfaces needed by the operations staff, the interfaces usually needed by the other infrastructure devices, and some ancillary interfaces.

Table 3: Some Interfaces of Infrastructure Devices

Operations and Interfaces	Infrasturcture Interfaces	Ancillary Interfaces
telnet, Kerberized telnet, SSH, rsh, rcmd, rexec, HTTP, FTP, tftp, rcp, scp, SNMP, LDAP, COPS, Finger	Syslog, ICMP, DNS, DHCP, RIP, OSPF, BGP, IS-IS, IGRP, EIGRP, HSRP, NTP, SNMP, Multicast controls	RADIUS, TACACS+, Kerberos Authentication, PAP, CHAP, EAP, chargen, echo, time, discard, Auth (Ident)

Each of these interfaces may be exposed to the nefarious forces that are known to inhabit large networks, and each of these exposures has vulnerabilities that may be exploited. Telnet sessions may be hijacked, DNS queries may be answered by nonauthoritative and possibly maliciously incorrect responses, and sinister people can insert forged routing updates to confound and disrupt the network. The network security policy should expect that these vulnerabilities may be exploited and it should address the mechanisms that may be used to either negate the vulnerabilities or to minimize the exposures. In this model, the process may be used to limit the sphere and level of the influences. The policy may also make some attempt to identify the potential consequences of the disruption caused by the exploitation of these interfaces. It should also describe an escalation procedure for dealing with encountered problems.

Possibly, during the exercise of identifying the open interfaces in an existing network, some of them may be closed or removed if it is determined that they are not needed or if their function can be fulfilled by the use of another interface. As an example, consider a UNIX host that has both the *Secure Shell Protocol* (SSH) and *finger* services running on it. If the policy of the network is to tightly control the information that anyone can obtain from any device, then the operators may want to remove the *finger* service. The operators will be able to obtain similar information by running the *who* command on the UNIX system through an SSH remote execution request. On the other hand, if the operations processes have been built upon the format of the information returned by *finger*, then the operators may want to prevent direct access to *finger* from the network and require that it be run on the device or through the SSH request.

At some point, it would be a good idea to run a scanner against the infrastructure devices. The *Network Mapper* (NMAP)[4] is a freely available tool that can pick out some of the active interfaces of a device. This, or a similar tool, should be periodically used by the operations staff to ensure that the open ports of an infrastructure device are those that are known to be open. This investigation should not be limited to operations channels, but should also include application channels. For example, the question should be asked if the operations workstations should have open application interfaces—such as *Simple Mail Transfer Protocol* (SMTP) or *Network File System* (NFS). There are exploitable

vulnerabilities associated with some application interfaces that should be addressed in the security policy. In most cases, it would be prudent to remove applications that are not needed from infrastructure devices and supporting servers, as well as from operations devices when they are not needed. In all cases, it is usually considered to be a good practice to review the entries in the *inetd* configuration in UNIX systems.

It should be remembered that there will almost certainly be an access path between the users and the network interfaces of the infrastructure devices. The network security model diagram shows that neither the users nor the servers should have any direct influence to change or control the infrastructure devices. This is somewhat analogous to the policy of giving privileges on a multiuser system. In most well-run multiuser computing systems, the operators give only the most meager of privileges to the users of the system. This prevents most accidental and malicious disruptions. If the users need to run a privileged process or to access the files of other users, processes that utilize setuid are used or consensual groups are established. Generally, efforts are made to prevent users from having significant privileges on these machines. The alternative of giving each user high-level privileges usually results in disaster after a short time because the users then have the ability to overwrite or delete files, and may run processes that are generally disruptive to the operating system and to others.

Similarly, giving users high-level access to the routers of a network would have a deleterious effect. In the case of *Quality of Service* (QoS), a user given the privileges to reconfigure routers along a path would be able to provide his/her own designated flows with bandwidth and priority assurances. Subsequent users would also have that capability, and their modifications may leave the first user without his/her expected QoS—and possibly without a session at all. A far better mechanism to fairly deploy QoS is through the use of a brokering service. In a "policy network," users or authenticated processes may request a level of service for their flows through a *Policy Manager*. This Policy Manager should have the capability to arbitrate requests to provide a semblance of fairness. The Policy Manager would then directly control the appropriate routers within the rules established by the administrators.

Along these lines, conveying security-related policy to infrastructure devices should take a similar path. For example, if the network security policy states that user access to a particularly sensitive network resource must be authenticated and controlled, the operators may elect to place a firewall between the users and that resource. That firewall would be classified as an infrastructure device and users should not directly access or control it. Rather, the users may authenticate themselves to an authentication service, which would notify the firewall that their access to the resource is permitted or denied. The authentication service may also send a set of restrictions for the access method; it may permit HTTP access but deny Telnet and *File Transfer Protocol* (FTP) for one person, but for another it may permit only Telnet.

The reasons for authentication, authorization, and access control must be described in the network security policy. It would be simple to mandate strict controls at many places in the network. However, that may not meet the needs of the business or the tolerance of the users. More to the point in this article is the requirement in the model that the disruptive influences be negated or minimized. Having a firewall or other access control device silently discard disruptive packets may be preferable to having a user or unconstrained process continue to spew garbage around the network.

Decide on the Methods of Securing the Channels and Interfaces

Some of the very first computing devices were designed to be managed locally and not remotely. Consoles consisting of a teletype device and a roll of paper were among the first interfaces to modern computing devices. Various methods were devised to extend these administrative interfaces beyond the confines of the frigid "Computer Room." The first efforts were to keep these interfaces out of band, a scenario that meant separate wires from the physical port on the machine to a console in the operations room. In many cases, the wires from the remote terminals to the system were still visible because they were laid along the floor and could, therefore, be considered a secure channel. While this maintained a secure administrative channel—or path—that could not be tapped or exploited by others, it didn't scale as more and more computing and ancillary devices were placed into the computer room, each requiring its own console. When remote terminals became commonplace, administrative functions were allowed over that channel. In almost all cases, the operating systems were mature enough to require some form of authentication before critical management operations were allowed.

The out-of-band channels for secure remote administration of devices may no longer be applicable to large networks. There are costs associated with running separate secure networks for the sole purpose of out-of-band operations, and there is the impracticality of one-at-a-time access through the console port of each device. This applies equally to the practice of placing a modem on the console ports of devices—a deployment that is not considered secure because there are still many automated dialers looking for answering modems. For these reasons, in-band access of operations has become the preferred method for modern networks. Telnet has been the oldest remote channel—and interface—for remote operations. Since then, other remote interfaces have been opened for controlling, commanding, and operating devices.

Many attempts have been made to "secure" Telnet and its use as a command and control channel. These efforts address the vulnerabilities of the protocol, and some address the interface itself. The *Berkeley Software Distribution* (BSD) "r" command set, such as *rlogin, rsh, rexec,* and others, were meant to be a substitute for the most common uses of Telnet within a trusted environment. It was assumed that the person initiating the command had previously been successfully authenticated.

SSH was meant to be a secure replacement of the Berkeley "r" tools. The SSH console session has been widely deployed to remotely operate devices. This replicated the Telnet interface while replacing the channel. The protocol addressed machine authentication, user authentication, and session confidentiality and integrity. When used as it was intended, it can effectively replace Telnet as a secure interface and channel. The *scp* feature of SSH can also securely replace *rcp,* and it has been used as a replacement for FTP. Likewise, a Kerberized Telnet and Kerberized FTP have been released to do the same.

Several other efforts have also been undertaken to secure some of the other administrative interfaces and channels. For example, the security issues of *Simple Network Management Protocol* (SNMP) are being addressed with the options of SNMPv3[5]. Also, applications that utilize HTTP can be secured with HTTP over SSL (HTTPS) (*Secure Sockets Layer/Transport Layer Security* [SSL/TLS])[6]. At this time, it appears that SSL/TLS is emerging as a mechanism that can be utilized to provide some security to many different applications. Beyond the operational interfaces and channels, work has been done to secure some of the infrastructure and ancillary interfaces. Some routing protocols have built-in authentication and integrity through the use of signing the routing updates with a shared key. Each mechanism that has been secured has been the subject of a focused effort to address that specific interface and channel. However, unlike those named above, some channels, such as Syslog and *Trivial File Transfer Protocol* (TFTP), have not been explicitly secured at this time.

IP Security (IPSec)[7] was developed as a general-purpose mechanism that may be used to provide a secure wrapper around any unicast flow. Its cryptographic mechanisms can provide strong authentication, confidentiality, and integrity. While IPSec can be used to secure any flow, it may require additional infrastructure. A *Public Key Infrastructure* (PKI) must be established within the network. The alternative is to use preshared keys, a solution that is operationally intensive and doesn't scale well. IPSec also requires consistent time synchronization between the devices, as well as a consistent DNS. If these pieces are in place, the operations staff can utilize IPSec to secure each of the needed operations channels. If the operators and administrators choose this method, then they should ensure that the unsecured channels are unavailable to anyone but themselves. For example, if the Telnet channel is secured with IPSec, then the Telnet port on remote devices should be closed for inbound access.

One method of closing the exposures is through *Access Control Lists.* Routers and switches usually have mechanisms that can be used to allow inbound and outbound sessions from only certain devices. UNIX devices usually have the ability to run TCP wrappers that can provide access-control mechanisms for inbound and outbound sessions. If infrastructure devices can be grouped together, the operators may decide to

place them behind an internal firewall. The decision to do that should be thought through. Generally the internal firewall will limit access of the protected devices to the specified interfaces[8]. If this is done for a group of network management stations, the net effect may be that any attempts to access those workstations from outside of the firewall would be denied. The only inbound flows may be SNMP responses and traps. This implementation would limit the operations staff to being physically present before they could operate those devices. On the other hand, the firewall would prevent users from mistakenly or intentionally forming sessions with those devices. Because any received packet would have to be assessed by the device, a firewall that would discard packets before they are received by the device would help to prevent denial-of-service attacks. The use of internal firewalls should not be used as an excuse for poor security measures on the protected devices. Regardless of how effective the operators feel their firewall is, the protected devices must be treated as if they were otherwise exposed.

In determining the channels that will be used for the administration of the infrastructure devices, the packages will also be selected. At this time, many devices are sporting Telnet, FTP, and HTTP channels and the operators may utilize workstations that have these packages already loaded onto them. Also, networks comprising Microsoft NT servers may be managed remotely by the NT administrative tools, which commonly run on NetBIOS over TCP/IP (NBT). When given the choice, most often the operations staff will select easy-to-use and commonly available packages to access the interfaces of the infrastructure devices for remote operations and control. In all cases, these will be packages that will be available to the user community of the network as well. The users of the network may also easily download packages of these types if they don't already have them on their machines. For example, the operators may choose to utilize SSH for secured access to some devices. It is a trivial task for the users to also download an SSH client package and to start poking around the network to see what they can find. Even SNMP packages can be easily downloaded to the workstations of the users.

The operators and administrators must avoid the temptation to select a less-well-known package for infrastructure management based upon the thought that the users probably won't know about it. Users may not be initially aware that some packages are being used, but they can also download sniffer packages. Given enough time, even passive sniffing will give them enough clues to determine the channels used for administration. When they know that, they can then probably download the package themselves, and may then attempt to use it to explore the network. It should also be noted that the more heavily used packages have been scrutinized much more than the newer or less used packages. As a very general rule, the older a package gets, the more it becomes trusted because more people have been using it and *probably* attempting to break it.

As described above, and as it is seen in the diagram of the model, some of the channels that are available to the operators are also available to the users. This means that if the operators utilize Telnet to control their routers, it may be possible for a user to also initiate a Telnet session to a router. There must be an extremely strong discriminator to differentiate between the authorized operators and the unauthorized users before access to control the device is granted. Almost exclusively, the discriminator used is some form of authentication. An operator should be able to satisfy an authorization challenge, whereas an unauthorized user should not. A username and password is the most common form of in-band authentication. Specifically within Telnet and FTP, an in-stream challenge is presented to the user attempting a session; the user is asked for a username and then for a password. If these credentials match the values stored on the host, then the session is permitted. In these sessions, the credentials are exposed to casual observation. Anyone with a packet-sniffing device will be able to plainly see the username and password. These credentials must be regarded as secrets that must be protected. If they are compromised or stolen, then the operators have lost their control of their network. Some packages, such as SSH and Kerberos, have addressed these problems and have found ways to prevent secrets from being passed during authentication.

It must also be noted that some infrastructure devices do not offer any in-band channels for control. Many *Channel Service Units/Data Service Units* (CSU/DSUs) are not IP aware and do not offer any in-band channels for control. In cases like those, physical access may be the discriminator that prevents unauthorized users from controlling the device. Typically, a lock on a door or a cabinet would be the "challenge," and the key would be the authentication credential, which must be treated like a secret. It cannot be emphasized enough that these secrets must be protected. The *CERT Coordination Center* has written a very broad Tech Tip, which explores the topic of password security[9]. Many companies have found it very beneficial to periodically hold training courses to highlight the importance of this subject both to their operators and to their users.

Ancillary Channels Also Require Security

One of the parallel problems with using authentication credentials is its distribution. Many devices are capable of maintaining a local database of usernames and passwords. However, maintaining identical databases on each device throughout large networks is infeasible. More often, the authentication credentials are stored in a centralized database and an *Authentication, Authorization, and Accounting* (AAA) protocol is used to transfer them as needed. The AAA protocols most often used are *Remote Access Dial-In User Service* (RADIUS), TACACS+, and *Kerberos* authentication. Each of these has different characteristics and security mechanisms. Kerberos authentication was designed to securely transport authentication material. A password is never transferred across the network in this architecture. This protocol has withstood the test of

time, but it has been difficult to establish in networks that aren't committed to maintaining it. This situation seems to be changing because more "productized" versions are becoming available on the market. TACACS+ has a mechanism to hide the exchanges between the TACACS+ client and the server. It is also capable of transferring authorization rules for each user. RADIUS uses a mechanism to hide portions of the exchange between the RADIUS client and server as well.

Beyond this, the channels for telemetry, audit, and accounting may need to be secured. There are no inherent mechanisms to secure syslog at this time, and SNMPv1 may be protected with a Community String, but that solution is considered weak. It is possible to allow read-only access to the SNMP interface, but SNMPv3 has many of the security features that have been requested to secure this protocol. Other channels that are required by the operations staff should also be critically reviewed because many forms of attacks are on open channels.

It would be appropriate for the operations staff to keep up with new exploits and to assume that the users of the network have access to the latest "hacker" tools. It is quite common for people to hear about an exploit or published vulnerability and then "try it out" in the nearest available network. For this reason, it should be in the security policy of the network that "security patches" be given the highest priority and should be loaded on the affected platforms as soon as they are available and have been approved for the environment.

Conclusions

When any security mechanism is applied, the appropriateness and applicability of the solution should be questioned. On the surface, some security solutions may appear to be good; however, their applicability to the situation must be verified. As an example, SSL may be used to secure HTTP traffic, and it is commonly found in many Web browsers. Unfortunately, not many people explore the browser options that are enabled by default. In most browsers, SSLv2 is still available, even though it has published and exploitable vulnerabilities. Additionally, even in SSLv3—which negates the vulnerabilities of SSLv2—low key-length cipher suits are still available and enabled by default. In many cases, a null-cipher crytpo algorithm is available. In the internal networks of many companies, SSL may be selected and implemented using a self-signed certificate. Care must be taken to ensure that this certificate is the one distributed to each administrative workstation. SSL sessions may be formed without certificates supplied by either endpoint. An attacker could exploit this through a man-in-the-middle attack. Another example would be the use of SSH. SSHv1 has known vulnerabilities. If the administrators decide to deploy SSH for the control of the remote infrastructure devices, they should first decide if they should be worried about attacks against those known vulnerabilities in their infrastructure. If they are, then they should either deploy SSHv2, which addresses the vulnerabilities of SSHv1, or they should explore the use of Telnet with IPSec.

In many cases, rather than using the "most secure" solution, perhaps a simpler solution would still provide adequate protection. The "most secure" solution—the one that mitigates all perceived threats—is usually too costly to implement. In many cases, network operators and administrators with many years of experience have decided that SSHv1 is adequate for their needs and they can mitigate or minimize the exposure. In other cases, some operators are turning to SSHv2 or IPSec to cover the vulnerabilities that have been found in SSHv1. In some cases, the use of SNMPv1 may also be acceptable as long as its exposures are understood and the operators determine that its use will not pose a problem.

Excessive "security" may also intolerably reduce the usability of the network. It is important to remember that the network is there for the users. Placing security restrictions upon them to keep them out of the infrastructure is like keeping the doors locked to the building boiler room. Untrained people entering that area may hurt themselves or they may cause serious problems to others. If they have malicious intent, they could damage the machinery. Excessive security for that analogy would be similar to locking the boiler room, locking the ingress and egress points to the building, and mandating that armed guards accompany anyone that is permitted to enter the building. In some cases, that may be appropriate for the perceived threat. However, in the case that this applies to an elementary school building, it is inappropriate and would make some parents think of moving their children to other schools.

The model described in this article may be used as a thought process to review an entire network at a high layer to see the relationships between the various devices. It may also be used to design the security policy and the acceptable use policy of the network. Another use for it may be to define the operational procedures for the operators to securely administer the network and to define how the infrastructure devices will communicate. However it is used, some settlements must be made between the desire to provide security and the usefulness of the network. The cost of the security mechanisms cannot be unreasonably high, and the mechanisms cannot change the business model of the company. The enforcement of the policy must be effective, yet above all it must not change the expectations of the users. In all cases, the administrators and operators must find some balance between their need to secure the infrastructure and the need for the users to have the ability to actually use their network.

Book Reviews

Multiwave Optical Networks

Multiwavelength Optical Networks: A Layered Approach, by Thomas E. Stern and Krishna Bala, ISBN 020130967X, Addison-Wesley, 1999.

Initial Impressions

This book attempts to fit into two camps; one, an overview of the potential choices that could be offered in wavelength-division multiplexing, or WDM, and the other, an academic text. Because of its scope, the treatment is uneven.

Organization

The first four chapters lay the groundwork. Chapter 1 starts by defining terms and positing why WDM is an enabling technology. The authors believe that the driving application will be LAN interconnection, ostensibly in metro areas. It is worthwhile noting that the authors make no claims about this text relating to an all-optical network. They simply expose the choices available to manipulate the various wavelengths, or lambda. The current methods for performing lambda manipulation are still bound in the electrical domain.

Chapter 2 covers the hierarchy or layering present in a WDM environment and some of the choices for configuration at each point in the hierarchy. The authors spend some time on the concepts of spectrum partitioning and what routing and switching in this domain means. A key point raised relates to the concept of wavelength conversion at network access points. The chapter closes with a brief review of some types of logical overlays that may sit on top of a WDM network. Three types are examined, ATM, *Synchronous Optical Network* (SONET), and IP networks.

The third chapter covers how network interconnection may occur and how the management and control features may be implemented. Four basic topologies are described, each with its salient features highlighted. These topologies include shared channel networks; wavelength routed networks, linear lightwave networks, and hybrid, logically routed networks. It is interesting to note that many commercial implementations, especially from traditional telecom providers, tend to follow the simpler topologies, while we are beginning to see newer telecom providers utilizing the more robust topologies.

Chapter 4 discusses what the authors consider enabling technology. To a large degree, these enabling technologies are the basic components of an optical system, for example, fibers, amplifiers, transmitters, and receivers. Crosstalk is mentioned in particular. The authors then delve into photonic device technologies and wavelength converters, and then they close with some simulation work on end-to-end transmission paths.

Chapters 5, 6, and 7 discuss in depth the ramifications of each of the four techniques. What is fairly intriguing here is that the authors have extensive bibliographies at the end of each chapter, and they include a series of problems that are left as an exercise to the reader.

The eighth chapter touches on the concepts involved with survivability and restoration of service. This chapter should help the practical network engineer in understanding most of the possible failure modes. In the last chapter, the authors look at current trends, and they try to predict business drivers for WDM deployment. Once again, they show their true colors as academics when they close with a statement on the importance of testbeds.

On to the Appendices! I am grateful to the authors for including some basic material on graph theory, scheduling algorithms, Markov chains and queuing, some work on minimal interference routing in the optical domain and, finally, close with a synopsis of the SONET standard.

Good Reference

Overall, there is a fair amount of practical material here, but it is tucked into large amounts of academic detail. I'm not sure this volume would work as a standalone textbook, but it clearly is a good reference for the state of optical networks in the last years of the 20th century.

Net Slaves

Net Slaves: True Tales of Working the Web, Bill Lessard and Steve Baldwin, ISBN 0-07-135243-0, McGraw-Hill, 2000.

How can you not want to read a book that opens with a quote from a Guns&Roses song, "Do you know where you are? You're in the jungle, baby!"? *Net Slaves* is about the people who maintain the jungle that big game hunters come to exploit. The same jungle marketed as the digital age and the e-generation. This is the land of the "dot-coms" and future big-buck IPOs. Has hubris masked your role in this jungle? *Net Slaves* will set you straight. Exactly who are these net slaves? Well, take the 15 question quiz provided by the authors and determine your Internet exploitation quotient. Don't be shocked to find yourself among the new media caste; the only question is, what part of the jungle are you assigned to clean after?

The authors spent a year interviewing people who work for Internet-based companies. Based on their findings, they created 11 character composites: Garbagemen; Cops or Streetwalkers; Social Workers; Cab Drivers; Cowboys or Card Sharks; Fry Cooks; Gold Diggers or Gigolos; Priests or Madmen; Robots; Robber Barons; and Mole People.

For each composite the authors cite someone's real-life work experience—of course, in order to protect the innocent (and the guilty), names have been altered.

I was annoyed with David Zorn, Card Shark; his type does nothing but give the industry a bad reputation. The story of Ken Hussein, Robot, both saddened and angered me. I truly hope he and his family are doing better. How can anyone not feel sorry for Kellner after being taken in by Gigolo Mira? Jane, Cab Driver, learned the hard way that you have to roll with the blows to survive in the jungle. Finally, I must confess, I found the most disturbing of all profiles to be of Outis, a Mole Person.

For each profile the authors provide some social-economic statistics. How old is the average Social Worker? How much does it cost to hire a Cowboy? What are the career aspirations of the average Cab Driver? How do you know if a Robot is annoyed with you? You're a Garbageman; what are your chances of upward mobility? A lot of this is funny, but to leave it at that would be missing the point entirely. Every composite represents scores of real people's lives, and how they live doesn't necessarily match up with the glamour often associated with the high-tech industry.

My favorite profile is of Jason Barstow, a Madman. Barstow arrives on the scene on his Harley, ready to participate in a two-day seminar put on by the Earth Business Network. A former chicken farmer and former guitar player, Barstow now finds himself lecturing to a room full of CEOs. He begins by telling them about the 5 milligrams of LSD he bought the previous night, and proceeds to plant seeds of anxiety—did he spike their morning juice? As Barstow delivers his lecture on the future of e-commerce and builds to the climax, a frustrated Slim Clarkston of NetScathe blurts out, "Mr. Barstow, I want you to tell us the truth about your little prank." With the lecture over, Barstow returns his pass to the security desk. "How did it go?" asks the security guard. "Same bull," Barstow responds, "but they never seem to get tired of it."

Are these stories true? I don't know—it doesn't matter! What are true are the composites. This book is funny. It is also humbling. Most important, it is true. It was fun to read. After each chapter, I found myself wearing an undeniable mischievous grin as I scanned the office looking for the person I just read about; this is all in good fun as long as I remember one important thing: I'm in the book—and you are too. In my experiences, I've found that a certain animosity always exists between people who work call centers, programmers, Web designers, managers, and the like. *Net Slaves* reminds us that we are all in this jungle together.

Implementing IPSec

Implementing IPSec: Making Security work on VPNs, Internets, and Extranets, Elizabeth Kaufman and Andrew Newman, ISBN 0-471-34467-2 Wiley Computers Publishing, 1999.

Organization

The book is organized into four parts. The first three chapters of Part One should be nothing more than review for anyone who has been in networking for even a short time. Chapter 4, "Encrypting within the Law," analyzes current worldwide regulatory trends for encryption technologies and examines how existing laws will impact your ability to legally purchase and install IPSec products. Included is some good information that may help keep you on the right side of the laws pertaining to encryption. Encryption is an area of potential problems, especially when you are running your network between countries.

Part Two is a primer on the basic technological components of IPSec. Chapter 5, "A Functional Overview of IPv4," and its basic design characteristics should be old news to anyone who is seriously thinking of running any type of encryption on his/her network. Chapter Six is an overview of cryptographic technologies. Chapter 7 "The Basics of IPSec and Public Key Infrastructures (PKIs) Fundamental to Current IPSec Standards," has some good information pertaining to IPSec and its different components, but leaves out an explanation of its two basic modes of operation: *transport* and *tunnel.*

Part Three analyzes how and why the IPSec protocols can break existing IP networks, and should provide the reader with some good information. Chapter 8, "What Won't Work with IPSec," describes the root cause of IPsec performance problems and protocol conflicts. Chapter 9, "IPSec and PKI Rollout Considerations," discusses gateway-to-gateway, end host-to-gateway, and end host-to-end host configuration options and explains some of the policy elements of PKI.

Part Four provides some criteria for evaluating vendors and products; this information would be of little interest if you are unfamiliar with writing an RFI. Also included is some reference material, including an appendix, with a complete copy of the IPSec RFC (2401), "Security Architecture for the Internet Protocol." A glossary, which does *not* offer a description of IPSec, is included as well.

Who Should Read This Book

By trying to appeal to the technical as well as the nontechnical reader, the book has missed both. There are areas that will appeal to the reader with a limited networking background, as well as areas for the more technical. However, if you are the type of reader inclined to read the RFCs, you will find very little reason to read the remainder of the book. Overall the book does not provide enough information for any one group. Inclusion of RFC 2401 seems unnecessary considering how easily RFCs can be obtained from the Internet.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

Scott Bradner Receives Postel Service Award

The Internet Society (ISOC) recently announced that noted Internet standards leader and Internet pioneer Scott O. Bradner has been awarded the prestigious *Jonathan B. Postel Service Award* for 2000. In presenting the award, Geoff Huston, Chair of ISOC, said, "Scott Bradner was introduced to many of us with his accurate and careful measurements of router performance. He has been a long standing participant in the *Internet Engineering Task Force* (IETF), and continues to serve on the *Internet Engineering Steering Group* (IESG) as the Area Director for Transport. He was a ISOC Trustee for six years from 1993 until 1999 and continues to serve as the Society's Vice-President for Standards. This is an impressive set of contributions and is worthy of recognition in Jon Postel's name as the 2000 recipient of the Jonathan B. Postel Service Award."

Don Heath, president and CEO of ISOC, said, "We established the award to honor the late Jon Postel by recognizing his unselfish and substantial contributions to the Internet over a 25 year period." He added, "Scott Bradner exemplifies the spirit of all that Jon brought to the Internet community and his outstanding contributions have made this year's choice an easy one. Scott's careful judgment and good humor has been a major contribution to many of the ISOC's activities, and we are pleased to be able to recognize his contributions in this unique fashion."

Bradner has been an active contributor to the IETF for over a decade, and has served as a Working Group Chair, the Area Director for Operations and currently serves as the Area Director for Transport. He also was the Director of the IPv6 area, and oversaw the process of refinement of a number of proposals into the definition of a coherent architecture for IPv6. Bradner has been the prime author of the current Internet Standards Process documents. He has also been an instructor at ISOC's *Network Training Workshops for Developing Countries* for many years, and has been a catalyst for the development of operationally robust Internet services in many areas of the world.

The Award is named for Dr. Jonathan B. Postel, an Internet pioneer and head of the organization that administered and assigned Internet names, protocol parameters, and Internet Protocol (IP) addresses. He was the primary architect behind what has become the *Internet Corporation for Assigned Names and Numbers* (ICANN), the successor organization to his work. The Award is presented at the Internet Society's annual INET Conference. It consists of an engraved crystal globe and US $20,000.00. Scott Bradner becomes the second recipient of the award. The first was presented posthumously to Dr. Postel in 1999.

The Internet Society is a non-profit, non-governmental, open membership organization whose worldwide individual and organization members make up a veritable "who's who" of the Internet industry. It provides leadership in technical and operational standards, policy issues, and education. ISOC hosts two annual Internet conferences, trains people from all over the world in networking technologies, conducts workshops for educators, and publishes an award-winning magazine, *OnTheInternet*. ISOC provides an international forum to address the most important economic, political, social, ethical and legal initiatives influencing the evolution of the Internet. This includes facilitating discussions on key policy decisions such as taxation, copyright protection, privacy and confidentiality, and initiatives towards self-governance of the Internet. ISOC created the Internet Societal Task Force as an ongoing forum for discussion, debate, and development of position papers, white papers, and statements on Internet related societal issues.

ISOC is the organizational home of the IETF, the Internet Architecture Board, the IESG, and the Internet Research Task Force—the standards setting and research arms of the Internet community. These organizations operate in an environment of bottom-up consensus building made possible through the participation of thousands of people from throughout the world. For more information, see **http://www.isoc.org/**

APNIC Policy Meeting

The *Asia Pacific Network Information Centre* (APNIC) will host an Open Policy Meeting October 25–27, 2000 in Brisbane, Australia. The meeting is open to anyone with an interest in Internet addressing issues. For more information see: **http://apnic.org**

APRICOT 2001

The *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT) will be held in Kuala Lumpur, Malaysia, February 26 to March 2, 2001. APRICOT is a forum that facilitates knowledge sharing among key Internet builders in the region, with peers and leaders from the Internet community worldwide. Since 1996, APRICOT has established itself as Asia Pacific's premier regional Internet Summit where related organisations converge and host their annual general meetings and other special events. The week-long summit comprises seminars, workshops, tutorials, conference sessions, Birds of a Feather (BOFs), and other forums, all geared towards spreading and sharing the knowledge required to operate the Internet within the Asia Pacific region. For more information see: **http://www.apricot2001.net**

From The Editor

Numerous technologies have been developed to protect or isolate corporate networks from the Internet at large. These solutions incorporate security, either end-to-end (IP security, or IPSec), or at the Internet/intranet border (firewalls). A third class of systems allows a range of IP addresses to be used internally in a corporate network, while preserving IP address consumption through the use of a *single* public address. This latter class of device is called a *Network Address Translator* (NAT), and while many Internet engineers consider NATs to be "evil," they are nonetheless very popular. Combining IPSec, NATs, and firewalls can be quite challenging, however. In our first article Lisa Phifer explains the problem and offers some solutions.

Successful network design is the result of many factors. In addition to the basic building blocks of routers, switches and circuits, network planners must carefully consider how these elements are interconnected to form an overall system with as few single points of failure as possible. In our second article, Valdis Krebs looks at how lessons learned from social network analysis can be applied to the design of computer networks.

The current Internet grew out of several government-funded research efforts that began in the late 1960s. Today, basic technology development as well as research into new uses of computer networks continues in many research "testbeds" all over the world. Bob Aiken describes the past, present and future state of network research and research networks.

The online subscription system for this journal will be up and running in January at **www.cisco.com/ipj**. In addition to offering a subscription form, the system will allow you to select delivery options, update your mailing and e-mail address, and much more. Please visit our Web site and give it a try. If you encounter any difficulties, please send your comments to **ipj@cisco.com**.

The Trouble with NAT

by Lisa Phifer, Core Competence

Those who are implementing virtual private networks often ask whether it is possible to safely combine *IP Security* (IPSec) and *Network Address Translation* (NAT). Unfortunately, this is not a question with a simple "yes" or "no" answer. IPSec and NAT can be employed together in some configurations, but not in others. This article explores the issues and limitations associated with combing NAT and "NAT-sensitive" protocols like IPSec. It examines configurations that do not work, and explains why. It illustrates methods for using NAT and IPSec together, and discusses an emerging protocol that may someday prove more IPSec friendly.

This article builds upon "IP Security and NAT: Oil and Water?"[1] and "Realm-Specific IP for VPNs and Beyond"[2], works previously published by *ISP-Planet*.

What Is Network Address Translation?

NAT was originally developed as an interim solution to combat IPv4 address depletion by allowing globally registered IP addresses to be reused or shared by several hosts. The "classic" NAT defined by RFC 1631[3] maps IP addresses from one realm to another. Although it can be used to translate between any two address realms, NAT is most often used to map IPs from the nonroutable private address spaces defined by RFC 1918[4], shown below.

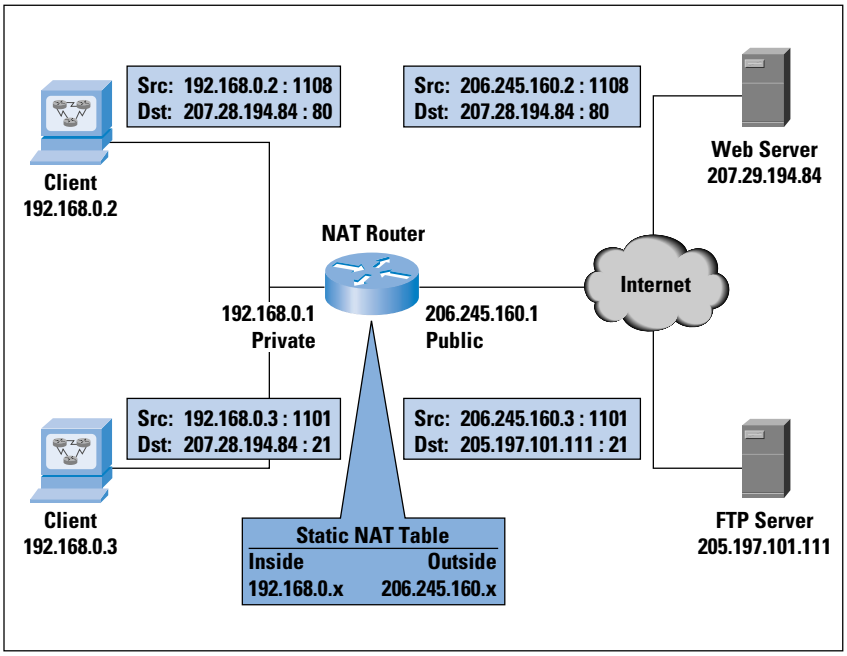
Class	Private Address Range
A	10.0.0.0 ... 10.255.255.255
B	172.16.0.0 ... 172.16.255.255
C	192.168.0.0 ... 192.168.255.255

These addresses were allocated for use by private networks that either do not require external access or require limited access to outside services. Enterprises can freely use these addresses to avoid obtaining registered public addresses. But, because private addresses can be used by many, individually within their own realm, they are nonroutable over a common infrastructure. When communication between a privately addressed host and a public network (like the Internet) is needed, address translation is required. This is where NAT comes in.

NAT routers (or NATificators) sit on the border between private and public networks, converting private addresses in each IP packet into legally registered public ones. They also provide transparent packet forwarding between addressing realms. The packet sender and receiver (should) remain unaware that NAT is taking place. Today, NAT is commonly supported by WAN access routers and firewalls—devices situated at the network edge.

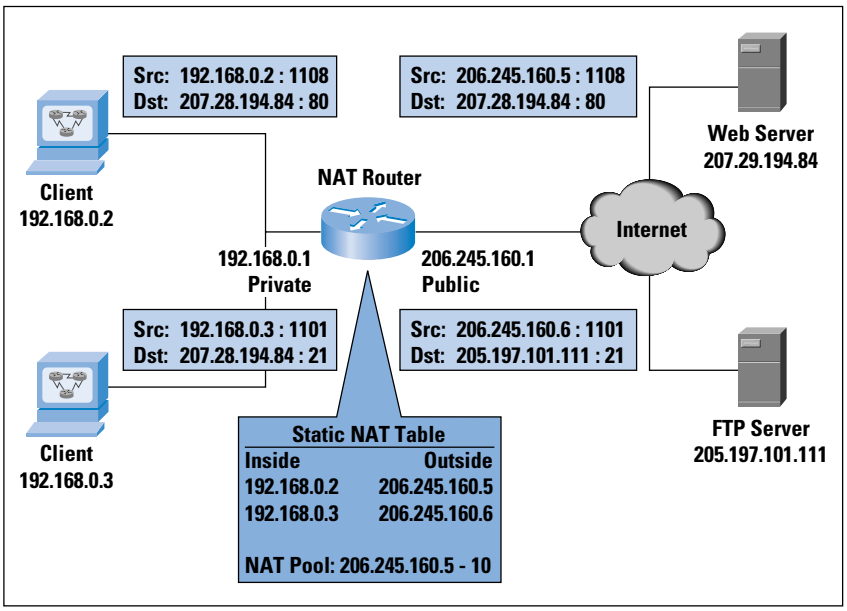
NAT works by creating bindings between addresses. In the simplest case, a one-to-one mapping may be defined between public and private addresses. Known as static NAT, this can be accomplished by a straightforward, stateless implementation that transforms only the network part of the address, leaving the host part intact. The payload of the packet must also be considered during the translation process. The IP checksum must, of course, be recalculated. Because TCP checksums are computed from a pseudo-header containing source and destination IP address (prepended to the TCP payload), NAT must also regenerate the TCP checksum.

Figure 1: Static NAT



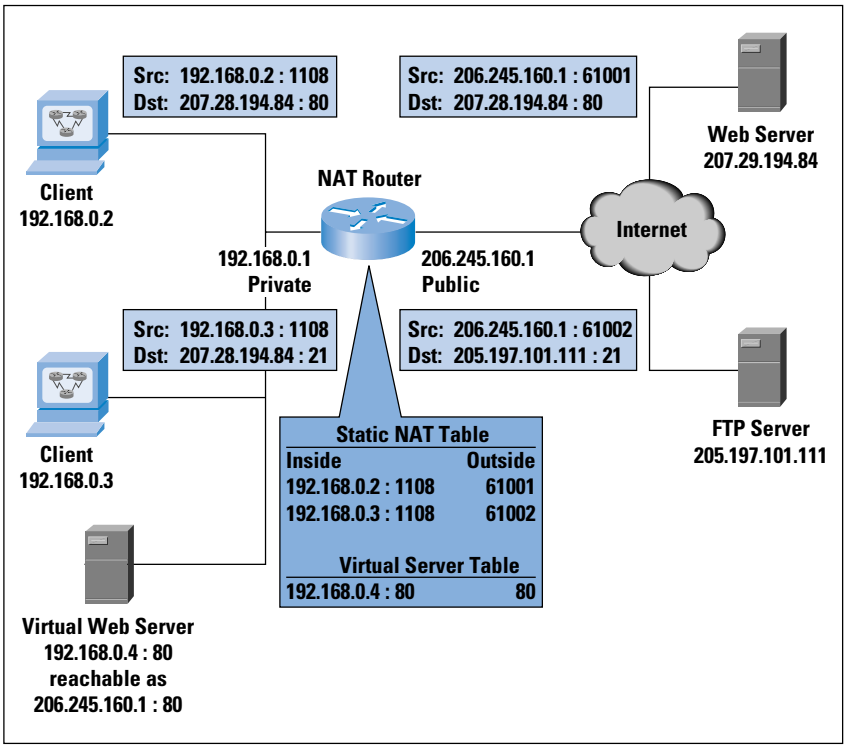
More often, a pool of public IP addresses is shared by an entire private IP subnet (dynamic NAT). Edge devices that run dynamic NAT create bindings "on the fly," building a NAT Table. Connections initiated by private hosts are assigned a public address from a pool. As long as the private host has an outgoing connection, it can be reached by incoming packets sent to this public address. After the connection is terminated (or a timeout is reached), the binding expires, and the address is returned to the pool for reuse. Dynamic NAT is more complex because state must be maintained, and connections must be rejected when the pool is exhausted. But, unlike static NAT, dynamic NAT enables address reuse, reducing the demand for legally registered public addresses.

Figure 2: Dynamic NAT



A variation of dynamic NAT known as *Network Address Port Translation* (NAPT) may be used to allow many hosts to share a single IP address by multiplexing streams differentiated by TCP/UDP port number. For example, suppose private hosts 192.168.0.2 and 192.168.0.3 both send packets from source port 1108. A NAPT router might translate these to a single public IP address 206.245.160.1 and two different source ports, say 61001 and 61002. Response traffic received for port 61001 is routed back to 192.168.0.2:1108, while port 61002 traffic is routed back to 192.168.0.3:1108.

Figure 3: NAPT



NAPT (masquerading) is commonly implemented on small Office/Home Office (SOHO) routers to enable shared Internet access for an entire LAN through a single public address. Because NAPT maps individual ports, it is not possible to "reverse map" incoming connections for other ports unless another table is configured. A virtual server table can make a server on a privately addressed DMZ reachable from the Internet via the public address of the NAPT router (one server per port). This is really a limited form of static NAT, applied to incoming requests.

In some cases, static NAT, dynamic NAT, NAPT, and even bidirectional NAT or NAPT may be used together. For example, an enterprise may locate public Web servers outside of the firewall, on a DMZ, while placing a mail server and clients on the private inside network, behind a NAT-ing firewall. Furthermore, suppose there are applications within the private network that periodically connect to the Internet for long periods of time. In this case:

- Web servers can be reached from the Internet without NAT, because they live in public address space.
- *Simple Mail Transfer Protocol* (SMTP) sent to the private mail server from the Internet requires incoming translation. Because this server must be continuously accessible through a public address associated with its *Domain Name System* (DNS) entry, the mail server requires static mapping (either a limited-purpose virtual server table or static NAT).
- For most clients, public address sharing is usually practical through dynamically acquired addresses (either dynamic NAT with a correctly sized address pool, or NAPT).
- Applications that hold onto dynamically acquired addresses for long periods could exhaust a dynamic NAT address pool and block access by other clients. To prevent this, long-running applications may use NAPT because it enables higher concurrency (thousands of port mappings per IP address).

Where is NAT used today? Outbound NAT is commonly employed by multihost residential users, teleworkers, and small businesses that share a single public IP for outbound traffic while blocking inbound session requests. In other words, small LANs connected via ISDN, *Digital Subscriber Line* (DSL), or cable modem.

Bidirectional static NAT/NAPT combinations are typically used by enterprises that host services behind a masquerading firewall. NAT can also be employed by enterprises wishing to insulate themselves from *Internet Service Provider* (ISP) address changes, or by those wanting to obscure private network topology for security reasons.

NAT-Sensitive Protocols

Our need to conserve IPv4 addresses has prompted many to overlook the inherent limitations of NAT, recognized in RFC 1631 but deemed acceptable for a short-term solution.

As noted previously, NAT regenerates TCP checksums. This, of course, requires the TCP header containing the checksum to be visible (that is, not encrypted). If only the TCP payload is encrypted and immutable between the application source and destination (for instance, *Secure Shell Protocol* [SSH], *Secure Sockets Layer* [SSL]), then the checksum in the TCP header can be recalculated without a visible TCP payload. But if the TCP header is encrypted (for instance, IPSec transport mode), the TCP checksum field in the TCP header cannot be modified.

Furthermore, many application protocols carry IP addresses in an application-level protocol. In such cases, an *Application-Level Gateway* (ALG) is needed to complete the translation. For example:

- Many *Internet Control Message Protocol* (ICMP) packets (for instance, "Destination Unreachable") carry embedded IP packets in ICMP payload. These require both address translation and checksum regeneration.
- A *File Transfer Protocol* (FTP) ALG is needed to rewrite IP addresses carried by FTP PORT and PASV control commands. In the IP header, these addresses are fixed-length words. Unfortunately, in the FTP protocol, these IP addresses are carried as human-readable, variable-length strings; rewriting can change the length of the TCP segment. If the segment is shortened, it can be padded. If the segment is lengthened, SEQ and ACK numbers must be transformed for the duration of the connection.
- Protocols like H.323 use multiple TCP connections or UDP streams to form "session bundles." If all connections in the bundle originate from the same end system, an ALG may be avoided. But H.323 presents other challenges, including ephemeral ports and embedded, ASN.1-encoded IP addresses in application payload.
- *NetBIOS over TCP/IP* (NBT) can be challenging to translate correctly because packet-header information is placed in NetBIOS payload at inconsistent offsets, and many embedded IP addresses are exchanged during an NBT session. Fortunately, most companies do not let NBT beyond their firewall anyway.
- *Simple Network Management Protocol* (SNMP) packets also carry IP addresses that identify trap source and object instance. Perhaps more important, dynamic NAT makes it impossible to uniquely identify hosts by IP address; public addresses are transient and shared. Remote management of private hosts can thus be impeded by NAT.
- Obviously DNS, responsible for domain name/IP address mapping, is impacted by NAT. From simple query handling to zone transfers, a robust DNS ALG is defined by RFC 2694[9].

NAT-sensitive protocols such as Kerberos, X-Windows, remote shell, Session Initiation Protocol (SIP), and others are further described in the Internet Draft *"Protocol Complications with the IP Network Address Translation"*[12]. Another Internet Draft, *"NAT Friendly Application Design Guidelines"*[13], explains how new application protocols can integrate smoothly with NAT. But there are still cases where ALGs simply cannot "fix" packets modified by NAT.

Impact of NAT on IPSec

The IPSec *Authentication Header* (AH)[5] is an example. AH runs the entire IP packet, including invariant header fields such as source and destination IP address, through a message digest algorithm to produce a keyed hash. This hash is used by the recipient to authenticate the packet. If any field in the original IP packet is modified, authentication will fail and the recipient will discard the packet. AH is intended to prevent unauthorized modification, source spoofing, and man-in-the-middle attacks. But NAT, by definition, modifies IP packets. Therefore, AH + NAT simply cannot work.

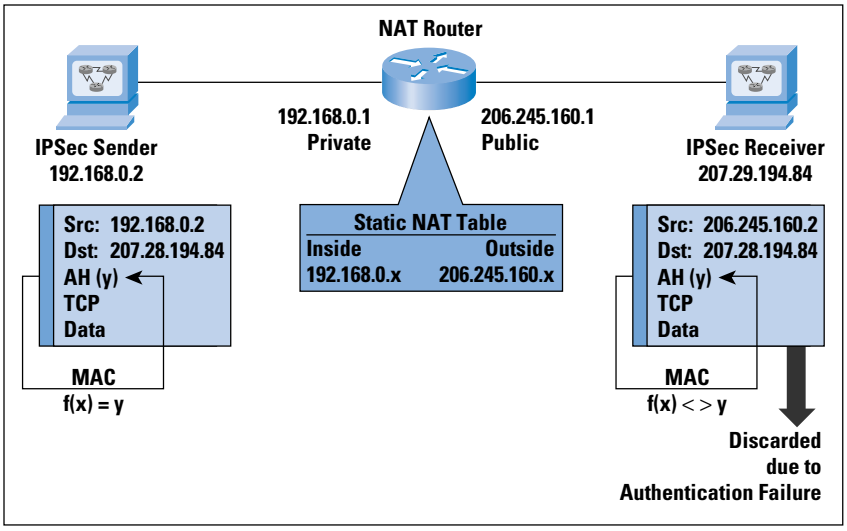


Figure 4: NAT vs. AH (Transport Mode)

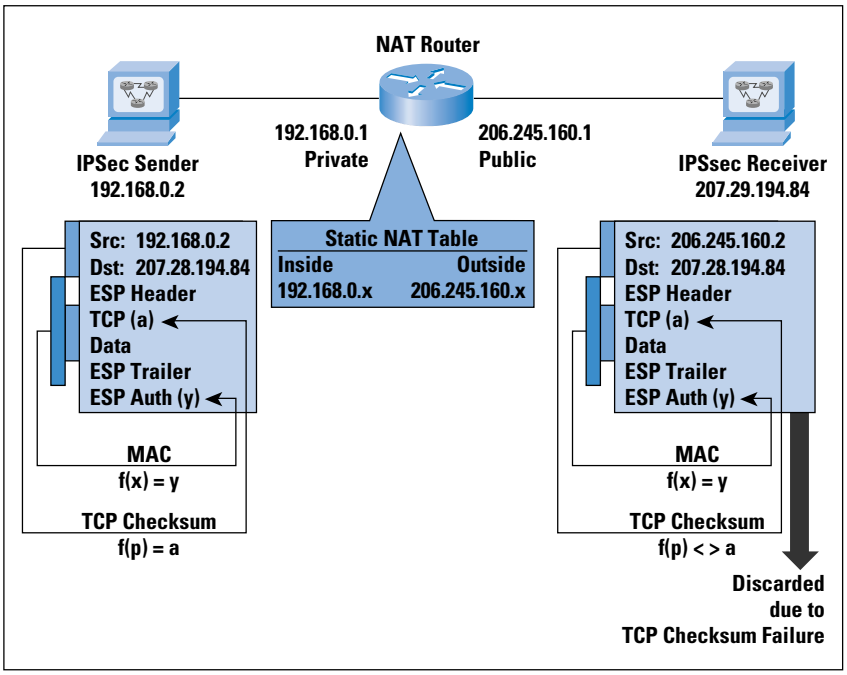
The IPSec *Encapsulating Security Payload* (ESP)[6] also employs a message digest algorithm for packet authentication. But, unlike AH, the hash created by ESP does not include the outer packet header fields. This solves one problem, but leaves others.

IPSec supports two "modes." Transport mode provides end-to-end security between hosts, while tunnel mode protects encapsulated IP packets between security gateways—for example, between two firewalls or between a roaming host and a remote access server. When TCP or UDP are involved—as they are in transport mode ESP—there is a catch-22. Because NAT modifies the TCP packet, NAT must also recalculate the checksum used to verify integrity. If NAT updates the TCP checksum, ESP authentication will fail. If NAT does not update the checksum (for example, payload encrypted), TCP verification will fail.

If the transport endpoint is under your control, you might be able to turn off checksum verification. In other words, ESP can pass through NAT in tunnel mode, or in transport mode with TCP checksums disabled or ignored by the receiver.

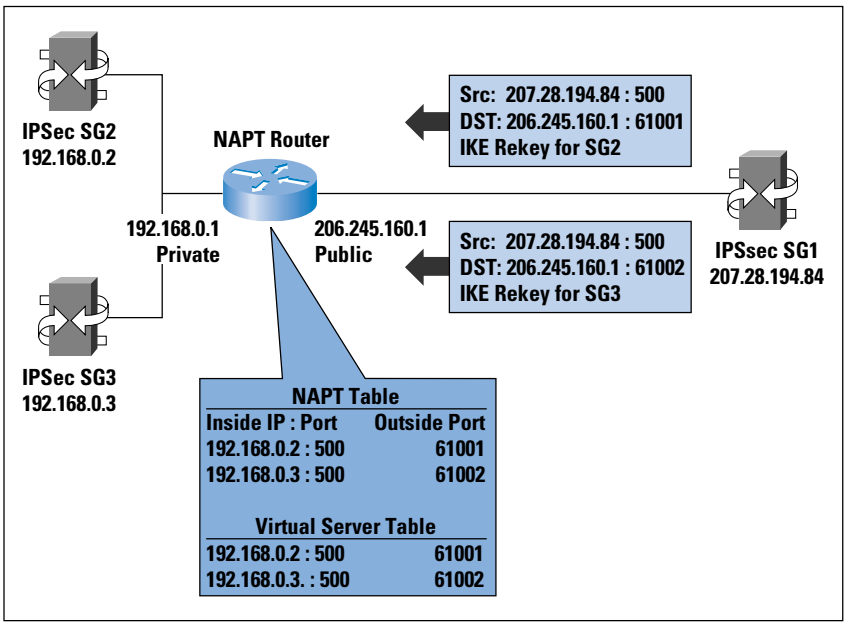
Figure 5: NAT vs. ESP (Transport Mode)



If we stick to ESP in tunnel mode or turn off checksums, there's still another obstacle: the *Internet Key Exchange* (IKE)[7]. IPSec-based *Virtual Private Networks* (VPNs) use IKE to automate security association setup and authenticate endpoints. The most basic and common method of authentication in use today is preshared key. Unfortunately, this method depends upon the source IP address of the packet. If NAT is inserted between endpoints, the outer source IP address will be translated into the address of the NAT router, and no longer identify the originating security gateway. To avoid this problem, it is possible to use another IKE "main mode" and "quick mode" identifier (for example, user ID or fully qualified domain name).

A further problem may occur after a *Security Association* (SA) has been up for awhile. When the SA expires, one security gateway will send a rekey request to the other. If the SA was initiated from the well-known IKE port UDP/500, that port is used as the destination for the rekey request. If more than one security gateway lies behind a NAPT router, how can the incoming rekey be directed to the right private IP address? Rekeys can be made to work by "floating" the IKE port so that each gateway is addressable through a unique port number, allowing incoming requests to be demultiplexed by the NAPT router.

Figure 6: NAT vs. IKE Rekey



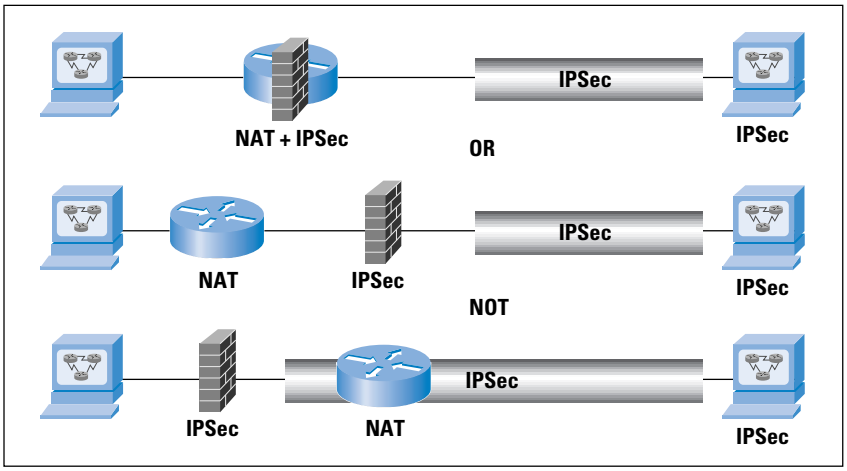
At this point, two things should be clear: (1) it is possible to find a "flavor" of IPSec that will run through NAT, but (2) one must do so with great care and attention to detail. Recent Internet Drafts[12] [14] have recorded these problems for further consideration, and RFC 2709[10] describes a security model for running tunnel-mode IPSec through NAT.

One Solution: Avoid the Problem

By far the easiest way to combine IPSec and NAT is to completely avoid these problems by locating IPSec endpoints in public address space. That is, NAT before IPSec; don't perform IPSec before NAT. This can be accomplished in two ways:

- Perform NAT on a device located behind your IPSec security gateway; or
- Use an IPSec device that also performs NAT.

Figure 7: Combining IPSec and NAT



Many routers, firewalls, security gateways, and Internet appliances implement IPSec and NAT in the same box. These products perform outbound address translation before applying security policies; the order is reversed for inbound packets. A typical "any-to-any" security policy is easily specified with such a product. Granular policies can be a bit more difficult because filters are often based on IP address, and care must be taken to avoid overlapping filters.

If you cannot avoid translating IPSec-protected traffic midstream, limit use of IPSec to tunnel-mode ESP and design security policies with care. If you simply cannot NAT before IPSec or require transport-mode ESP, there may still be hope. The *Internet Engineering Task Force* (IETF) is now defining *Realm-Specific IP* (RSIP), an alternative that may someday prove kinder to IPSec.

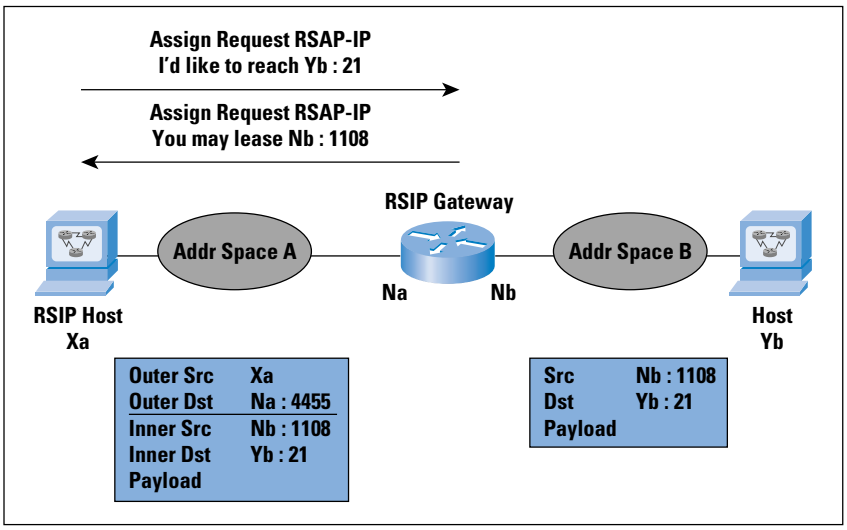
What Is RSIP?

RSIP[16] leases public IP addresses and ports to RSIP hosts located in private addressing realms. Unlike NAT, RSIP does not operate in stealth mode and does not translate addresses on the fly. Instead, RSIP allows hosts to directly participate concurrently in several addressing realms. Although RSIP does require host awareness, it avoids violating the end-to-end nature of the Internet. With RSIP, IP payload flows from source to destination without modifications that cripple IPSec AH and many other NAT-sensitive protocols.

RSIP gateways are multihomed devices that straddle two or more addressing realms, just as NAT-capable firewalls and routers do today. When an RSIP-savvy host wants to communicate beyond its own private network, it registers with an RSIP gateway. The RSIP gateway allocates a unique public IP address (or a shared public IP address and a unique set of TCP/UDP ports) and binds the private address of the RSIP host to this public address. The RSIP host uses this public source address to send packets to public destinations until its lease expires or is renewed.

But the RSIP host cannot send a publicly addressed packet as-is; it must first get the packet to the RSIP gateway. To do this, the host wraps the original packet inside a privately addressed outer packet. This "encapsulation" can be accomplished using any standard tunneling protocol: IP-in-IP, the *Generic Routing Encapsulation* (GRE), or the *Layer 2 Tunneling Protocol* (L2TP). Upon receipt, the RSIP gateway strips off the outer packet and forwards the original packet across the public network, toward its final destination.

Figure 8: RSIP



For simplicity, we talk about RSIP linking one private network to the public Internet, but RSIP can also be used to relay traffic between several privately addressed networks. An RSIP host can lease several different addresses as needed to reach different destinations networks. We've also focused on outgoing traffic, but an RSIP host can ask the RSIP gateway to "listen" and relay incoming packets addressed to a public IP and port.

Combining RSIP and IPSec

At first glance, RSIP sounds like a promising way for hosts to share public addresses while avoiding the pitfalls associated with applying NAT to IPSec traffic. But it turns out that RSIP extensions are needed to accommodate end-to-end IPSec[17].

Basic RSIP relies on unique port numbers to demultiplex arriving packets, but IPSec ESP encrypts port numbers. When several RSIP hosts use the same RSIP gateway to relay ESP, another discriminator is needed. Fortunately, every IPSec packet carries a unique *Security Parameters Index* (SPI), assigned during security association setup. Unfortunately, the SPI is guaranteed unique only for the responder. To enable demultiplexing, the tuple (SPI, protocol [AH or ESP], destination IP address) must also be unique at the initiating RSIP gateway.

A similar problem occurs during association setup with the IKE. IKE packets usually carry the well-known source port UDP/500. Using different source ports is the preferred solution, but if several RSIP hosts use the same RSIP gateway to relay IKE from port UDP/500, another discriminator is needed. Again, there is a convenient answer: every IKE packet carries the initiator cookie supplied in the first packet of an IKE session. The RSIP gateway can route IKE responses to the correct RSIP host using the tuple (initiator cookie, destination port [IKE], destination IP address). But rekeys may still be an issue.

To fix these problems, extensions have been proposed to allow RSIP hosts to register with an RSIP gateway for IPSec support, and allow hosts to request and receive unique SPI values along with leased IP addresses and ports.

Possible Applications for RSIP

RSIP specifications[16][17][18] are still at the Internet Draft stage. If and when RSIP matures, there may be a wide variety of applications:

- Residential power users and teleworkers with multihost LANs that share a single, publicly known IP address leased by an RSIP-enabled Internet appliance, DSL router, or cable modem;
- Small-to-midsize enterprise customers with dozens or hundreds of hosts, sharing a small pool of public IPs leased by an RSIP-enabled WAN access router or firewall;
- Multidwelling units (apartments, shared office buildings) with many private LANs, sharing public Internet access through an RSIP-enabled device;
- Hospitality networks (airports, hotels) where roaming hosts briefly lease the public IP(s) shared by the entire network;
- Remote access concentrators that use RSIP to lease private IP(s) to roaming corporate users that access the Internet via dynamically assigned public addresses; and
- Wireless devices (cell phones, personal digital assistants [PDAs]) that lease public IP(s) for "sticky sessions" that persist even when the mobile device moves from one location to another, updating its local access IP.

These scenarios, and the relationship of RSIP to IP multicast and differentiated services, are more fully explored in the RSIP framework[18].

Conclusion

Although NAT can be combined with IPSec and other NAT-sensitive protocols in certain scenarios, NAT tampers with end-to-end message integrity. RSIP—or whatever RSIP evolves into—may someday prove to be a better address-sharing solution for protocols that are adversely impacted by NAT. If RSIP fails to mature, another solution may be developed to broaden use of NAT with IPSec. Alternatives now under discussion within the IETF include UDP encapsulation and changes to IKE itself[14][15].

Despite its origin as a short-term solution, NAT is unlikely to disappear in the very near future. Until it does, understanding the relationship between NAT and IPSec and alternatives for safe combined deployment will remain an important aspect of VPN design.

The Social Life of Routers

Applying Knowledge of Human Networks to the Design of Computer Networks

by Valdis Krebs

We often forget that computer networks are put in place to support human networks—person-to-person exchanges of information, knowledge, ideas, opinions, insights, and advice. This article looks at a technology that was developed to map and measure human networks—social network analysis—and applies some of its principles and algorithms to designing computer networks. And as we see more peer-to-peer (P2P) models of computer-based networks, the P2P metrics in human network analysis become even more applicable.

Social network analysts look at complex human systems as an interconnected system of nodes (people and groups) and ties (relationships and flows)—much like an internetwork of routers and links. Human networks are often unplanned, emergent systems. Their growth is sporadic and self-organizing[1]. Network ties end up being unevenly distributed, with some areas of the network having a high density of links and other areas of the network sparsely connected. These are called "small world networks"[2]. Computer networks often end up with similar patterns of connections—dense interconnectivity within subnetworks, and sparser connections uniting subnetworks into a larger internetwork.

Social network researchers and consultants focus on *geodesics*—shortest paths in the network. Many of today's social network algorithms are based on a branch of mathematics called *graph theory*. Social network scientists have concentrated their work, and therefore their algorithms, in the following areas:

- Individual node centrality within a larger network—network dependency and load upon individual routers
- Overall path distribution—good connectivity without excessive routing tables
- Improving communication flow within and between groups—designing better topologies
- Network patterns surrounding ego networks—strategies for analyzing and manipulating individual router connections
- Analyzing information flow behavior of client organization—how computer networks can support human networks

One of the methods used to understand networks and their participants is to evaluate the location of actors in the network. Measuring the network location is finding the *centrality* of a node[3]. All network measures discussed here are based on geodesics—the shortest path between any two nodes. We will look at a social network, called the *kite network*, that effectively shows the distinction between the three most popular centrality measures—the ABCs—*A*ctivity, *B*etweenness, and Closeness.

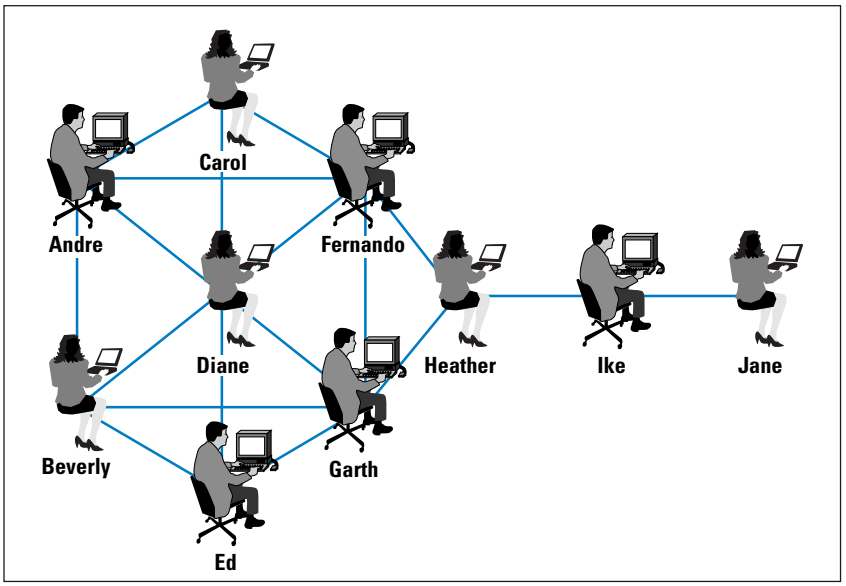
This model[4] was first developed by David Krackhardt, a leading researcher in social networks.

Activity

Figure 1 shows a simple social network. A link between a pair of nodes depicts a bidirectional information flow or knowledge exchange between two individuals. Social network researchers measure network activity for a node by using the concept of *degrees*—the number of direct connections a node has.

In this human network, Diane has the most direct connections in the network, making hers the most active node in the network with the highest degree count. Common wisdom in personal networks is "the more connections, the better." This is not always so. What really matters is where those connections *lead to*—and how they connect the otherwise unconnected![5] Here Diane has connections only to others in her immediate cluster—her clique. She connects only those who are already connected to each other—does she have too many redundant links?

Figure 1: Human Network



Betweenness

While Diane has many direct ties, Heather has few direct connections—fewer than the average in the network. Yet, in may ways, she has one of the best locations in the network—she is a boundary spanner and plays the role of broker. She is *between* two important constituencies, in a role similar to that of a border router. The good news is that she plays a powerful role in the network, the bad news is that she is a single point of failure. Without her, Ike and Jane would be cut off from information and knowledge in Diane's cluster.

Closeness

Fernando and Garth have fewer connections than Diane, yet the pattern of their ties allow them to *access* all the nodes in the network more quickly than anyone else. They have the shortest paths to all others—they are *close* to everyone else. Maximizing closeness between *all* routers improves updating and minimizes hop counts. Maximizing the closeness of only one or a few routers leads to counterproductive results, as we will examine below.

Their position demonstrates that when it comes to network connections, quality beats out quantity. Location, location, location—the golden rule of real estate also works in networks. In real estate it is geography—your physical neighborhood. In networks, it is your virtual location determined by your network connections—your network neighborhood.

Network Centralization

Individual network centralities provide insight into the individual's location in the network. The relationship between the centralities of all nodes can reveal much about the overall network structure. A very centralized network is dominated by one or a few very central nodes. If these nodes are removed or damaged, the network quickly fragments into unconnected subnetworks. Highly central nodes can become critical points of failure. A network with a low centralization score is not dominated by one or a few nodes—such a network has no single points of failure. It is resilient in the face of many local failures. Many nodes or links can fail while allowing the remaining nodes to still reach each other over new paths.

Average Path Length in Network

The shorter the path, the fewer hops/steps it takes to go from one node to another. In human networks, short paths imply quicker communication with less distortion. In computer networks, the signal degradation and delay is usually not an issue. Nonetheless, a network with many short paths connecting all nodes will be more efficient in passing data and reconfiguring after a topology change.

Average Path Length is strongly correlated with Closeness throughout the network. As the closeness of all nodes to each other improves (average closeness), the average path length in the network also improves.

Internetwork Topology

In the recent network design book, *Advanced IP Network Design*[6], the authors define a well-designed topology as the basis of a well-behaved and stable network. They further propose that "three competing goals must be balanced for good network design":

- Reducing hop count
- Reducing available paths
- Increasing the number of failures the network can withstand

Our social network algorithms can assist in measuring and meeting all three goals.

- Reducing the hop count infers minimizing the average path length throughout the network—maximize the closeness of all nodes to each other.
- Reducing the available paths leads to minimizing the number of geodesics throughout the network.
- Increasing the number of failures a network can withstand focuses on minimizing the centralization of the whole network.

On the following pages we examine various network topologies and evaluate them using social network measures while remembering these three competing goals of network design.

The models we examine do *not* cover hierarchical structures—with Core, Distribution, and Access layers—found in networks of hundreds or thousands of routers. We examine flat, nonhierarchical topologies such as those found in smaller internetworks, area subnetworks, or within core backbones. The topologies we model are the most commonly used—Star, Ring, Full Mesh, and Partial Mesh. We compute the social network measures on each of the topologies and discuss how the various measures help us meet the competing goals discussed above.

Star Topology

The Star topology, shown in Figure 2, has many advantages—but one glaring fault. The advantages include ease of management and configuration for the network administrators. For the Star, the three competing goals delineate as follows:

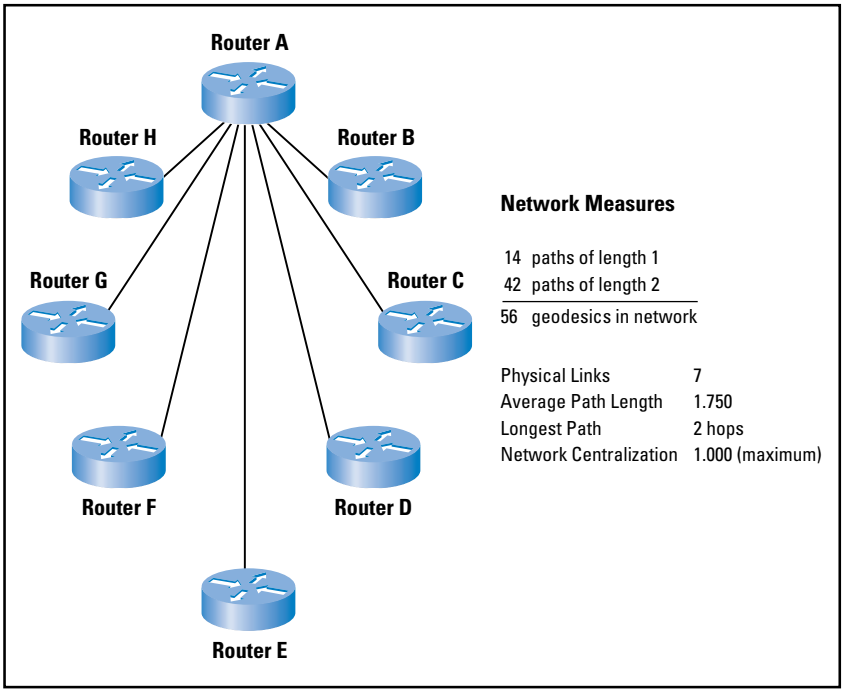
- *Reducing hop count:* The short average path length (1.75) throughout the network meets this goal well. Any router can *reach* any other router in two steps or less.
- *Reducing available paths:* The fact that there are a minimum number of possible available paths (56) to reach all other nodes—will not overload the routing tables, nor cause delays during routing table updates. It takes only seven bidirectional links to create the available paths.

- *Reducing network failures:* The network fails miserably if Router A goes down. Also, any link failure isolates the attached router—there are no multiple paths to reach each router.

Router A is not only a single point of failure—it is also a potential bottleneck—it will likely become overburdened with packet flows and routing updates as more routers are added in the star structure.

Router A receives the top score (1.000) in Activity, Betweenness, and Closeness. As a result, the network is very centralized around Router A from the perspective of all measures.

Figure 2: Routers in Star Topology



Ring Topology

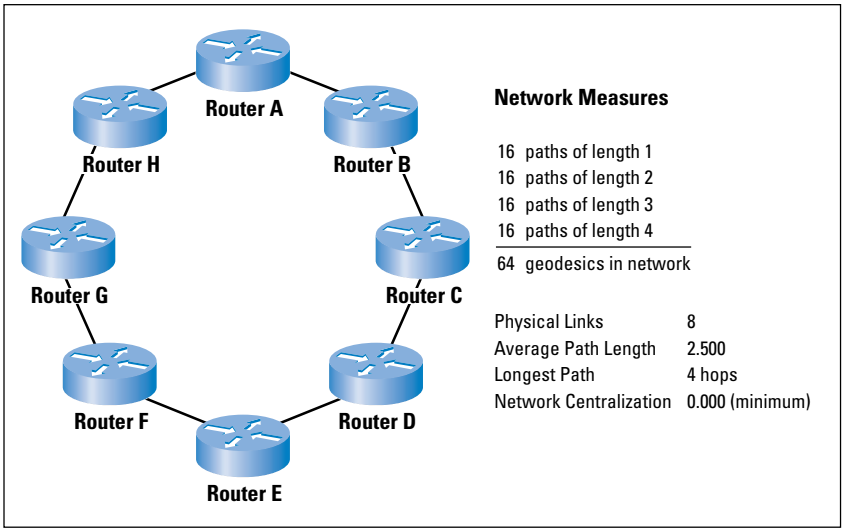
The Ring topology, shown in Figure 3, is an improvement over the Star. It has some of the same advantages, but does not eliminate all of the drawbacks of the Star. The advantages include ease of management and configuration for the network administrators—adding another router is very simple. Unlike the Star topology, the Ring provides some redundancy and, therefore, eliminates the single point of failure—all nodes have an alternate path through which they can be reached. Yet it is still vulnerable to both link and router failures. For the Ring, the three competing goals delineate as follows:

- *Reducing hop count:* The average path length of 2.5 is quite long for a small network of eight nodes. Some routers (that is, A and E) require four steps to reach each other! Many ring physical layers hide this complexity from the IP layers in order to make those hops invisible to routing protocols.

- *Reducing available paths:* This configuration has more geodesics (64) than Star, yet not significantly more to overload the routing tables, nor cause delays during table updates.
- *Reducing network failures:* Even though network centralization is at the minimum (no node is more central than any other), this network reaches failure quickly because of its weak redundancy. The Ring topology can withstand one link failure or one router failure and still keep a contiguous network. Two simultaneous failures can cause unreachable segments because of the lack of redundancy.

Most modern ring technologies such as *Synchronous Optical Network* (SONET) or the Cisco *Dynamic Packet Transport Protocol* (DPT) add a measure of redundancy by running a dual ring that heals itself if a link gets cut. The network "wraps" to avoid the downed line and operates at lower speed. A two-hop path can become a six-hop path if a single link fails. This can cause network congestion if the original dual ring was being used for data in all directions.

Figure 3: Routers in Ring Topology



Full Mesh Topology

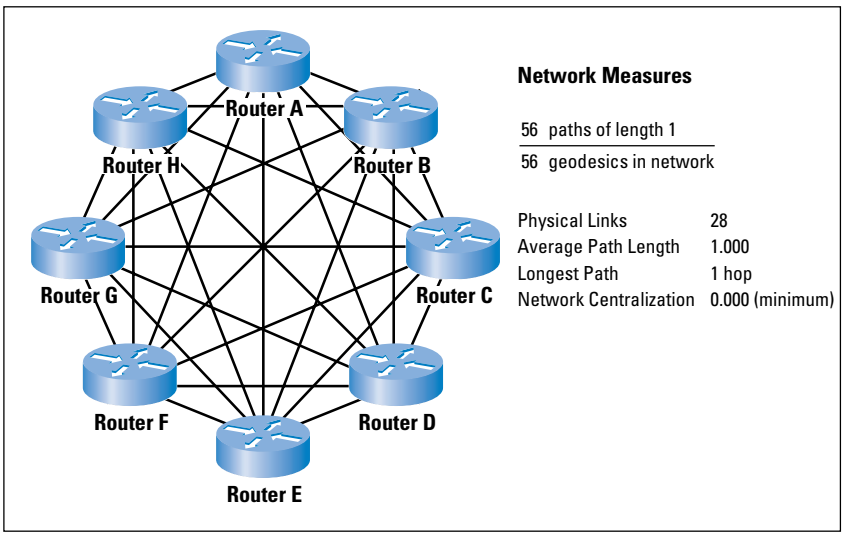
The Full Mesh topology has several big advantages and several faults. The advantages include short path length (one hop) to all other routers and maximum resilience to failure if links or routers start failing. The disadvantages revolve around the complexity created by this topology. For the Full Mesh, the three competing goals delineate as follows:

- *Reducing hop count:* The shortest path length possible is attained for all routes—all nodes can reach each other in one hop.
- *Reducing available paths:* There are a minimum number of possible available paths (56) to reach all other nodes. The routing entries will not overload the routing tables, nor cause delays during routing table updates.

- *Reducing network failures:* The network is not dependent upon any single node (network centralization = 0.000). This configuration represents the most robust topology available—chances are very slim that the number of failures necessary to fragment the network will actually occur within the same time period.

The disadvantages of the Full Mesh topology all focus on one glaring fault—there are too many physical links. If the routers are far apart, the link costs can quickly become prohibitively expensive because adding routers creates a geometrical explosion in links required—soon the routers do not have enough ports to support this topology. Administering the system and keeping an up-to-date topology map becomes more and more complex as routers are added. The network in Figure 4 has 28 two-way links. Double the routers, in a full mesh topology, and the link count increases by a factor greater than 4.

Figure 4: Routers in Full Mesh Topology



Partial Mesh Topology

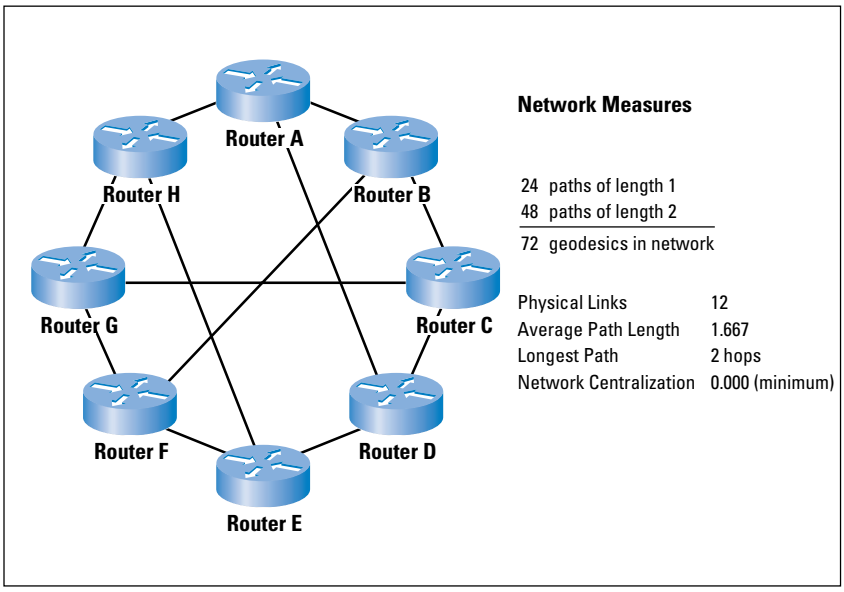
The Partial Mesh topology is quite different. It is the most difficult to build—there is no simple rule to follow (rule for Star: connect everyone to Router A; rule for Full Mesh: connect everyone to everyone). If built incorrectly, the partial mesh layout can have many of the disadvantages of the former topologies without many of the benefits. If built correctly, the opposite is true—more advantages, fewer disadvantages.

Building a successful partial mesh topology is where the interactive use of our social network measures really comes into play. The design below evolved after several iterations. With every iteration the average path length dropped until it appeared to reach a plateau where no further changes lowered the hop count without noticeably increasing the number of physical links. For the Partial Mesh, the three competing goals delineate as follows:

- *Reducing hop count:* The short average path length (1.667) throughout the network meets this goal well. Any router can *reach* any other router in two steps or less. Path length is less than that for the Star and Ring topologies.
- *Reducing available paths:* The number of available paths in the network (72) is the highest among all topologies, though not significantly more than the Ring topology. As the number of nodes in a network increases, this could become a problem—the average path length vs. path count trade-off needs to be closely monitored.
- *Reducing network failures:* Network centralization (0.000) is the same as for the Full Mesh topology—no router, nor link, is more important than any other. As nodes or links are removed from this network, it does not fragment quickly. Chances are slim that the number of failures necessary to fragment the network will actually occur within the same time period. Although we optimized our network centralization for this small "toy" network, we cannot expect this for most real networks. Yet, the goal remains to keep this metric as small as possible.

This topology in Figure 5 was built starting with a Ring topology—a simple architecture. A link was added and the network was remeasured. Was this structure better than the previous? If so, the current structure was kept and another link was added and the network was remeasured. This iterative process was continued until no further improvements happened after several changes. This process does not guarantee an *optimum* solution, yet it quickly converges on a *good* solution—even large networks improve quickly with just a few added links.

Figure 5: Routers in Partial Mesh Topology



A quirky aspect of networks is that sometimes you can subtract by adding—add a link to a network and reduce the average path length. The opposite also works, sometimes. You can add by subtracting—remove a tie and watch the average hop count grow. Yet, you never know for certain what effect adding or removing a link will have—it is neither a linear nor a local phenomenon. The size and direction of these changes depend upon the existing topology of the network and the location of the added or removed tie. It is key to have a model that allows quick what-if calculations.

Let's experiment with removing random ties—a situation similar to links between routers failing. If we remove the link between Router A and Router H in Figure 5, the number of geodesics in the network increases from 72 to 76, and the average path length increases to 1.815. Yet, removing a different link, G to F, reduces the the number of geodesics in the network from 72 to 66, while the average path length increases only to 1.727. If we are concerned about too many paths in the network, we can remove another link, B to C. This further decreases the number of shortest paths to 60, while reducing physical links to 10. This is very near the 56 paths in the very efficient star topology. Whereas the star is very vulnerable because of its single point of failure, this partial mesh, with the two links removed, is still robust. While the number of geodesics drops, the average path length creeps up slightly to 1.80 with the removal of the second link. Figure 5 has no paths greater than two hops. With the two links (G to F, B to C) removed, we now have 8 geodesics of three hops, while at the same time 12 fewer geodesics to load into routing tables, and two fewer physical links. It is a constant trade-off.

NSFnet Backbone

The NSFnet Backbone network, shown in Figure 6, connected the supercomputing centers in the USA in 1989. It is a partial mesh design that functions as a real-life example to test our social network algorithms.

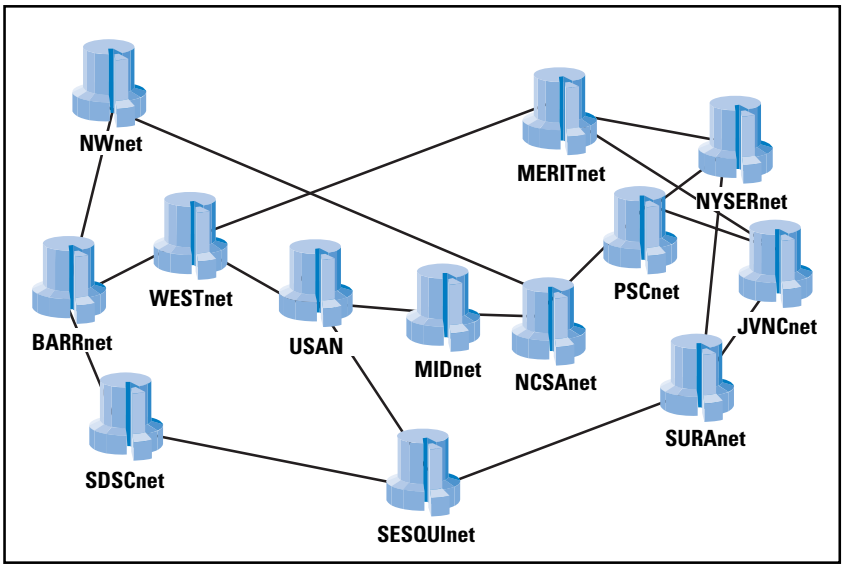


Figure 6: NSFnet in 1989

We remember our three competing goals for good internetwork design.

- Reducing hop count: average path length in steps/hops
- Reducing available paths: total geodesics in the network
- Increasing the number of failures the network can withstand: network centralization

What happens to these goals as we experience failures in the links or the nodes of the network? Table 1 shows the base metrics for Figure 6 and then shows what happens to the metrics, and our three goals, when five different failures occur.

Table 1: Possible Link and Node Failures

Scenario	Number of Geodesics in the Network	Network Centralization	Longest Path (hops)	Average Path Length (hops)
Original Design (Figure 6)	200	0.062	4	2.370
1) Node failure: NCSA	180	0.208	5	2.689
2) Node failure: MID	180	0.083	4	2.489
3) Node failure: JVNC	148	0.046	4	2.324
4) Link failure: NCSA–PSC	230	0.167	6	2.974
5) Link failure: USAN–MID	212	0.123	5	2.660
6) Link failure: MERIT–JVNC	192	0.069	4	2.458

The most damaging was link failure 4—the link failure between NCSA and PSC. This link is between two of the most central nodes in the network. If the flows between nodes are distributed somewhat evenly, then this link is one of the most traveled in the network.

The least damaging is node failure 3—the node failure at JVNC. In fact, this failure improved most metrics! By removing this node from the network, the number of network paths drops significantly, network centralization decreases, path length decreases slightly, and the longest path is still four hops.

The original NSFnet topology design is very efficient. I tried two different strategies to improve the network. The first strategy involved moving existing links to connect different pairs of routers. No obviously better topology was found by rearranging links among the routers. I was not able to find a better design that reduced both the number of geodesics and the average path length without significantly increasing the number of physical links in the network.

The second strategy is counter-intuitive, yet often networks respond well to this approach. It is the "subtracting by adding" approach described above. By adding new links in the right place in the network, we not only reduce the distance between nodes, we also decrease the number of geodesics in the network.

Because the NSFnet nodes had a maximum limit of three direct neighbors, I started connecting the nodes of Degree = 2. Options 1 through 3 show the various combinations and their effect on the total network. The improvements are minimal, yet each option offers specific strengths.

Option 2 offers more improvements than the others.

- The longest geodesic was reduced to three hops.
- The average path length was reduced throughout the network.
- The number of paths for the routers to remember was reduced slightly.
- Network centralization did not increase enough to noticeably affect the number of failures the network could withstand.

Table 2: Possible Network Improvements

Scenario	Number of Geodesics in the Network	Network Centralization	Longest Path (hops)	Average Path Length (hops)
Original Design (Figure 6)	200	0.062	4	2.370
Option 1 (add link: SDSC–MID)	202	0.071	4	2.287
Option 2 (add link: NW–DSC)	198	0.074	3	2.273
Option 3 (add link: NW–MID)	202	0.050	4	2.356

The improvement in Option 2 (add link: NW–SDSC) was actually implemented in the 1991 version of NSFnet—an excellent example of the "subtracting by adding" network dynamic. Networks are complex systems. How the network responds to change is based on the distribution and pattern of connections throughout the network.

Conclusion

In the real world we may not have the flexibility to experiment with our network model as we have with these examples. There will be more constraints. The information flows in your organization may require that specific pairs of routers have direct links—even if those connections would not be recommended by the algorithms we have been examining. Yet, when we have our "must-have" connections in place, we can experiment with the placement of the remaining connections using these social network metrics to indicate when we are getting close to a robust, yet efficient topology.

Given "initial conditions," social network methods can model our computer networks and suggest link changes[7] to form an effective topology that has a short average hop count, not too many paths, and just enough redundancy.

New Frontiers for Research Networks in the 21st Century

by Robert J. Aiken, Cisco Systems, Inc.

A famous philosopher, Yogi Berra, once said, "Prediction is hard. Especially the future."[1] In spite of this sage advice, we will still make an attempt at identifying the frontiers for research networks. By first examining and then extrapolating from the evolution and history of past research networks, we may be able to get an idea about the frontiers that face research networks in the future. One of the initial roles of the research network was to act as a testbed for network research on basic network protocols, mostly focusing on network Layers 1 through 4 (that is, the physical, data link, network, transport, and network management layers), but also including basic applications such as file transport and e-mail. During the early phases of the Internet, the commercial sector could not provide the network infrastructure sought by the research and education communities. Consequently, research networks evolved and provided backbone and regional network infrastructures that provided production-quality access to important research and education resources such as supercomputer centers and collaboratories[2]. Recent developments show that most research networks have moved away from being testbeds for network research and have evolved into production networks serving their research and education communities. It's time to make the next real evolutionary step with respect to research networks, and that is to shift our research focus toward maximizing the most critical of resources—*people*.

Given the growth and maturity of commercial service providers today, there may no longer be a pressing technical need for governments to continue to support pan-national backbone networks, or possibly even production-like national infrastructures, for Internet-savvy countries. Since commercially available *Virtual Private Networks* (VPNs) can now easily support many of the networked communities that previously required dedicated research networks, government and other supporting organizations can now support their research and education communities by providing the funding for backbone network services much as it does for telephony, office space, and computing capabilities; that is, as part of their research award. However, there may be valid social, political, and long-term economical reasons for continuing the support for such networks. For instance, a nation may decide that in order to ensure its economic survival in the future it wishes to accelerate the deployment and use of Internet technologies among its people, and thus the nation may decide to subsidize national research networks. In addition, it should be noted that VPNs often recreate the "walled" separation of communities, a scenario that was previously accomplished through the hard multiplexing of circuits.

But, in order to make technical advances in the e-economy, governments should now focus on supporting the evolution of intelligent and adaptable edge and access networks. These, in turn, will support the *Ubiquitous Computing* (UC) and persistent presence environments that will soon be an integral part of our future Internet-based economies.

The United States's recently expanded *National Science Foundation* (NSF)[3] research budget and the *Defense Advanced Projects Agency's* (DARPA's)[4] prior support of middleware research are good examples of moving in the right direction. The Netherland's Gigaport[5] project, which incorporates network and application research as well as an advanced technology access and backbone network infrastructure, is a good example of how visionary research networks are evolving.

Just as Internet technologies and network research have matured and evolved, so should the policies concerning the support of research networks. Policies need to be developed to again encourage basic network research and the development of new technologies. In addition, research networks need to encourage and accentuate new network capabilities in edge networks, on campus infrastructures, and in the end systems to support the humans in these new environments. This article focuses mainly on the future of research networks in e-developed nations; but, this is not to diminish the need or importance for e-developed nations to help encourage the same development in network-challenged nations.

Context and Definitions

Before delving into our discussion, we first need to define a few terms. These definitions will not only aid in our discussion, but may also help to highlight the role and function of various types of research networks. The most important terms to define are "network research" and "research network," both of which often get interchanged during discussions concerning policy, funding, and technology.

In this article, the term "network research" means long-term basic research on network protocols and technologies. The many types of network research can be categorized into three classes. The first category covers research on network transport infrastructure and generally includes research on the *Open System Interconnection* (OSI) Model Layers 1 through 4 (that is, the physical, data link, network, and transport layers) as well as research issues relating to the interconnection and peering of these layers and protocols. We will refer to this class of research as "transport services."

The second class consists of research covering what can nominally be referred to as "middleware"[6]. Middleware basically includes many of the services that were originally identified as network Layers 4 through 6. Layer 4 is included because of the need for interfaces to the network layer (sockets, TCP, and so on).

In addition, it nominally includes some components, such as e-mail gateways or directory services, which are normally thought of as being network applications, but which have subcomponents that may also be included in middleware. Given that the definition of middleware is far from an exact science, we shall say that middleware depends on the existence of the network transport services and supports applications.

The third area covers research on the real applications (for example, e-commerce, education, health care, and so on), network interfaces, network applications (for example, e-mail, Web, file transfer, and so on), and the use of networks and middleware in a distributed heterogeneous environment. Applications depend on both the middleware and transport layers. Advanced applications include *Electronic Persistence Presence* (EPP) and UC. EPP, or e-presence, describes a state of a person or application as always being "on the network" in some form or another. The concept of session-based network access will no longer apply. EPP assumes that support for UC and both mobile and nomadic networking exists. UC refers to the pervasive presence of computing and networking capabilities throughout all of our environments; that is, in automobiles, homes, and even on our bodies.

A "research network," on the other hand, is a production network; that is, one aspiring to the goal of 99.99999-percent "up time" at Layers 1 through 3, which supports various types of domain-specific application research. This application research is most often used to support the sciences and education, but can also be used in support of other areas of academic and economic endeavor. These networks are often referred to as *Research Networks* (RNs) or *Research and Education* (R&E) *Networks*. In this article, we further classify these RNs based on their general customer base. *Institutional Research Networks* (IRNs) support universities, institutes, libraries, data warehouses, and other "campus"-like networks. *National Research Networks* (NRNs)[7], such as the Netherland's Gigaport or Germany's DFN networks, support IRNs or affinity-based networks. *Pan National Research Networks* (PNRNs) interconnect and support NRNs. An example of a couple of current production PNRNs are Dante's Ten-155 and the NORDUNET[8] networks. In this article we will also classify the older *National Science Foundation Network's* (NSFNET's), *very-high-performance Backbone Network Service* (vBNS), CANARIE's CA*NET 3[9], and the Internet 2[10] Abilene networks as PNRNs because in terms of scale and policy they address the same issues of interconnecting a heterogeneous set of regionally autonomous networks (for example, NSFNET's regionals and Internet 2's Gigapops) as do the PNRNs.

A hybrid state of RN also exists. When we introduce one or more advanced technologies into a production system, we basically inject some amount of chaos into the system. The interplay between the new technologies and other existing technologies at various levels of the infrastructure, as well as scaling issues, can cause unanticipated results.

Research quality systems engineering and design is then required to address these anomalies. An example of this phenomenon is the problem encountered with ATM cell discard and its effect on TCP streams and subsequent retransmissions (that is, early packet discard and partial packet discard). The term *Virtual Private Network* (VPN) is used in this article in the classical sense; that is, a network tunneled within another network (for example, IP within IP, ATM virtual circuits [VCs], and so on), and it is not necessarily a security-based network VPN. *Acceptable Use Policy* (AUP) refers to the definition of the type of traffic or use that is allowed on a network infrastructure. *Conditions of Use* (COU) is basically another version of AUP.

Background

During the early phases of the evolution of research networks and the Internet, national research networks were building and managing backbone networks because there was a technical reason to do so. Governments supported these activities, because at the time the commercial sector Internet Service Providers (ISPs) could not do it and the expertise to do so resided within the R&E community. Much of the research or testing of this time still focused on backbone technologies as well as aggregation networks and architectures. Research networks started out by supporting longer-term risky network research and quickly evolved to support shorter-term no-risk production infrastructure.

The research during the *Advanced Research Projects Agency Network* (ARPANET) and early NSFNET phases of the Internet focused on basic infrastructure protocols and technologies. Now commodity services, these services are both easily and cost-effectively available from the commercial sector. We have come a long way since then. Except for a few universities and research centers, the commercial sector now dominates R&D in the backbone technology space. Commercially provided VPNs can now cost-effectively support most of the requirements of the R&E communities. Given the current domination of R&D in backbone technologies by the commercial sectors, as well as the need to address true end-to-end services, it is time that network research and research networks realign their focus onto the research and development of end-system and campus and edge network technologies. Most of the intelligence of the network (for example, *Quality of Service* [QoS], security, content distribution and routing, and so on) will live at the edges, and in some way will be oblivious to the backbone service over which it will operate. In addition, in order for applications to be able to make use of this network, intelligent RNs need to be able to provide the middleware and services that exist between the application and the transport systems. The real future for most RNs is in helping to analyze and identify, not necessarily run and manage, advanced network infrastructures for their R&E communities.

One of the problems faced by the R&E community is how to obtain support from their governments and other supportive organizations (both for-profit and nonprofit). In attempts to support advanced applications and end-user research, organizations and governments may be convinced into supporting RNs, which end up providing commodity services and competing with the commercial sector. One reason that this can occur is that governments often wish to see results very quickly in order to justify their support of the research community; but, by doing so they drive the recipient researchers and research network providers to focus on short-term results and abandon basic long-term research. This pressure from the supporting organizations can also force researchers to compete in a space—that is, transport layers—for which industry may be better suited and adapted in both scale and time. Another issue facing today's research networks is that many of the R&E community, who once would endure downtime and assume some risk in trade for being part of an experimental network, are now demanding full production-quality services from those same R&E networks. Subsequently, the RNs are then being precluded from aggressively pursuing and using really advanced technologies that may pose a risk. And finally, many times research networks, science communities, and researchers claim they are doing network research, when in reality they are not, because they wish to have decent network connectivity, and they assume that this is the only way to get funding and support for good network connectivity with which to support their real research objectives. All of these issues have driven RNs at all levels into difficult positions. RNs need to be able to again take risks if they are to push the envelope in adopting new technology. Likewise, it is also valid to provide production-quality network transport services to support research for middleware, network application (for example collaborative technologies), and R&E application (for example, medical, sciences, education, and so on) research. All of these requirements need to be addressed in the manner most expedient and cost-effective to the government or organization providing the support.

All research carries with it a certain amount of risk. There is theoretical and experimental research. Some research is subject to validation; some is *retrospective*—for example, examining packet traces to verify the existence of nonlinear synchronization—but some is *prospective* and involves reprogramming network resources, and any reprogramming is susceptible to bugs. The amount of risk often depends on the area of research undertaken. The lower down in the network structure that one performs experimental research, the more difficult it is to support this research and still maintain a production-like environment for the other researchers and applications; yet we need to provide support for all levels of experimental research, as described in MORPHNET[11]. The ideal environment would support applications that could easily migrate from a production network to one prototyping recent network research, and then back again if the experiment fails. Recent advances in optical networking show promise in realizing this goal, but many technical and policy-based challenges are yet to be addressed.

ARPANET and Early NSFNET Phase: 1980s

The ARPANET, one of the many predecessors of today's Internet, was a research project run by researchers as a sandbox where they could develop and test many of the protocols that are now integral components of the Internet. Because this was a research network that supported network research, there were times the network would "go down" and become unavailable. Although that was certainly not the goal, it was a reality when performing experimental network research. This was acceptable to all involved and allowed for the quick "research-to-production" cycle, now associated with the Internet, to develop. The management of the network with respect to policy was handled by the *Internet Activities Board* (IAB), which has since been renamed the *Internet Architecture Board,* and revolved around the actual use of the network as a research vehicle. The research focused mainly on Layers 1 through 4, and application research was secondary and used to demonstrate the underlying technologies.

At the end of the 1980s, the Internet and its associated set of protocols rapidly gained speed in deployment and use among the research community. This started the major shift away from research networks supporting experimental network protocols toward RNs supporting applications via production research networks; for example, the mission agencies' (that is, those agencies whose mission was fairly well focused in a few scientific areas) networks at the *Department of Energy* (DoE) (ESnet[12]) and NASA (NSInet). At the same time, the NSFNET was still somewhat experimental with the introduction and use of "home-grown" T1 and T3 routers, as well as with pioneering research on peering and aggregation issues associated with the hierarchical NSFNET backbone. It also focused on issues relating to the interconnection of the major agency networks and international networks at the *Federal Internet Exchanges* (FIXes), as well as the policy landscape of interconnecting commercial e-mail (MCIMail) with the Internet. The primary policy justification for supporting these networks (for example ESnet, NSInet, NSFNET) in the late 1980s was to provide access to scarce resources, such as supercomputer centers, although the NSFNET still supported network research, albeit on peering and aggregation.

In addition, the NSFNET was first in pioneering research on network measurement and characterization, leading to today's *Cooperative Association for Internet Data Analysis* (CAIDA) as well as to Surveyor installations on Abilene. As researchers became dependent on the network to support their research, the ability to introduce new and risky technologies into the network became more difficult, as shown by the second-phase T3 router upgrade for the NSFNET when many researchers vehemently complained about any "downtime."

At this time, there were still no commercial service providers from which to procure IP services to connect the numerous and varied sites of the NSFNET and other research networks. Hence there were still valid technical reasons for NRNs and R&E networks to exist and provide backbone services.

The policy decisions affecting the interconnection of the agency networks at the FIXes, as well as engineering international interconnectivity, were loosely coordinated by an ad hoc group of agency representatives called the *Federal Research Internet Coordinating Committee* (FRICC). The FRICC became the *Federal Networking Council* (FNC) in the early 1990s, and then became the *Large-Scale Network* (LSN) working group by the mid-1990s.

The FNC wisely left the management of the Internet protocols to the IAB, the *Internet Engineering Task Force* (IETF), and the *Internet Engineering Steering Group* (IESG); however, the FNC did not completely relinquish its responsibility, as evidenced by its prominent role in prodding the development of *Classless Interdomain Routing* (CIDR) and originating the work that led to new network protocols (for example, IPv6).

The Next-Generation NSFNET: Early 1990s

During the early 1990s, the Internet evolved and grew larger. It could no longer remain undetected on the government policy radar screen. Many saw the NSFNET and agency networks as competing with commercial *Internet Service Providers* (ISPs). Because of the charters of the agencies of the U.S.-based RNs (for example NSF, DoE, NASA), all traffic crossing their networks had to adhere to their respective AUPs. These AUPs prohibited any "commercial entity-to-commercial entity traffic" to use a U.S. government supported network as transit. In addition, the demand for generic Internet support for all types of research and education communities became much stronger, and at the same time there was growing support among the U.S. Congress and Executive branches to end the U.S. Federal Government support of the U.S. Internet backbone.

In response to these pressures and the responses to a NSF draft "New NSFNET" proposal, the NSF elected to get out of the business of being the Internet backbone within the United States. This policy change was the nexus for the design of the vBNS, *Network Access Points* (NAPs), and *Routing Arbiter* (RA) described in the ABF paper[13] by early 1992. The vBNS was meant to provide the NSF supercomputer sites a research network that was capable of providing the high-end network services required by the sites for their Metacenter, as well as to provide the capability for their researchers to perform network research because the centers were still the locus for network expertise. The NAPs were designed to enhance the AUP free interconnectivity of both commercial and R&E ISPs and to further evolve the interconnection of the Internet started by the FIXes and the *Commercial Internet eXchange* (CIX).

The research associated with NRNs is already evolving from dealing with mainly IP and transport protocol research to research addressing the routing and peering issues associated with a highly interconnected mesh of networks. Research was an integral part of the NAP and RA design, but it was now focused on peering of networks as opposed to the transport layer protocols themselves. Although this network was not official until 1995, commercial prototype AUP free NAPs (for example, MAE-EAST) immediately sprang up and hastened the transition to a commercial network. The network was transformed from a hierarchical network topology to a decentralized and distributed peer-to-peer model. It no longer existed for the sole purpose of connecting a large aggregation of R&E users to supercomputer centers and other "one-of-a-kind" resources. The NAPs and the "peering" advances associated with the NAPs constituted a very crucial step for the success of applications such as the *World Wide Web* (WWW) and the subsequent commercialization of the Internet because they provided the required seamless interconnected infrastructure. Although some ISPs, for example UUNET and PSInet, were quickly building out their infrastructure at that time, there still existed the need for PNRNs to act as brokers for acquiring and managing end-to-end IP services for their R&E customer base; it would not be much longer, however, before the ISPs had the necessary infrastructure in place to do this themselves.

The Internet 2 Phase: 1996–2000

The transition to the vBNS, NAP, and RA architecture became official early in 1995 and, as a result, the United States university community lost its government-subsidized production backbone. NSF-supported regionals had lost their support years earlier, and many had already transitioned to become commercial service providers, and the NSF "connections" program for tier 2 and lower schools persisted because it was felt (policy wise) that it was still valid to support such activities. The result of this set of affairs led to the creation of the Internet 2. Many of the top research universities in the United States felt that the then-current set of ISPs could not affordably provide adequate end-to-end services and bandwidth for the academic community's perceived requirements. As a result, the NSF decided to again support production-quality backbone network services for an elite set of research institutions. This was clearly a policy decision by NSF that had support from the U.S. Congress and Executive branches of government, even though in the early 1990s both Congress and the Executive branches were fairly vocal about not supporting such a network.

The initial phase was to expand to the vBNS and connect hundreds of research universities. The vBNS again changed from a research network, connecting a few sites and focusing on network and Metacenter research, back into a production research network. The vBNS is soon eclipsed by the OC-48 Abilene network. Gigapops, which are localized evolutions of NAPs, are used to connect the top R&E institutions to the Internet 2 backbones (that is, vBNS and Abilene).

These backbones were subject to COU as a way to restrict the traffic to that in direct support of R&E, much like the NSFNET was subject to its AUP.

The ISPs who complained so bitterly about unfair competition in the early 1990s no longer cared, because they had more business than they could handle in selling to corporate customers. An ironic spin on this scenario is that the business demands placed on the commercial ISPs by the late 1990s drove them to aggressively adopt new technologies to remain competitive. Not only were they willing to act as testbeds, they paid for that privilege since it gave them a competitive edge. The result is that in a lot of cases regarding the demonstration and testing of backbone-class technologies, the R&E community was time-wise behind the commercial sector. This situation is further aggravated by the fact that many, but not all, backbone network-savvy R&E folks went to work in industry. Another side effect of this transition is the loss of available network monitoring data. The data used by CAIDA, *The National Laboratory for Applied Network Research* (NLANR), and other network monitoring researchers had been gathered at the FIXes where most traffic used to pass. With the transition to a commercially dominated infrastructure, meaningful data becomes harder to obtain. In addition, as a result of the COU of the Internet 2 network, and the type of applications it supports (for example, trying to set bandwidth speed records), the traffic passing over its networks can no longer be assumed to be representative Internet data, and its value in this regard is diminished.

Another milestone is reached. ISPs have grown or merged so that they are offering both wide- and local-area network services, and anyone can now easily acquire national and international IP and transport services. The deployment and use of VPNs allows the commercial service providers (SPs) to provide and support various acceptable policy networks with differing AUP/COU on the same infrastructure. The technical need for most PNRNs or NRNs to exist to fulfill this function fades away. Researchers should now be able to specify wide-area network support as a line item in their research proposal budgets, just as they do for telephony and computing support. Most governments do not support separate research "Plain Old Telephone Service" (POTS) networks so that researchers can talk with one another. They provide funding in the grants to allow the researchers to acquire this from the commercial sector. However, valid technical reasons for selectively supporting some research networks still exist. A prime example is the CA*Net 3 network in Canada, which has been extremely aggressive in the adoption and use of preproduction optical networking technologies and infrastructure and has been instrumental in advancing our knowledge on this area.

During this evolution of research networks capabilities, network research is also going through its own evolution. DARPA starts focusing its research on optics, wireless, mobility, and network engineering as part of its Next-Generation Internet program. In addition, the research moves up the food chain of network layers. DARPA and DoE start supporting research on middleware. Globus[14], along with Legion[15], Condor[16], and POLDER[17], are major middleware research efforts that become the main impetus for GRIDs; and although they are focused mainly on seeking the holy grail of distributed computing, many of the middleware services they are developing are of value in a broader research and infrastructure context. The focus of network research and research networks now starts moving away from backbone transport services to research on advanced collaboratory, ubiquitous computing, mobile, nomadic, and EPP environments.

The policy management of the Internet now becomes an oxymoron and reflects the completion of the transition of the Internet to a distributed commercial Internet. Many organizations are now vying for a say in how the Internet evolves. Even the IETF is suffering from its own success. It now faces many of the same political challenges the ITU faced, that is, some commercial companies now try to affect the standards process for their own benefit by introducing standards contributions and only later disclosing the fact that they have filed patents on the technology in question. It is now much more difficult to make policy decisions regarding the future of Internet protocols, technologies, and architectures.

Future Frontiers

UC and EPP are the paradigm shifts at the user level that are already drastically altering our concept and understanding of networks. The scale, number, and complexity of networks supporting these new applications will far exceed anything we have experienced or managed in the past. Users will "be on the net" all the time, either as themselves or indirectly through agents and "bots." They will be mobile and nomadic. There will be "n" multiple instances of a user active on a network at the same time, and not necessarily from the same logical or geographical location. The frontiers associated with this new focus are many times more complex from a systems integration level than any work we have done in the past with backbone networks. This new frontier will provide new technical challenges at the periphery of the network; that is, the intelligent access and campus networks necessary to support these new environments. EPP and UC will drastically affect our research networks and application environments, much as the Web and its protocols drastically changed Internet and traffic patters in the 1990s.

The frontiers faced by research networks of the future will depend upon many technical and sociopolitical factors on a variety of levels. The sociopolitical frontiers can be divided into two different classes, one for e-developed nations who have already gone through the learning process

of building an Internet-based infrastructure, and another for the e-challenged nations who still face the challenges of building a viable network transport infrastructure. The developed nations need to now grapple with how they can encourage the next evolutionary phase of their Internet-based economies. Because of the fast evolution of technology, the technical need for subsidizing transport-based network infrastructure is no longer the pressing need it was in the 1990s. The future research network will most likely be nothing more than a VPN based on a commercial ISP "cloud" service that interconnects researchers. The *High Energy Physicists* (HEPs) have already proved that life as a VPN-based affinity group overlaid on production network services is a viable solution to providing for their network requirements. The *High-Energy Physics Network* (HEPnet)[18] is a virtual set of users and network experts using ESnet and other ISP VPN-based network services to support the HEP scientists. Although we still have some technical challenges associated with backbone network technology (for example, optics), there are now only a very small number of institutions and organizations capable of working with industry and making substantial contributions in this area.

The new technical challenges that need to be addressed now include how to build and deploy intelligent edge and campus networks, content delivery and routing, mobile/nomadic/wireless access to the Internet, and the support for both UC and EPP. The latter two require major advancements and will require a whole bevy of middleware that is both network aware and an integral component of an intelligent network infrastructure. This includes, but is not limited to, directories, locators, presence servers, call admission control services, self-configuring services, mobility, media servers, policy servers, bandwidth brokers, intrusion-detection servers, accounting, authentication, and access control. IRNs and RNs can contribute to our knowledge and growth of these new areas by acting as leaders in areas that tend to be more difficult for the commercial sector to address, for instance, the development and deployment of advanced end-to-end services that operate over one or more ISP-provided clouds. Examples include interdomain bandwidth broker services, multi *Public Key Infrastructure* (PKI) trust models, defining multisite policies and schemas for directory-based policy services, and developing scalable naming conventions.

In order for policy makers to make informed decisions on the evolution and support of Internet technologies and architectures, they will need access to a generic mix of real backbone network data. There still exists a dire need at this point for such data. Innovative solutions that respect the privacy and business concerns of all types of ISPs and RNs, while at the same time making available "scrubbed" data, need to be developed. In addition, with the new focus on edge and metro networks, we might be able to shift our monitoring attentions to this area as well in order to better understand traffic demands and patterns on these scales of networks. Network monitoring is only one of the challenges facing us.

As the scale and complexity of networks grows, even at the pico and body area network level, we will need to develop new techniques to support network modeling, simulation, and experimentation. The University of Utah is developing a test facility[19] comprising a large number of networked processors, the network equivalent of a supercomputer center, to be used experimentally in the design and development of new transport layer protocols.

Summary

"Being on the net" will change our way of doing e-everything, and the evolution of the underlying infrastructure will need to change in order to support this paradigm shift. The intelligence of the network will not only move to the periphery, but even beyond, to the personal digital assistant and body area network. Therefore, it is important that the goals and focus of the research networks also evolve. Leave the R&D associated with backbone networks mainly with the commercial sector because this is their raison d'etre. The research networks of the future will be mostly VPNs, with a few exceptions, as noted earlier in this article. Research networks need to focus on the new technologies at the periphery as well as the middleware necessary to support the advanced environments that will soon be commonplace. Many research networks will themselves become virtual, for example, HEPnet, providing expertise but not necessarily a network service.

Policy makers must adapt to address not only these substantial technical and architectural changes but also second-order policy issues such as security and privacy and how to ensure that we don't end up with a bifurcated digital economy of e-savvy and e-challenged communities.

E-developed nations have already been through the technology learning curve of implementing and deploying a transport infrastructure. The e-challenged nations, with respect to network infrastructure, still face these same challenges, and they have the benefit of taking advantage of the knowledge of the nations who have successfully made the transition. In order to speed up the deployment of Internet technologies and infrastructure in the e-challenged nations, it may be best to first create technologically educated people and then to provide them an economic and social environment where they can apply their knowledge and build the infrastructure. E-savvy nations should help by providing the "know-how." The *North Atlantic Treaty Organization* (NATO) has a joint program with the *Trans-European Research and Education Networking Association* (TERENA) to provide for the instruction of Eastern European nations on the use and deployment of Internet technology (that is, how to configure and manage routers).

In lieu of subsidizing networks in these nations, NATO and TERENA are providing the basic knowledge that these people need to build, manage, and evolve their own networks and infrastructure. This should be the model to consider for e-developing nations. This is not to diminish the challenges of building network infrastructure in some areas where there is no such infrastructure, and perhaps in some of these areas working with other utility infrastructure providers might advance this cause.

Disclaimer

The ideas, comments, and projections proffered in this article are the sole opinions of the author, and in no way represent or reflect official or unofficial positions or opinions on the part of Cisco Systems, Inc. This article is based on my experience designing and managing operational international research networks, as well as being a program manager for network research, during the formative years of the Internet (that is, my tenure as a program manager for the United States Government's National Science Foundation and the Department of Energy), and my recent experience within Cisco working with next-generation Internet projects and managing its University Research Program. Many of the examples that I cite in this work are based on the development and deployment of the U.S.-based Internet and research networks, although the lessons learned in the United States may also be illuminating elsewhere.

Gratitude

I would like to thank my friend and colleague, Dr. Stephen Wolff, of the Office of the CTO, Cisco Systems Inc., for many good suggestions with respect to improving the content and presentation of this article; but, mostly for his good-humored authentication of my history and facts.

ROBERT J. AIKEN has an MS in Computer Science from Temple University. He is the Manager of the Cisco University Research Program. Prior to joining Cisco, Bob was the network and security research program manager for DoE's HPCC program and Next-Generation Internet (NGI) initiative. He was a program manager at the National Science Foundation (NSF), and with colleagues Peter Ford and Hans-Werner Braun coauthored the conceptual design and architecture of the second-generation National Science Foundation Network (NSFNET) (vBNS, Network Access Points [NAPs], and the Routing Arbiter [RA]), which enabled the commercialization of the then-U.S.-federally supported Internet. Before his NSF tenure, he served as DoE's ESnet program manager and was the creator and manager of the ESnet Network Information and Services group. Prior to his career in networking, Bob was responsible for managing supercomputers and coding their operating systems. His academic experience includes being an Assistant Professor of Computer Science at Hood College in Maryland, an adjunct Professor at California State University, Hayward, and the Manager of Technology Services at Gettysburg College in Pennsylvania. Book Review

Intrusion Detection

Network Intrusion Detection—An Analyst's Handbook, by Stephen Northcutt, ISBN 0735708681, New Riders Publishers, 1999.

Network security and the ability to detect intrusion attempts has become extremely important in today's networks, regardless of size. I was looking for a book that would get technical on the details in these matters. Laura Chappell, the guru of packet-level information (**www.packet-level.com**), recommended this book to me. I should have realized what I was getting into at that point. I purchased the book, which was a bit expensive for its size at $39.99, and eagerly began reading it.

Mr. Northcutt starts out with a good discussion on how Kevin Mitnick conducted his famous attack. The book presents some very good information on a variety of topics, intermixed with personal observations and opinion. This made for an enjoyable read. If you are considering getting an *Intrusion Detection System* (IDS), then this book will provide you with some valuable insight and guidelines to consider from a recognized industry expert in this field. Mr. Northcutt is affiliated with The *System Administration, Networking, and Security* (SANS) *Institute* (**www.sans.org**).

Be aware that this book is not for the faint of heart. You will dive into the depths of packets and intrusion detection rather quickly, and never look back. This is both good and bad. I prefer an easy-to-read technical book, but the level of technical knowledge required to make sense of many of the examples is rather extensive. This includes how the many trace examples are presented in rather specialized fashion; in addition, the touted "detailed" explanations varied in usefulness quite a bit.

The book was marketed as a training aid; however, I suspect most readers need to be quite experienced to benefit from it. I admit I had to read many sections more than once in order to grasp the finer points being conveyed. I am confident that many readers have already echoed this sentiment to the author and publisher, since the second edition of this book was published in September 2000 and the page count has doubled, with only a modest price increase. I put it on my Christmas list!

—Tom Thomas, Mentor Technologies Group

Would You Like to Review a Book for IPJ?

We receive numerous books on computer networking from all the major publishers. If you've got a specific book you are interested in reviewing, please contact us and we will make sure a copy is mailed to you. The book is yours to keep if you send us a review. We accept reviews of new titles, as well as some of the "networking classics." Contact us at **ipj@cisco.com** for more information.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

Fragments

New Top-Level Domains

On November 16, 2000 The board of directors of the *Internet Corporation for Assigned Names and Numbers,* (ICANN) announced its selections for registry operators for new top level domains. The applications selected for further negotiation are the following:

.aero	Societe Internationale de Telecommunications Aeronautiques SC, (SITA)
.biz	JVTeam, LLC
.coop	National Cooperative Business Association, (NCBA)
.info	Afilias, LLC
.museum	Museum Domain Management Association, (MDMA)
.name	Global Name Registry, LTD
.pro	RegistryPro, LTD

The ICANN staff will now work through the end of the year to negotiate registry agreements with the applicants selected. The proposed schedule for completion of negotiations is December 31, 2000. The negotiated registry agreements must then be approved by the board of directors. Following that approval, the ICANN board will forward its recommendations to the U.S. Department of Commerce for implementation. For more on the history of ICANN's new TLD application process, please see **http://www.icann.org/tlds/** Multimedia archives of the annual meeting can be reviewed at **http://cyber.law.harvard.edu/icann/la2000/**

ICANN is a technical coordination body for the Internet. Created in October 1998 by a broad coalition of the Internet's business, technical, academic, and user communities, ICANN is assuming responsibility for a set of technical functions previously performed under U.S. government contract by IANA and other groups. Specifically, ICANN coordinates the assignment of the following identifiers that must be globally unique for the Internet to function: Internet domain names, Internet Protocol address numbers, and protocol parameter and port numbers. In addition, ICANN coordinates the stable operation of the Internet's root server system. As a non-profit, private-sector corporation, ICANN is dedicated to preserving the operational stability of the Internet; to promoting competition; to achieving broad representation of global Internet communities; and to developing policy through private-sector, bottom-up, consensus-based means. ICANN welcomes the participation of any interested Internet user, business, or organization. See **http://www.icann.org**

ISOC Launches Platinum Membership Level

The *Internet Society* (ISOC) is pleased to announce its *Platinum Sponsorship Program,* The Platinum program, which is in addition to and distinct from ISOC's standard organizational membership categories, provides interested organizations with the ability to designate support for specific areas of ISOC's work.

The initial participants, who also helped define the program, included Cisco, IBM, Microsoft, Nortel, RIPE NCC and SoftComca.com. APNIC has since joined the list of Platinum sponsors. Platinum level sponsors contribute $100,000 annually, with non-profit organizations eligible for funding at half that amount.

The Platinum program was initially developed to bolster support for the standards activities of ISOC, specifically ISOC's support of the *Internet Engineering Task Force* (IETF). Recently the program was expanded beyond Standards to include the three remaining areas of ISOC activities: Education & Training, Public Policy, and Member Services. As a result, participants in the Platinum program can now earmark their contribution for any of these four functional areas, or choose to allocate support for multiple areas, should they so desire.

ISOC is dependent upon individual and organizational members for its funding. ISOC believes that allowing contributors to designate where their money will be spent through the Platinum program enhances the Society's ability to undertake activities in these four areas, and, at the same time, provides an attractive support option for many organizations. ISOC will provide a report on the use of funds to each Platinum-Level sponsor at the end of each year. More information on the Platinum-Level Support Program can be found at:
`http://www.isoc.org/isoc/membership/platinum.shtml`

More information on ISOC's standard membership categories is available from: **`http://www.isoc.org/orgs/benefits.shtml`**

100 Million Internet Hosts

The Internet reached 100,000,000 hosts on 2 November 2000, according to John S. Quarterman, founder of Matrix.Net, a provider of Internet performance, measurement and intelligence. From its humble beginnings of 4 sites in the western United States in December 1969, the Internet has now reached over 150 countries and is nearly pole to pole. "This is an impressive achievement," said Quarterman. "We have been tracking the growth and development of the Internet for this entire decade. If this kind of growth continues, we will hit 1,000,000,000 hosts in 2006." For more information, see **`http://www.matrix.net/`**

From The Editor

The rapid growth of the Internet has led to numerous changes to the underlying technologies. In the early days, host names and their corresponding IP addresses were kept in a flat text file ("**HOSTS.TXT**"), updated weekly by the Network Information Center at SRI International. In the mid 1980s it became clear that this method of name/address mapping would not scale, and a new distributed lookup mechanism was designed and deployed. This new method, known as the *Domain Name System* (DNS), has proven successful even in the face of millions of Internet hosts.

Another result of Internet growth is the potential for depletion of the IP Version 4 (IPv4) 32-bit address space. In the early 1990s, this became a matter of great focus for the Internet Engineering Task Force (IETF). The "short-term" fix for this problem was to abandon the original concept of A, B and C address classes and introduce *Classless Interdomain Routing* (CIDR), which consumes addresses in a much more efficient manner—that is to say, more slowly. Address consumption has also been slowed by the use of *Network Address Translation* (NAT) and private address space. Predictions for when the Internet will finally run out of IPv4 addresses varies. The long-term solution is to replace IPv4 with IPv6 which uses 128 bits for addressing.

One area of Internet growth that is currently causing some concern among ISPs is the growing size of the routing table that each router participating in the *Border Gateway Protocol* (BGP) must keep in memory. Our first article, by Geoff Huston, is a detailed look at this problem. Geoff takes an historical look at the BGP routing table, and discusses ways to address some of the issues.

In our March 2000 issue, Geoff Huston wrote an article entitled "Quality of Service—Fact or Fiction?" that discussed the prospects for achieving QoS on an Internet-wide scale. In this issue, Bill Stallings looks at QoS in the LAN environment, which is generally easier to control than the Internet as a whole. LAN QoS has been standardized in IEEE 802.1D which is the subject of this article.

We apologize for the delay in getting our online subscription system up and running. It should be available in the very near future. Meanwhile, please continue to use **ipj@cisco.com** for any subscription questions or to give feedback on anything you read in this journal.

Analyzing the Internet BGP Routing Table

by Geoff Huston, Telstra

The Internet continues along a path of seemingly inexorable growth, at a rate that has, at a minimum, doubled in size each year. How big it needs to be to meet future demands remains an area of somewhat vague speculation. Of more direct interest is the question of whether the basic elements of the Internet can be extended to meet such levels of future demand, whatever they may be. To rephrase this question, are there inherent limitations in the technology of the Internet—or its architecture of deployment—that may impact the continued growth of the Internet to meet ever-expanding levels of demand?

Numerous potential areas can be searched for such limitations, including the capacity of transmission systems, the switching capacity of routers, the continued availability of addresses, and the capability of the routing system to produce a stable view of the overall topology of the network. This article examines the Internet routing system and the longer-term growth trends that are visible within this system.

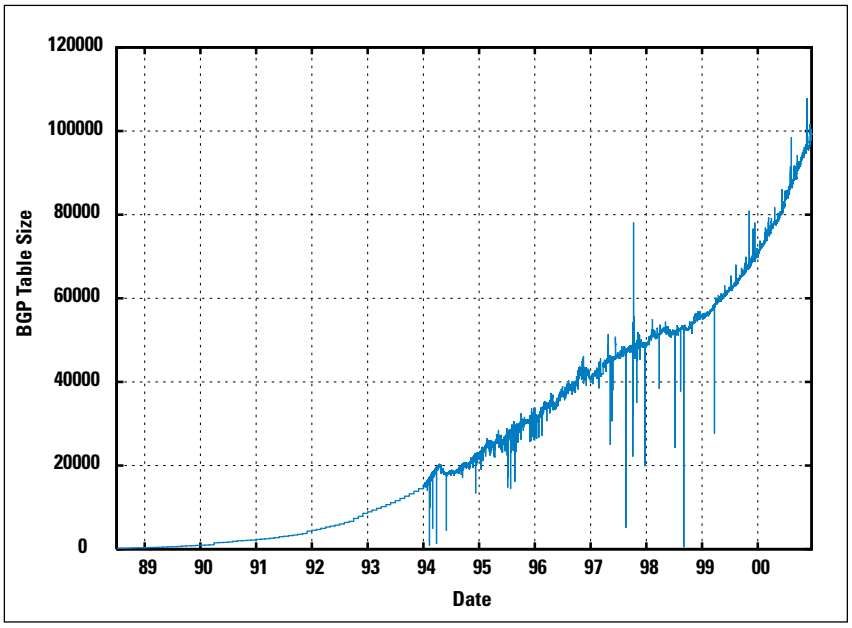
The structure of the global Internet can be likened to a loose coalition of semi-autonomous constituent networks. Each of these networks operates with its own policies, prices, services, and customers. Each network makes independent decisions about where and how to secure the supply of various components that are needed to create the network service. The cement that binds these networks into a cohesive whole is the use of a common address space and a common view of routing. Integrity of routing within each constituent network, or *Autonomous System* (AS), is maintained through the use of an interior routing protocol (or *Interior Gateway Protocol,* or IGP). The collection of these networks is joined into one large routing domain through the use of an inter-network routing protocol (or *Exterior Gateway Protocol,* or EGP).

When the scaling properties of the Internet were studied in the early 1990s, two critical factors identified in the study were, not surprisingly, routing and addressing[1]. As more devices connect to the Internet, they consume addresses, and the associated function of maintaining reachability information for these addresses implies ever-larger routing tables. The work in studying the limitations of the 32-bit IPv4 address space produced many outcomes, including the specification of IPv6, as well as the refinement of techniques of *Network Address Translation* (NAT) intended to allow some degree of transparent interaction between two networks using different address realms. Growth in the routing system is not directly addressed by these approaches, because the routing space is the cross product of the complexity of the topology of the network, multiplied by the number of autonomous domains of connectivity policy multiplied by the base size of a routing-table entry. When a network advertises a block of addresses into the exterior routing space, this entry is generally carried across the entire exterior routing domain of the

Internet. To measure the characteristics of the global routing table, it is necessary to establish a point in the default-free part of the exterior routing domain and examine the *Border Gateway Protocol* (BGP) routing table that is visible at that point.

Measurements of the size of the routing table were somewhat sporadic in the beginning, and many measurements were taken at approximately monthly intervals from 1988 until 1992 at Merit[2]. This effort was resumed in 1994 by Erik-Jan Bos at Surfnet in the Netherlands, who commenced measuring the size of the BGP table at hourly intervals at the start of that year. This measurement technique was adopted by the author in 1997, using a measurement point located at the edge of AS 1221 in Australia, again using an hourly interval for the measurement[6]. The result of these efforts is that we now have a detailed view of the dynamics of the Internet routing-table growth that spans 13 years (Figure 1).

Figure 1: BGP Table Growth 1988–2000



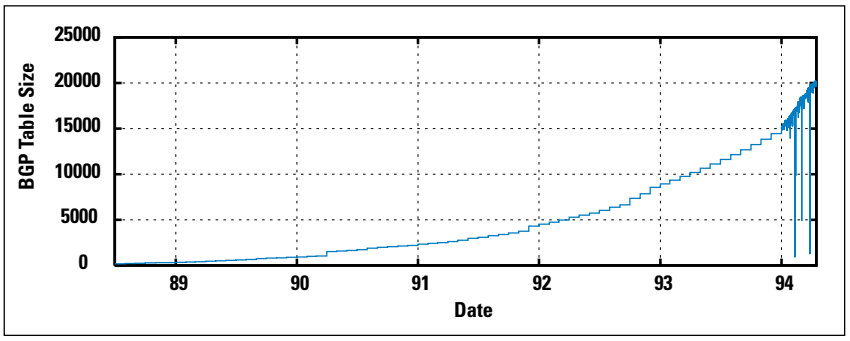
BGP Table Growth

At a gross level, there appear to be four distinct phases of growth visible in this data.

Pre-CIDR Growth

The initial characteristics of the routing-table size from 1988 until April 1994 show definite characteristics of exponential growth (Figure 2). Much of this growth can be attributed to the growth in deployment of the historical Class C address space (/24 address prefixes). Unchecked, this growth would have lead to saturation of the BGP routing tables in nondefault routers within a few years. Estimates of the time at which this would have happened vary somewhat, but the overall observation was that the growth rates were exceeding the growth in hardware and software capability of the deployed network at that time.

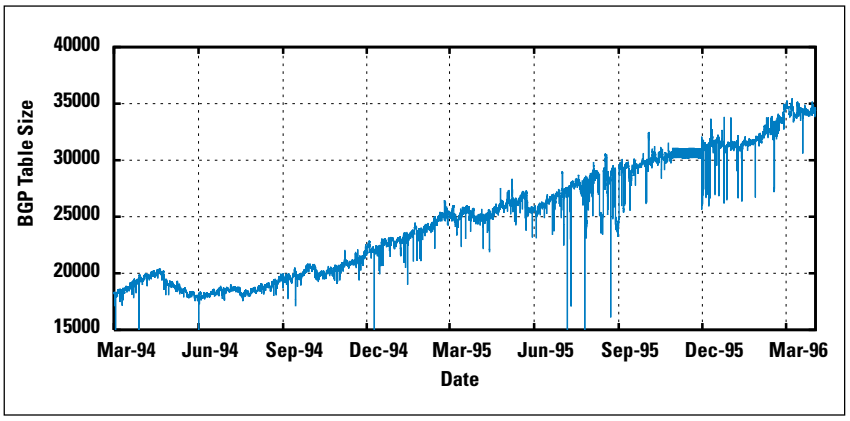
Figure 2: BGP Table Growth 1988–1994



CIDR Deployment

The response from the engineering community was the introduction of routing software that dispensed with the requirement for the Class A, B, and C address delineation, replacing this scheme with a routing system that carried an address prefix and an associated prefix length. A concerted effort was undertaken in 1994 and 1995 to deploy *Classless Interdomain Routing* (CIDR), based on encouraging deployment of the CIDR-capable version of the BGP protocol, BGP4. The effects of this effort are visible in the routing table (Figure 3). Interestingly enough, the efforts of the *Internet Engineering Task Force* (IETF) CIDR Deployment Working Group are visible in the table, with downward movements in the size of the routing table following each IETF meeting.

Figure 3: BGP Table Growth 1994–1995

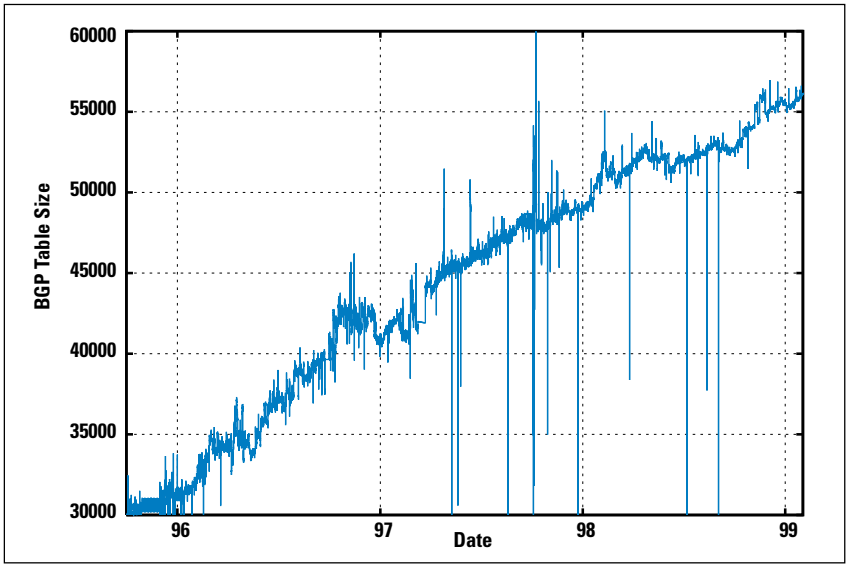


The intention of CIDR was one of supporting an address architecture termed "provider address aggregation," where a network provider is allocated an address block from the address registry, and announces this entire block into the exterior routing domain. Customers of the provider use a suballocation from this address block, and these smaller routing elements are aggregated by the provider and not directly passed into the exterior routing domain. During 1994, the size of the routing table remained relatively constant at approximately 20,000 entries as the growth in the number of providers announcing address blocks was matched by a corresponding reduction in the number of address announcements as a result of CIDR aggregation.

CIDR Growth

For the next four years until the start of 1998, CIDR proved remarkably effective in damping unconstrained growth in the BGP routing table. While other metrics of Internet size grew exponentially during this period, the BGP table grew at a linear rate, adding about 10,000 entries per year. (Figure 4). Growth in 1997 and 1998 was even lower than this linear rate. Although the reasons behind this are somewhat speculative, it is relevant to note that this period saw intense aggregation within the *Internet Service Provider* (ISP) industry, and in many cases this aggregation was accompanied by large-scale renumbering to fit within provider-based aggregated address blocks. During this period, credit for this trend also must be given to Tony Bates, whose weekly reports of the state of the BGP address table, including listings of further potential for route aggregation, provided considerable incentive to many providers to improve their levels of route aggregation[4].

Figure 4: BGP Table Growth 1995–1998

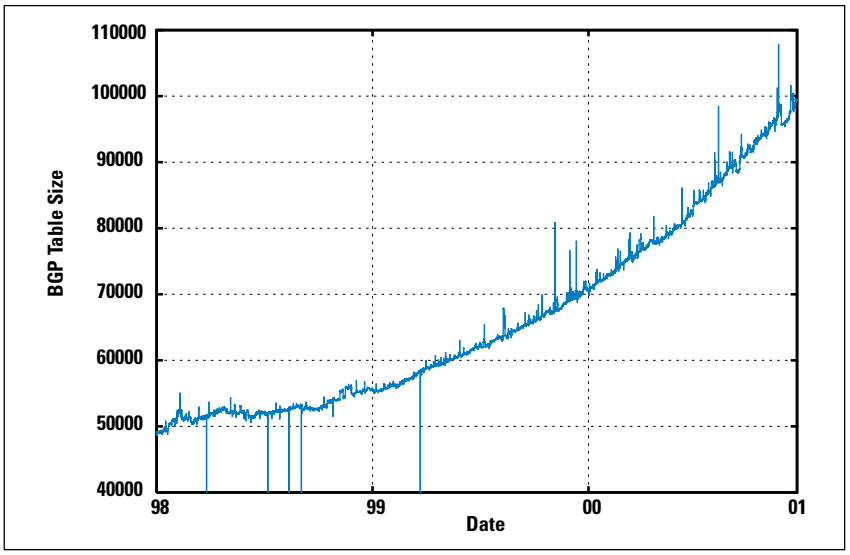


A close examination of the table reveals a greater level of stability in the routing system at this time. The short-term (hourly) variation in the number of announced routes decreased, both as a percentage of the number of announced routes and in absolute terms. One of the other benefits of using large aggregate address blocks is that an instability at the edge of the network is not immediately propagated into the routing core. The instability at the last hop is absorbed at the point at which an aggregate route is used in place of a collection of more specific routes. This, coupled with widespread adoption of BGP route flap damping, has been every effective in reducing the short-term instability in the routing space. It has been observed that whereas the absolute size of the BGP routing table is one factor in scaling, another is the processing load imposed by continually updating the routing table in response to individual route withdrawals and announcements. The encouraging picture from this table is that the levels of such dynamic instability in the network have been reduced considerably by a combination of route flap damping and CIDR.

Current Growth

In late 1998, the trend of growth in the BGP table size changed radically, and the growth for the past two years is again showing all the signs of a reestablishment of exponential growth. It appears that CIDR has been unable to keep pace with the levels of growth of the Internet. (Figure 5). Once again the concern is that this level of growth, if sustained, will outstrip the capability of hardware, or current capability of the BGP routing protocol, or possibly both.

Figure 5: BGP Table Growth 1998–2000



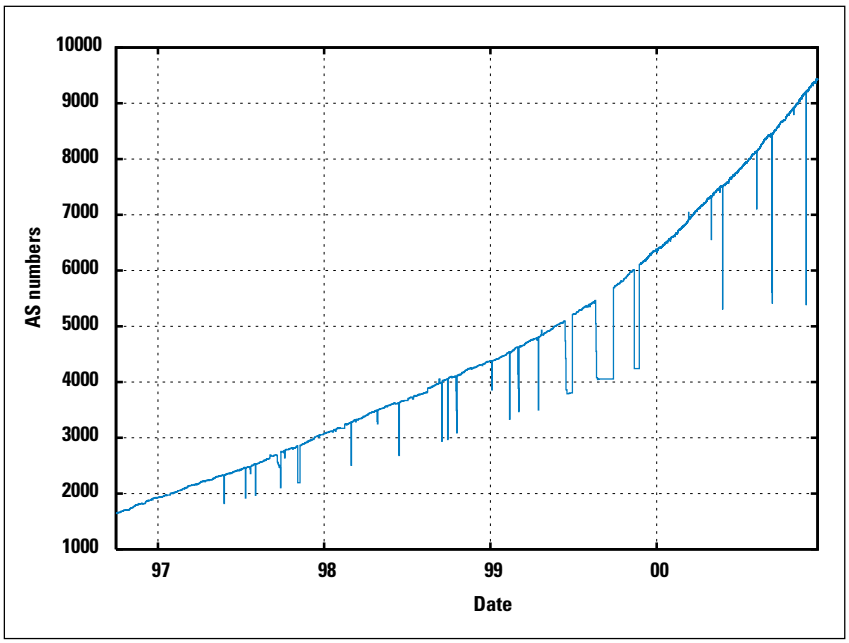
Related Measurements Derived from BGP Table

The level of analysis of the BGP routing table has been extended in an effort to identify the reasons for this resumption of exponential growth. Current analysis includes measuring the number of ASs in the routing system, and the number of distinct AS paths, the range of addresses spanned by the table, and the average span of each routing entry.

AS Number Consumption

Each network that is multihomed within the topology of the Internet and wishes to express a distinct external routing policy must use an AS to associate its advertised addresses with such a policy. In general, each network is associated with a single AS, and the number of ASs in the default-free routing table tracks the number of entities that have unique routing policies. There are some exceptions to this, including large global transit providers with varying regional policies, where multiple ASs are associated with a single network, but such exceptions are relatively uncommon. The trend of AS number deployment over the past four years is also exponential (Figure 6). The growth in the number of ASs can be correlated with the growth in the amount of address space spanned by the BGP routing table. At the end of 2000, the span of advertised addresses is growing at an annual rate of 7 percent, while the number of ASs is growing by 51 percent. Each AS is, on average advertising smaller address ranges. This points to increasingly finer levels of routing detail being announced into the global routing domain, a trend that causes some level of concern.

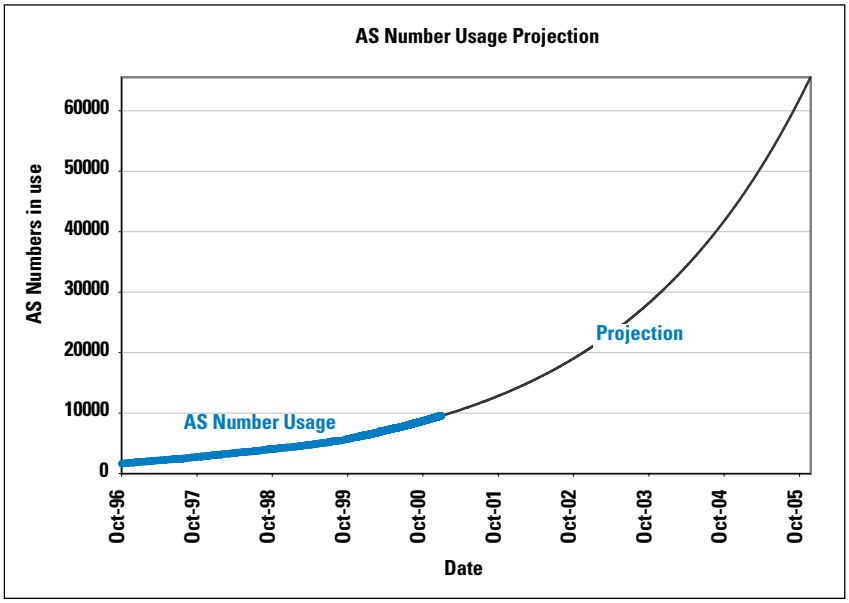
Figure 6: AS Number Deployment



This is a likely result of an increasingly dense interconnection mesh, where an increasing number of networks are moving from a single-homed connection into multihoming and peering. The spur for this may well be the declining unit costs of communications bearer services.

If this rate of growth continues, the 16-bit AS number set will be exhausted by late 2005 (Figure 7). Work is under way within the IETF to modify the BGP protocol to carry AS numbers in a 32-bit field[5]. Although the protocol modifications are relatively straightforward, the major responsibility rests with the operations community to devise a transition plan that will allow gradual transition into this larger AS number space.

Figure 7: AS Number Projections

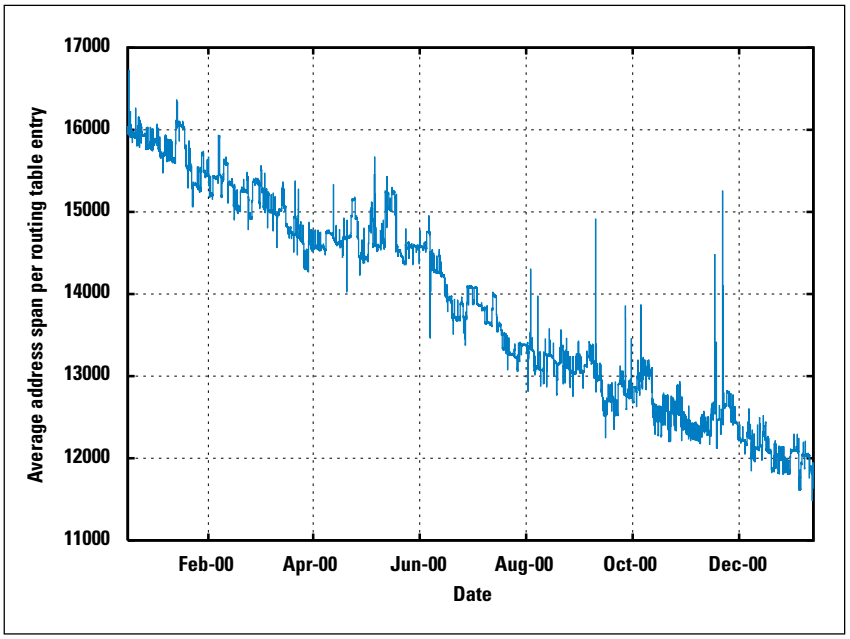


Average Prefix Length of Advertisements

The intent of CIDR aggregation was to support the use of large aggregate address announcements in the BGP routing table. To check whether this is still the case, researchers have tracked the average span of each BGP announcement for the past 12 months. The data indicates a decline in the average span of a BGP advertisement from 16,000 individual addresses in November 1999 to 12,100 in December 2000 (Figure 8). This corresponds to an increase in the average prefix length from /18.03 to /18.44. Separate observations of the average prefix length used to route traffic in operation networks in late 2000 indicate an average length of 18.1[8]. Again, this trend is cause for concern because it implies the increasing spread of traffic over greater numbers of increasingly finer forwarding-table entries. This, in turn, has implications for the design of high-speed core routers, particularly when extensive use is made of cached forwarding entries within the switching subsystem.

One potential scenario is that the size of the advertisement continues to decrease. With the widespread use of address translation gateway systems, such as NAT, and the continued concern over the finite nature of the IPv4 address pool, this is certainly a highly likely scenario. Projections of the average prefix length of advertisements using current trends in the number of BGP table entries and the total address span advertised in the BGP table indicate a lengthening of the average prefix length of advertisements by 1 bit length every 29 months. This has implications in the lookup algorithms used in routing design, depending on the space/time trade-offs used in the lookup algorithm design. This trend implies that either lookups need to search deeper through the prefix chain to find the necessary forwarding entry, requiring faster memory subsystems to perform each lookup, or the lookup table needs to be both larger and more sparsely populated, increasing the requirements for high-speed memory within the router forwarding subsystem.

Figure 8: Average Span of BGP Advertisement



Prefix Length Distribution

In addition to looking at the average prefix length, the analysis of the BGP table also includes an examination of the number of advertisements of each prefix length.

An extensive effort was introduced in the mid-1990s to move away from extensive use of the Class C space and to encourage providers to advertise larger address blocks. This has been reinforced by the address registries who have used provider allocation blocks of /19 and, more recently, /20. These measures were introduced when there were approximately 20,000 to 30,000 entries in the BGP table. It is interesting to note that five years later, of the 96,000 entries in the routing table, about 53,000 entries have a /24 prefix. In absolute terms, the /24 prefix set is the fastest-growing prefix set in the entire BGP table.

The routing entries of these smaller address blocks also show a much higher level of change on an hourly basis. Although a large number of BGP routing points perform route flap damping, there is still a very high level of announcements and withdrawals of these entries in this particular area of the routing table when viewed using a perspective of route updates per prefix length. Given that the number of these small prefixes is growing rapidly, there is cause for some concern that the total level of BGP flux, in terms of the number of announcements and withdrawals per second, may be increasing, despite the pressures from flap damping. This concern is coupled with the observation that, in terms of BGP stability under scaling pressure, it is not the absolute size of the BGP table that is of prime importance, but the rate of dynamic path recomputations that occur in the wake of announcements and withdrawals. Withdrawals are of particular concern because of the number of transient intermediate states that the BGP distance-vector algorithm explores in processing a withdrawal. Current experimental observations indicate a typical convergence time of about 2 minutes to propagate a route withdrawal across the BGP domain[7]. An increase in the density of the BGP mesh, coupled with an increase in the rate of such dynamic changes, does have serious implications in maintaining the overall stability of the BGP system as it continues to grow.

The registry allocation policies also have had some impact on the routing-table prefix distribution. The original registry practice was to use a minimum allocation unit of a /19, and the 10,000 prefix entries in the /17 to /19 range are a consequence of this policy decision. More recently, the allocation policy now allows for a minimum allocation unit of a /20 prefix, and the /20 prefix is used by about 4000 entries; in relative terms, this is one of the fastest-growing prefix sets.

The number of entries corresponding to very small address blocks (smaller than a /24), although small in number as a proportion of the total BGP routing table, is the fastest growing in relative terms. The number of /25 through /32 prefixes in the routing table is growing faster, in terms of percentage change, than any other area of the routing table. If prefix length filtering were in widespread use, the practice of announcing a very small address block with a distinct routing policy would have no particular beneficial outcome, because the address block would not be passed throughout the global BGP routing domain and the propagation of the associated policy would be limited in scope. The growth of the number of these small address blocks, and the diversity of AS paths associated with these routing entries, points to a relatively limited use of prefix-length filtering in today's Internet. In the absence of any corrective pressure in the form of widespread adoption of prefix-length filtering, the very rapid growth of global announcement of very small address blocks is likely to continue.

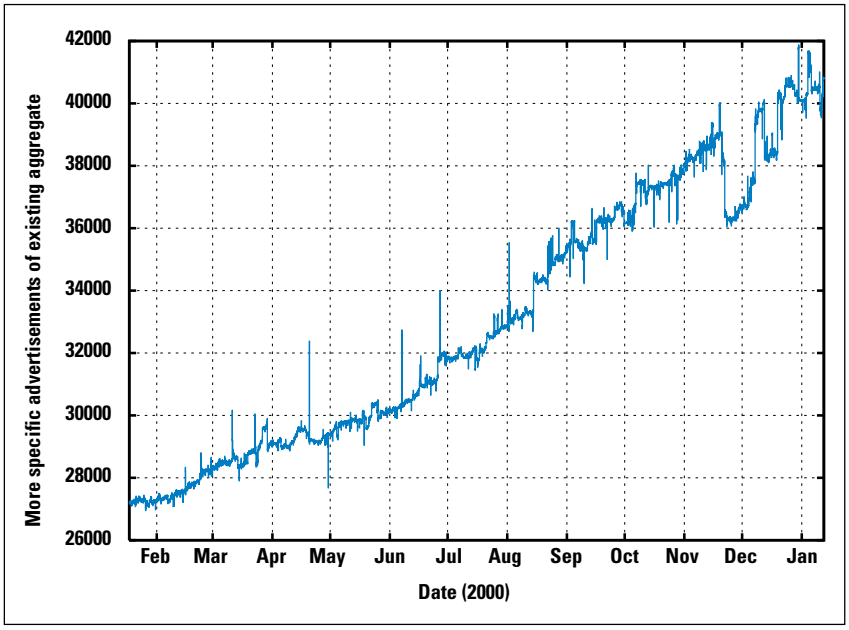
Aggregation and Holes

With the CIDR routing structure, it is possible to advertise a more specific prefix of an existing aggregate. The purpose of this more specific announcement is to punch a "hole" in the policy of the larger aggregate announcement, creating a different policy for the specifically referenced address prefix. Another use of this mechanism is not to promulgate a different connectivity policy, but to perform some rudimentary form of load balancing and mutual backup for multihomed networks. In this model, a network may advertise the same aggregate advertisement along each connection, but then advertise a set of specific advertisements for each connection, altering the specific advertisements such that the load on each connection is approximately balanced. The two forms of holes can be readily discerned in the routing table—while the approach of policy differentiation uses an AS path that is different from the aggregate advertisement, the load balancing and mutual backup configuration uses the same AS path for both the aggregate and the specific advertisements.

Although it is difficult to understand whether the use of such specific advertisements was intended to be an exception to a more general rule or that it was not intended to be within the original intent of CIDR deployment, there appears to be very widespread use of this mechanism within the routing table. Approximately 37,500 advertisements, or 37 percent of the routing table, is being used to punch policy holes in existing aggregate announcements (Figure 9). Of these, the overall majority of about 30,000 routes use distinct AS paths, so that once more we are seeing a consequence of finer levels of granularity of connection policy in a densely interconnected space.

Although long-term data is not available for the relative level of such advertisements as a proportion of the full routing table, the growth level does strongly indicate that policy differentiation at a fine level within existing provider aggregates is a significant driver of overall table growth.

Figure 9: More Specific Advertisements

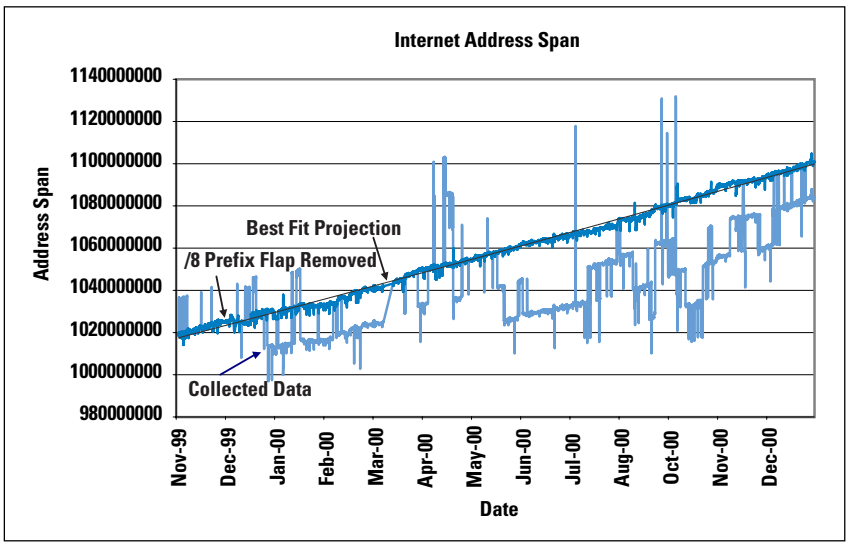


Address Consumption

A decade ago there were two major concerns over scaling of the Internet, and of the two, the consumption of address space was considered to be the more immediate and compelling threat to the continued viability of the network to sustain growth.

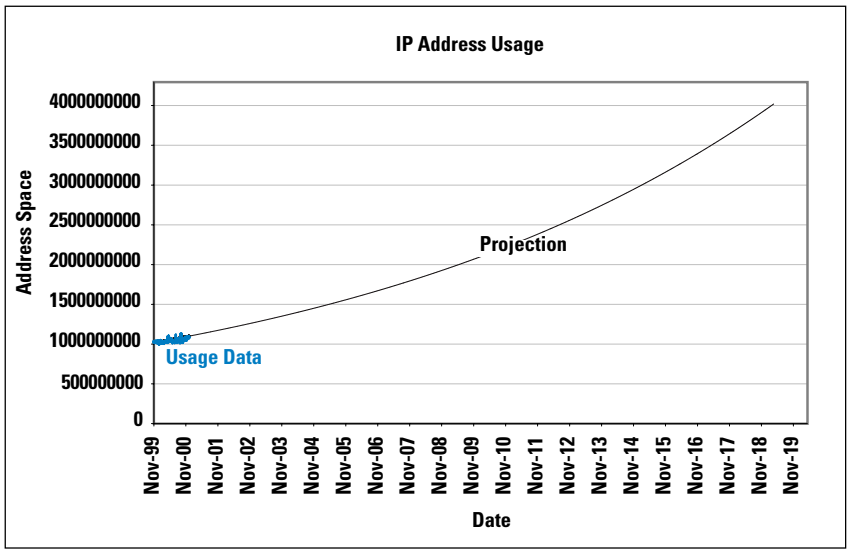
Within the scope of this exercise, it has been possible to track the total span of address space covered by BGP routing advertisements. Over the period from November 1999 until December 2000, the span of address space has grown from 1.02 billion addresses to 1.06 billion. However, numerous /8 prefixes are periodically announced and withdrawn from the BGP table, and if the effects of these prefixes are removed, the final value of addresses spanned by the table is approximately 1.09 billion addresses (Figure 10).

Figure 10: Total Address Space



This is an annual growth rate of a little less than 7 percent, and at that rate of address deployment, the IP Version 4 address space will be able to support another 19 years of such growth (Figure 11). Compared to the 42-percent growth in the number of routing advertisements, it would appear that much of the growth of the Internet in terms of growth in the number of connected devices is occurring behind various forms of NATs. In terms of solving the perceived finite nature of the address space identified just under a decade ago, the Internet appears so far to have embraced the approach of using NATs, irrespective of their various perceived functional shortcomings[3]. This observation also supports the observed increase of smaller address fragments supporting distinct policies in the BGP table, because such small address blocks encompass arbitrarily large networks located behind one or more NAT gateways.

Figure 11: Address Space Projection



Anomalies

A common space such as the inter-provider domain is not actively managed by any single entity, and various anomalies appear in the routing table from time to time.

One notable event occurred in late 1997, when some large prefixes were deconstructed into a massive set of /24 prefixes and this set was inadvertently passed into the inter-provider BGP domain. The BGP table graphs show a sudden upswing in the number of routing table entries from 50,000 entries to about 78,000 entries. It could have been higher, except that a commonly used routing hardware platform at the time ran into table memory exhaustion at that number of table entries, and further promulgation of additional routing entries ceased. Numerous other anomalies also exist in the table, including the presence of a /31 prefix and several hundred /32 prefixes.

Although many of these anomalies can be attributed to configuration errors of various forms, the underlying observation is that there are no universally used strong filters on what can broadcast into the BGP routing space. Considering the distributed nature of this table and the critical role that it plays in supporting the global Internet, this can be considered a significant current vulnerability. One potential response is to make more use of authentication measures. A validity check could be a precondition to accepting any route advertisement, allowing the receiver of the advertisement a means to check that the origin AS intended to advertise this route. This would create greater resiliency against inadvertent leaks of large sets of advertisements into the broader inter-domain space. It would also improve the resiliency of the BGP domain against some forms of deliberate attack.

Conclusions

There are strong parallels between the BGP routing space and the condition commonly referred to as "The Tragedy Of The Commons." The BGP routing space is simultaneously everyone's problem, because it impacts the stability and viability of the entire Internet, and no one's problem, in that no single entity can be considered to manage this common resource.

In other common resource domains, when the value of the resource is placed under threat because of damaging exploitative practices, the most typical form of corrective action is through the imposition of a consistent set of policies and practices intended to achieve a particular outcome. The vehicle for such an imposition of policies and practices is most commonly that of regulatory fiat. In a globally distributed space such as the BGP table, it is a challenging task to identify the source and authority of such potential regulatory activity.

Multihomed Small Networks

It would appear that one of the major drivers of the recent growth of the BGP table is that of small networks multihoming with numerous peers and numerous upstream providers. In the appropriate environment where numerous networks are in relatively close proximity, using peer relationships can reduce total connectivity costs, as compared to using a single upstream service provider. Equally significantly, multihoming with numerous upstream providers is seen as a means of improving the overall availability of the service. In essence, multihoming is seen as an acceptable substitute for upstream service resiliency.

This has a potential side effect: When multihoming is seen as a preferable substitute for upstream provider resiliency, the upstream provider cannot command a price premium for proving resiliency as an attribute of the provided service, and, therefore, has little incentive to spend the additional money required to engineer resiliency into the network. The actions of the multihomed network clients then become self-fulfilling.

One way to characterize this behavior is that service resiliency in the Internet is becoming the responsibility of the customer, not the service provider.

In such an environment resiliency still exists, but rather than being a function of the bearer or switching subsystem, resiliency is provided through the function of the BGP routing system. The question is not whether this is feasible or desirable in the individual case, but whether the BGP routing system can scale adequately to continue to undertake this role.

A Denser Interconnectivity Mesh

The decreasing unit cost of communications bearers in many part of the Internet is creating a rapidly expanding market in exchange points and other forms of inter-provider peering. The deployment model of a single-homed network with a single upstream provider is rapidly being supplanted by a model of extensive interconnection at the edges of the Internet. The underlying deployment model assumed by CIDR assumed a different structure, more akin to a strict hierarchy of supply providers. The business imperatives driving this denser mesh of interconnection in the Internet are irresistible, and the casualty in this case is the CIDR-induced dampened growth of the BGP routing table.

Traffic Engineering via Routing

Further driving this growth in the routing table is the use of selective advertisement of smaller prefixes along different paths in an effort to undertake traffic engineering within a multihomed environment. Although considerable effort is being undertaken to develop traffic-engineering tools within a single network using *Multiprotocol Label Switching* (MPLS) as the base flow management tool, inter-provider tools to achieve similar outcomes are considerably more complex when using such switching techniques. At this stage, the only tool being used for inter-provider traffic engineering is that of the BGP routing table, further exacerbating the growth and stability pressures being placed on the BGP routing domain.

The effects of CIDR on the growth of the BGP table have been outstanding, not only because of their initial impact in turning exponential growth into a linear growth trend, but also because CIDR was effective for far longer than could have been reasonably expected in hindsight. The current growth factors at play in the BGP table are not easily susceptible to another round of CIDR deployment pressure within the operator community. It may well be time to consider how to manage a BGP routing table that has millions of small entries, rather than the expectation of tens of thousands of larger entries.

We started this journey over ten years ago when considering the scaling properties of addressing and routing. It is perhaps fitting that we tie the two concepts back together again as we consider the future of the BGP inter-provider routing space. The observation that the BGP growth pressures are largely due to an uptake in multihoming and the associated advertisement of discrete connectivity policies by increasingly smaller networks at the edge of the network has a corollary for address allocation policy. In such a ubiquitous environment of multihomed networks, we will also need to review how address blocks are allocated to network providers, because the concept of provider-based address allocation that assumes a relatively strict hierarchical supply structure is becoming less and less relevant in today's Internet.

LAN QoS

by William Stallings

A typical organization's on-premise network configuration has multiple *Local-Area Networks* (LANs) connected by bridges or Layer 2 switches. The LANs may all be of one type (for example, Ethernet) or may be of mixed types (for example Ethernet, Token Ring, wireless). In either case, the issue of *Quality of Service* (QoS) arises.

User Priority and Access Priority

The first attempt to deal with LAN QoS in a standardized fashion appears in the original version of IEEE 802.1D, which is a specification that defines the protocol architecture for bridges and Layer 2 switches, which operate at the *Media Access Control* (MAC) level. IEEE 802.1D deals with the interconnection of LANs with the same MAC protocol and with LANs with different MAC protocols. In addition to passing MAC frames from one LAN to another across the bridge, the bridge is able to pass parameters from software that controls the incoming port to the software that controls the outgoing port. Two of these parameters are *user_priority* and *access_priority*.

The *user_priority* and *access_priority* parameters relate to the problem of how to handle priorities. In the case of IEEE 802.3 (Ethernet) and 802.11 (wireless LAN), priority is not supported. Other 802 LAN types support up to eight levels of priority. The *user_priority* value provided to the MAC- layer entity at the incoming port is derived from the incoming MAC frame; in the case of an incoming frame with no priority value, a value of *unspecified* is used. The *user_priority* value issued to the MAC entity at the outgoing port is to be placed in the outbound MAC frame for LAN types that provide a priority field. The *access_priority* refers to the priority used by a bridge MAC entity to access a LAN for frame transmission. We may not want the *access_priority* to be equal to the *user_priority* for several reasons:

- A frame that must go through a bridge has already suffered more delay than a frame that does not have to go through a bridge; therefore, we may wish to give such a frame a higher access priority than the requested user priority.
- It is important that the bridge not become a bottleneck. Therefore, we may wish to give all frames being transmitted by a bridge a relatively high priority.

The rules for handling priorities can now be summarized. The *user_priority* is determined from the priority field of the incoming frame and placed in the priority field of the outbound frame. Priorities are not used to transmit 802.3 and 802.11 MAC frames, and the frames themselves have no priority field. Therefore, if the outbound frame is 802.3 or 802.11, any incoming priority field (from a frame that has such a field) is ignored. If the incoming frame is 802.3 or 802.11 and the outbound frame requires a priority field, then the priority field in the outbound frame is set to a default *user_priority* value. If both incoming and outbound frames carry a priority field, then the priority field in the outbound MAC frame is set equal to the priority field in the inbound MAC frame.

The *access_priority* is also determined from the priority field of the incoming frame. For incoming 802.3 and 802.11 frames, a *user_priority* of 0 (lowest priority) is assumed. Table 1 shows the access priorities assigned to outgoing MAC frames for each of the LAN types, as a function of incoming user priority value. For 802.3 and 802.11, there is no access priority mechanism and, therefore, a priority of 0 is used. For 802.4 and 802.6, there are eight available access priorities, so the incoming user priority is mapped to the outgoing access priority using equality. IEEE 802.12 permits only two priority levels; half of the possible user priority values are mapped into each of these levels. For the two Token Ring types (802.5 and Fiber Distributed Data Interface [FDDI]), although eight priority levels are available, the highest priority (level 7) is not used in bridge forwarding. The reason for this restriction is that the token-passing protocol reserves priority 7 for its use in transmitting frames needed to manage the token-passing process, such as recovering from a frame loss.

Table 1: Outbound Access Priorities

User Priority	Outbound Access Priority per MAC Method						
	802.3	802.4	802.5	802.6	802.11	802.12	FDDI
0	0	0	0	0	0	0	0
1	0	1	1	1	0	0	1
2	0	2	2	2	0	0	2
3	0	3	3	3	0	0	3
4	0	4	4	4	0	4	4
5	0	5	5	5	0	4	5
6	0	6	6	6	0	4	6
7	0	7	6	7	0	4	6

802.3 = CSMA/CD
802.4 = Token bus
802.5 = Token ring
802.6 = DQDB (Distributed Queue, Dual Bus) MAN
802.11 = Wireless LAN
802.12 = Demand priority (100VG-AnyLAN)
FDDI = Fiber Distributed Data Interface (token ring)

Traffic Classes

These rules, summarized in Table 1, are effective in communicating a priority requested by a user and in obtaining access to a LAN in competition with other devices also attempting to transmit on that LAN. However, the rules do not directly provide guidance concerning the relative priority with which frames are to be handled by a bridge. For example, consider a bridge connected to a Token Ring on one side and an Ethernet on the other, and suppose that the bridge receives a large volume of traffic from the Token Ring so that a number of frames are buffered waiting to be transmitted onto the Ethernet. Should the bridge transmit these frames in the order in which they were received, or should the bridge account for the user priority of all waiting frames in determining which frame to transmit next? Consideration of this issue led to the development of a new concept, *traffic class,* which is incorporated in the 1998 version of IEEE 802.1D. This new material is sometimes referred to as 802.1p in the literature. This was the designation when the traffic-class standard was in draft form. In the 802 scheme, a lowercase letter refers to a supplement to an existing standard and an uppercase letter refers to a base standard. Thus 802.1D is a base standard defining bridge operation, and 802.1p is a supplement to the earlier version of 802.1D. With the publication of the 1998 version, the traffic-class supplement was incorporated into 802.1D, and the designation 802.1p is no longer used.

The goal of the traffic-class addition to 802.1D is to enable Layer 2 switches and bridges to support time-critical traffic, such as voice and video, effectively. In the remainder of this article, we begin with an overview of the use of traffic classes in bridges. Next, we examine the mapping of user priorities into traffic classes. Finally, we look at the larger issue of QoS in an internet that includes bridges as well as routers and other Layer 3 switches.

The 1998 version of IEEE 802.1D distinguishes three concepts:

- *User priority:* The user priority is a label carried with the frame that communicates the requested priority to downstream nodes (bridges and end systems). Typically, the user priority is not modified in transit through bridges, unless a mapping is needed for the use of a different number of priority levels by different MAC types. Thus, the user priority has end-to-end significance across bridged LANs.
- *Access priority:* The access priority is used, on LANs that support priority, to compete for access to the shared LAN with frames from other devices (end systems and other bridges) attached to the same LAN. For example, the token-passing discipline in a Token Ring network enables higher-priority frames to gain access to the ring ahead of lower-priority frames when frames from multiple stations are waiting to gain access. When both the incoming and outbound LAN are of the same MAC type, the bridge assigns an access priority equal to the incoming user priority. Otherwise, the bridge must perform a mapping as defined in Table 1.

- *Traffic class:* A bridge can be configured so that multiple queues are used to hold frames waiting to be transmitted on a given outbound port, in which case the traffic class is used to determine the relative priority of the queues. All waiting frames at a higher traffic class are transmitted before any waiting frames of a lower traffic class. As with access priority, traffic class is assigned by the bridge on the basis of incoming user priority.

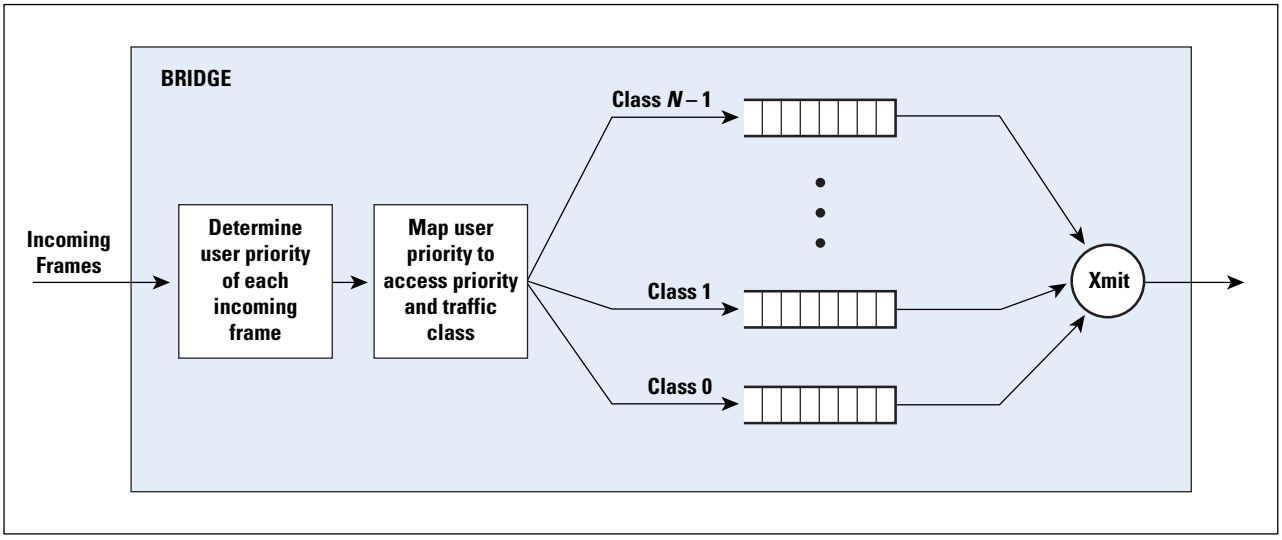
The significance of traffic classes can be seen by recognizing that a frame experiences two types of delay at a bridge:

- *Queuing delay:* The time that a frame waits until it becomes first in line for transmission on the outbound port. This delay is determined by the queuing discipline used by the bridge. The simplest scheme is first-in, first-out (FIFO). Traffic classes permit more sophisticated schemes.
- *Access delay:* The delay that a frame experiences waiting for permission to transmit on the LAN, in competition with frames from other stations attached to the same LAN. This delay is determined by the MAC protocol used (for example Token Ring, Carrier Sense Multiple Access Collision Detect [CSMA/CD]).

The total delay experienced by a frame at a bridge is the sum of its queuing delay and its access delay.

Figure 1 illustrates the mechanism used to support traffic classes at a bridge. A bridge may support up to eight different traffic classes on any outbound port by implementing up to eight distinct queues, or buffers, for that port. A traffic-class value is associated with each queue, ranging from a low of 0 to a high of $N - 1$, where N is the number of traffic classes associated with a given outbound port ($N \leq 8$).

Figure 1: IEEE 802.1 D Traffic Class Operation



On a given output port with multiple queues, the rules for transmission follow:

1. A frame may be transmitted from a queue only if all queues corresponding to numerically higher values of traffic class are empty. For example, if there is a frame in queue 0, it can be transmitted only if all the other queues at that port are currently empty.
2. Within a given queue, the order of frame transmission must satisfy the following: The order of frames received by this bridge and assigned to this outbound port shall be preserved for:
    - Unicast frames with a given combination of destination address and source address
    - Multicast frames for a given destination address

In practice, a FIFO discipline is typically used. Thus, a strict priority mechanism is used. It follows that during times of congestion, lower-priority frames may be stuck indefinitely at a bridge that devotes its resources to moving out the higher-priority frames.

Mapping of User Priority to Traffic Class

IEEE 802.1D provides guidance on the mapping of user priorities into traffic classes. Table 2 shows the recommended mapping. We can make two comments immediately:

1. The mapping is based on the user priority associated with the frame, which, as was mentioned earlier, has end-to-end significance. However, the 802.3 and 802.11 frame formats do not include a priority field, meaning that this end-to-end information could be lost. To address this issue, the bridge is able to reference the priority field contained in a tag header defined in IEEE 802.1Q, which deals with virtual LANs. The 802.1Q specification defines a tag header of 32 bits that is inserted after the source and destination address fields of the frame header. This tag header includes a 3-bit priority field. Thus, if 802.1Q is in use by Ethernet and wireless LAN sources, a user priority can be defined that stays with the frame from source to destination.
2. Outbound ports associated with MAC methods that support only a single access priority, such as 802.3 and 802.11, can support multiple traffic classes. Recall that the traffic class deals with queuing delay, while the access priority deals with access delay.

To understand the reason for the mappings recommended in Table 2, we need to consider the types of traffic that are associated with each traffic class. IEEE 802.1D provides a list of traffic types, each of which can benefit from simple segregation from the others. In descending importance, these types include:

- Network control (7): Both time critical and safety critical, consisting of traffic needed to maintain and support the network infrastructure, such as routing protocol frames.

- Voice (6): Time critical, characterized by less than 10-ms delay, such as interactive voice.
- Video (5): Time critical, characterized by less than 100-ms delay, such as interactive video.
- Controlled load (4): Non-time-critical but loss sensitive, such as streaming multimedia and business-critical traffic. A typical use is for business applications subject to some form of reservation or admission control, such as capacity reservation per flow.
- Excellent effort (3): Also non-time-critical but loss sensitive, but of lower priority than controlled load. This is a best-effort type of service that an information services organization would deliver to its most important customers.
- Best effort (2): Non-time-critical and loss insensitive. This is LAN traffic handled in the traditional fashion.
- Background (0): Non-time-critical and loss insensitive, but of lower priority than best effort. This type includes bulk transfers and other activities that are permitted on the network but that should not impact the use of the network by other users and applications.

Only seven traffic types are defined in IEEE 802.1D. The standard leaves as spare an eighth type, which could be used for traffic of more importance than background but less importance than best effort. The numbers in parentheses in the preceding list are the traffic-class values corresponding to each traffic type if there are eight queues and hence eight traffic classes available at a given output port.

Table 2: Recommended User Priority to Traffic Class Mapping

		Number of Available Traffic Classes							
		1	**2**	**3**	**4**	**5**	**6**	**7**	**8**
User Priority	0 (default)	0	0	0	1	1	1	1	2
	1	0	0	0	0	0	0	0	0
	2	0	0	0	0	0	0	0	1
	3	0	0	0	1	1	2	2	3
	4	0	1	1	2	2	3	3	4
	5	0	1	1	2	3	4	4	5
	6	0	1	2	3	4	5	5	6
	7	0	1	2	3	4	5	6	7

We can now address the issue of the mapping between user-priority and traffic-class value. If eight traffic class values are available (eight queues at this output port), the obvious mapping would be equality; that is, a user priority of K would map into traffic class K for $0 \leq K < 7$. This obvious mapping is not desirable because of the treatment of default priorities. For 802.3 and 802.11, which do not use priorities, the de-

fault user priority is 0. For other MAC types, such as 802.5, if the user does not specify a priority, the MAC level assigns a default value of 0. The 802.1D standard points out that using a different default value would result in some confusion and probably a lack of interoperability. However, the logical default traffic type is best effort. The solution proposed by 802.1D is to map a user priority of 0 to traffic-class value 2. When there are eight traffic class values available, then user-priority values 1 and 2 map to traffic-class values 0 (background) and 1 (spare value), respectively.

This solution is reflected in Table 2, which shows the mapping of user priority to traffic class when there are eight available traffic classes. The table also shows the mapping when there are fewer traffic classes. To understand the entries in this table, we need to consider the way in which 802.1D recommends grouping traffic types when fewer than eight queues are configured at a given output port. Table 3 shows this grouping. The first row in the table shows that if there is only one queue, then all traffic classes are carried on that queue. This is obvious. If there are two queues (second row), 802.1D recommends assigning network control, voice, video, and controlled load to the higher-priority queue, and excellent effort, best effort, and background to the lower-priority queue. The reasoning supplied by the standard follows: To support a variety of services in the presence of bursty best-effort traffic, it is necessary to segregate time-critical traffic from other traffic. In addition, further traffic that is to receive superior service and that is operating under admission control also needs to be separated from the uncontrolled traffic. The allocation of traffic types to queues for the remaining rows of the table can be explained similarly.

Table 3: Suggested Traffic Types

		Traffic Types							
Number of Queues	1	**BE** (EE, BK, VO, CL, VI, NC)							
	2	**BE** (EE, BK)				**VO** (CL, VI, NC)			
	3	**BE** (EE, BK)				**CL** (VI)		**VO** (NC)	
	4	**BK**		**BE** (EE)		**CL** (VI)		**VO** (NC)	
	5	**BK**		**BE** (EE)		**CL**	**VI**	**VO** (NC)	
	6	**BK**		**BE**	**EE**	**CL**	**VI**	**VO** (NC)	
	7	**BK**		**BE**	**EE**	**CL**	**VI**	**VO**	**NC**
	8	**BK**	**—**	**BE**	**EE**	**CL**	**VI**	**VO**	**NC**
		1	**2**	**0**	**3**	**4**	**5**	**6**	**7**
		User Priority							

Note: In each entry, the boldface type is the traffic type that has driven the allocation of types to classes.

BK = Background
BE = Best Effort
EE = Excellent Effort
CL = Controlled Load
VI = Video (<100 ms latency and jitter)
VO = Voice (<10 ms latency and jitter)
NC = Network Control

Internet Traffic Quality of Service

The user-priority and traffic-class concepts enable MAC-level bridges and Layer 2 switches to implement a traffic-handling policy within a bridged collection of LANs that gives preference to certain types of traffic. These concepts are needed because these bridges and switches cannot see "above" the MAC layer and hence cannot recognize or utilize QoS indications in higher layers such as IP. However, it is often the case that traffic from a bridged set of LANs must cross Wide-Area Networks (WANs) that make use of QoS functionality. An example of this is an ATM network, which provides for user-specified QoS. Another example is an IP-based internet, which can provide IP-level QoS. Some means is needed for mapping between traffic classes and QoS for such configurations. This is an evolving area of technology and standardization, but a general picture can be provided.

In the case of IP-based internets, the IP *Type-of-Service* (ToS) field provides a way to label traffic with different QoS demands. The ToS field is preserved along the entire path from source to destination through, potentially, multiple routers. Fortunately, the mapping from traffic class to ToS is straightforward. The ToS field includes a 3-bit Precedence subfield. A router connecting a LAN to an internet can be configured to read the Layer 2 Traffic-Class field and copy that into the ToS Precedence field in one direction, and copy the 3-bit Precedence field into the User Priority field in the other direction.

In the case of an ATM connection, a bridge or Layer 2 switch might be connected to a LAN on one side and an ATM network on the other, using the ATM network to link to other remote LANs. For local LAN traffic arriving at the bridge, the bridge must match the user priority level with the appropriate ATM service class and other ATM parameters. For this purpose, the bridge can consult a mapping table whose settings have been predefined through the policy controls of network management software. An appropriate virtual connection is used to carry the traffic. If the traffic exits the ATM network at another LAN, the bridge on that end can map incoming traffic from each virtual connection into the appropriate traffic class and user priority.

References

A more detailed discussion of bridges, Layer 2 switches, and IEEE 802.1D is contained in [1]. The IEEE 802.1 working group is at **`http://grouper.ieee.org/groups/802/1/index.html`**.

Book Reviews

E-mail Books

Essential Email Standards: RFCs and Protocols Made Practical by Pete Loshin, ISBN 0-471-34597-0, John Wiley & Sons, Inc., 2000. **www.wiley.com**

Internet Email Protocols: A Developer's Guide, by Kevin Johnson, ISBN 0-201-43288-9, Addison-Wesley, 1999. **www.awl.com**

Deciding when to write a book about an exciting new technology is pretty easy. At first issuance of the standards for it, or emergence of a market for it, out will come the requisite texts. In 1993, when the commercial Internet started to surface, Marshall Rose produced *The Internet Message: Closing The Book With Electronic Mail* [Prentice Hall, 1993]; it's an excellent introduction to the core e-mail services. As the market grew, Rose and David Strom issued a more operations-oriented effort, *Internet Messaging; From Desktop to the Enterprise* [Prentice Hall, 1998]. For anyone serious about e-mail technology and operations, it remains required reading.

But what about straight technology exposition when the standards that have been in use for more than 20 years keep getting modified? In the case of Internet mail, this dilemma has been exacerbated by an extended recent effort to coalesce documentation for the service, compiling and clarifying the contents of many independent *Internet Engineering Task Force* (IETF) documents into two, one for the transfer service and one for the mail object definition. The best time to publish a book on the subject would be at the issuance of the two revisions. Unfortunately, the IETF effort has taken perhaps 3 years longer than expected, and Wiley and Addison-Wesley decided the market needed these books earlier. Hence the authors were faced with a juggling act, referring to original specifications, with appropriate nods to the new—but unstable—drafts.

Comprehensive Introductions

This tactical caveat notwithstanding, Peter Loshin's *Essential Email Standards: RFC and Protocols Made Practical* and Kevin Johnson's *Internet Email Protocols: A Developer's Guide* are credible and reasonably thorough. They introduce the reader to the technical details of Internet mail. Loshin adds detail about the standards culture that produced the specification. Johnson adds a bit of programming detail. No textbook on a technology should be used as the primary reference by someone building products, of course; and these are no exception. These are comprehensive introductions.

With such books, the criteria are simple. I look for helpful overall organization, clear language, and accurate content. These two books qualify. They summarize and restate the basic descriptions of services, data formats, protocol commands, and responses associated with the various standards.

Extra points are assigned when a book comes with commentary that provides some insight into the technical philosophy or operational pragmatics of the technology. Pleasantly, both books have a bit of these extras, too. Such texts typically also have minor technical errors; and these fit that profile, too. Since the reader is not using the book as an implementation reference, the occasional, small errors cause no harm.

Loshin's effort is 330 hardbound pages. Johnson's is about a third longer, softbound. Both books cover the core services of *Submit, Simple Mail Transfer Protocol Service Extensions* (ESMTP), the *Post Office Protocol* (POP), the *Internet Mail Access Protocol* (IMAP), RFC 822, and *Multipurpose Internet Mail Extensions* (MIME), that is, posting, relaying, and accessing e-mail, as well as description of the e-mail object. Both also discuss security. Submit is a recent spinoff from SMTP, for local user-relay posting. It began as a clone of ESMTP, but on a different port, and will permit service-to-service relaying functionality to diverge from the local, first-hop posting process. The market treats POP and IMAP as essentially competitive protocols, and both books explain their details adequately. I wish they had made the very simple architectural point that POP does last-hop delivery, to the user's PC-based message store, whereas IMAP is primarily for user access to a message store on a remote system. That is, one is for simply dumping an entire message queue onto the waiting user machine, whereas the other is for ongoing and interaction with portions of message data. On the other hand, an example of Loshin's extra credit is for noting that ISPs are reticent to support IMAP—they have not yet discovered that they could make money being a small business' back-office data store—whereas corporations like IMAP because it is an open standard that permits replacing proprietary workgroup message stores.

E-mail address resolution can be a bit tricky, requiring general understanding of the Domain Name Service and specific cleverness with MX "routing" records. Johnson devotes a useful, but very terse 2+ pages to the topic. Loshin allocates a 8+ pages.

Security

As with every other aspect of Internet standards making, e-mail security is problematic because no IETF-originated security protocol has yet gained wide deployment and use. Oddly continuing the peculiarity of security as a topic, both books are a little off-beat, albeit differently. Johnson provides a relatively extensive introduction to basic security technology, including descriptions of various algorithms, as well as a listing of the types of security attacks that can occur. He also discusses enhancements to the basic e-mail protocols for invoking security mechanisms. Loshin has a more functional systems orientation concerning overall e-mail security architecture. Although Loshin does not usually spend much time on ancient history, for some reason in this chapter he discusses two IETF failures of *Privacy Enhanced Mail* (PEM) and *MIME Object Security Services* (MOSS).

Both discuss *Pretty Good Privacy* (PGP), and PGP is certainly the long-standing popular choice among the technical community. Johnson discusses it in some detail; Loshin's coverage is minimal. *Secure MIME* (S/MIME) has support from major industry software vendors. Loshin treats it equally as tersely as he treats PGP. Johnson barely mentions it.

Standards

Loshin spends the first 50 pages on the Internet standards community, process, and documents. His book also covers Internet News (NNTP) and some work involving standard data for business cards (vCard) and calendaring and scheduling (iCalendar). Besides being interesting topics, these last two were probably included because the Internet Mail Consortium acquired intellectual property rights to the precursor work and highlights the topics on its Web page. Loshin also ends with a chapter about the future, where he adds the topics of instant messaging and message tracking, based on continuing IETF standards work. An included CD-ROM contains a copy of the book, with Web links to cited documents such as RFCs.

Johnson's forays beyond the core services discuss messaging filtering and mailing-list processing, UNIX file issues, and generic, terse descriptions of some programming languages. He also discusses the *Internet Message Support Protocol* (IMSP), the *Application Configuration Access Protocol* (ACAP), and the *Lightweight Directory Access Protocol* (LDAP), protocols for accessing user configuration data. Obviously he intends that the reader take seriously the "Developer's" reference in the book title.

The Differences

Perhaps it is the programmer's orientation that caused Johnson to be so thorough with his discussions. This includes discussion of e-mail protocols that are not standards and not in use. Loshin in far more selective and reflective. And therein lies the easy distinction between the two efforts. Loshin gives an understanding of a portion of application space, providing the basic technical details tidbits of useful insight. Johnson is more mechanical and more detailed; in effect he chooses to be less selective and more detailed in what he dumps on the reader, letting the reader decide what is useful.

Wireless and Mobile Network Architectures

Wireless and Mobile Network Architectures, by Yi-Bing Lin and Imrich Chlamtac, ISBN 0-471-39492-0, John Wiley & Sons, 2001.

Paging through this book, my first impressions are that it uses very little math and that it is a comprehensive standards-based overview of practical wireless systems. The authors' multidisciplinary tack—systems, networks, and services—is evidenced by their conceptual approach to engineering design issues and their straightforward explanations of implementation issues. The primary concern of the book as a whole is: "How does it all fit together?"

Organization

The authors divide the book into five major units. The first three units covered their topics well and enhanced my understanding of wireless communications. However, the final two units fell short of my expectations. Coverage of the *Wireless Application Protocol* (WAP) and other up-and-coming issues in wireless networking was patchy and unbalanced.

The "PCS Network Management" section provides an overview of the concepts, definitions, and procedures used in current wireless network implementations. Basic roaming concepts including handoff geometry, detection, and queuing schemes are briefly discussed. An understanding of foundational engineering concepts is assumed as the authors provide detailed algorithmic descriptions of hard and soft handoff message flows.

The "IS-41 Mobile Systems" section provides an introductory overview of *Signaling System 7* (SS7) as a supporting protocol for the IS-41 mobile communications protocol. The importance of integration between these two protocols is presented in practical example format. Intersystem handoff and authentication techniques applicable to IS-41 are then discussed. Included in this section is a functional overview of network signaling for *Personal Access Communications* (PACS) networks as related to IS-41. However, a general understanding of the PACS radio system is assumed.

GSM

Global System for Mobile Communication (GSM) systems are the largest focus of this book. A full ten chapters are dedicated to the concepts and applications of this technology. The section appropriately starts with a high-level overview of the GSM system architecture and moves through mobility management and roaming. Here, the authors present several alternative roaming concepts aimed at reducing the cost of roaming service. Additionally, mobile number portability mechanisms and costs are also addressed. Likewise, significant attention is given to the technical aspects of GSM networks and their integration with data networks. Full chapters are dedicated to describing the GSM network signaling software platform (MAP), operations, administration, and management functions, Voice over IP integration, and General Packet Radio Service over GSM.

For the student, *Wireless and Mobile Network Architectures* is a capstone reference that ties together several courses worth of technical information with a practical focus toward real-world applications. For professional IT managers, engineers, and software developers, it is a practical and handy tutorial for getting up-to-speed on second-generation wireless and mobile technologies.

Questions

Each chapter ends with a set of very open-ended and thought-provoking analysis and design questions. Reading the chapter does not necessarily prepare you to do in-depth design; rather, you gain enough knowledge to sketch out a basic approach to solving the problem. It is obvious that many of the problems would require interdisciplinary collaboration to arrive at a tenable solution. Members of such a team would contribute different perspectives based on their particular area of expertise.

Worthwile Reference

This book assumes that the reader has mastered the basics in the field of mobile communications and is seeking to implement a practical design. Throughout the book are many easy-to-follow algorithmic or flow-chart explanations of various wireless communications processes. However, the information gleaned from these treatments tended to be more about functionality than design. Although a worthwhile reference, this book is by no means "all you need to design and implement a mobile services network."

—Albert C. Kinney

Would You Like to Review a Book for IPJ?

We receive numerous books on computer networking from all the major publishers. If you've got a specific book you are interested in reviewing, please contact us and we will make sure a copy is mailed to you. The book is yours to keep if you send us a review. We accept reviews of new titles, as well as some of the "networking classics." Contact us at **ipj@cisco.com** for more information.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

Fragments

ICANN Launches At-Large Membership Study

The *Internet Corporation for Assigned Names and Numbers* (ICANN) recently announced that it was commencing a comprehensive study of the structure of its At Large membership. The study will be conducted by an *At Large Membership Study Committee* that will make recommendations to ICANN's Board of Directors on how individuals can effectively participate in ICANN's policy development, deliberations and actions for technical coordination of the Internet.

Mr. Carl Bildt, the former Prime Minister of Sweden and noted United Nations envoy, will serve as Chair of the nine member Study Committee. An international statesman and information technology advisor, Bildt's current duties include Special Envoy of the Secretary General of the United Nations to the Balkans, Member of Parliament of Sweden, and Advisor and Board Member of several Internet and technology-related corporations.

"The Board's approval of the Study Committee and Carl Bildt's selection as Chair is a demonstration of ICANN's commitment to finding an effective way for the perspectives of individuals in every country to be heard and given due consideration," said Vint Cerf, Chairman of the ICANN Board of Directors. "We are extremely fortunate to have someone with Carl Bildt's international consensus building experience to lead this critical effort."

The Committee, which is chartered to seek input from all interested parties and to work toward a broad consensus on ICANN's At Large membership, will use multiple mechanisms for input, including public forums, mailing lists, and a public website. The Committee will encourage the participation of organizations and individuals worldwide, including the development of independent studies and analyses from across the global Internet's constituencies.

"ICANN's actions affect the whole world's Internet users, and I look forward to the challenging task of forging a consensus on the best method for representing this ever-growing constituency," said Bildt. "This will be an international cooperative effort, and I am counting on the participation of a diversity of Internet stakeholders that have an interest in ICANN to help us deliver a workable solution."

The Board invited Charles Costello and Pindar Wong to serve as the Committee's Vice-Chairs. Costello is director of the Carter Center's Democracy Program, and served as an outside monitor for ICANN's At Large elections held last year. Wong served as an ICANN Director and Vice Chairman of the Board during 1999–2000. He also is an active Internet policy leader in the Asia Pacific Region, and Chairman of Verifi (Hong Kong) Ltd., an Internet infrastructure consultancy. The remaining members of the committee are Pierre Dandjinou, Esther Dyson, Oliver Iteanu, Ching-Yi Lu, Thomas Niles, and Oscar Robles.

ICANN also announced the appointment of Denise Michel as the Committee's Executive Director. Ms. Michel has extensive experience in both private and public sector technology policy development, having served previously on the staff of the U.S. National Science Foundation, the American Electronics Association and the U.S. Department of Commerce. From 1993–1995, she was Sr. Technology Advisor to the Secretary of Commerce, Mr. Ronald Brown.

Following public comment, the Board also adopted a charter for the study to ensure a consistent base of expectations on the scope and details of the study committee's work. ICANN has posted the charter on its website at:
http://www.icann.org/committees/at-large-study/charter-22jan01.htm

For more information about the At Large Membership Study Committee, see: **http://www.atlargestudy.org/**

Correction

In the article "The Trouble with NAT," which appeared in our previous issue, a table of private nonroutable IP addresses taken from RFC 1918 was shown. The table contained an error, as pointed out by a couple of our readers. The correct table appears below.

Class	Private Address Range
A	10.0.0.0 … 10.255.255.255
B	172.16.0.0 … 172.31.255.255
C	192.168.0.0 … 192.168.255.255

Upcoming Events

The Internet Society (ISOC) will hold its annual conference INET in Stockholm, Sweden, June 5–8, 2001. For more information, see:
http://www.isoc.org/inet2001/

Just before INET, The Internet Corporation for Assigned Names and Numbers (ICANN) will hold its meeting in the same venue. The dates are June 1–4, 2001 and you can find more information at:
http://www.icann.org/calendar.htm

The Internet Engineering Task Force (IETF) will next meet in London, England, August 5–10. For more information, see:
http://www.ietf.org

In This Issue

From The Editor

A user of a laptop computer "on the road" typically connects to the Internet in one of two ways. The oldest, and most common method, is to dial into an ISP's network and obtain an IP address using the *Point-to-Point Protocol* (PPP). The other method involves attaching the laptop to a local network (usually via Ethernet) and obtaining an IP address through the *Dynamic Host Configuration Protocol* (DHCP). The "local network" could be anything from the high-speed connection provided in some hotels, to an enterprise network at some corporation or other institution. In all cases, the IP address is fixed for the duration of the network session, and the routing of packets from the laptop back to its "home" network remains a relatively straight-forward task (ignoring NATs, firewalls and other complexities for the moment). Suppose however, the mobile computer is using a wireless connection and traveling between several networks over a short period of time. In this scenario one would still like to maintain network connectivity in a seamless manner. The IETF has been working on Mobile IP to address this problem. Mobile IP is the subject of our first article by Bill Stallings.

The art of cryptography is certainly not new, but its use in computer-communications is a more recent phenomena. The *Data Encryption Standard* (DES) has been widely used since it was standardized in 1977. The strength of a particular encryption scheme depends on the key length and the sophistication of the mathematics involved in transforming the so-called cleartext to the encrypted form. As computers have become more powerful it is now possible to systematically "guess" the 56-bit DES keys in a matter of hours, thus a new encryption standard is needed. This new standard, known as the *Advanced Encryption Standard* (AES), is described by Edgar Danielyan.

Many aspects of computer networking can be described as "controversial," that is, there are strongly held opinions about a particular technology or its use. In this issue we begin a new series of articles labelled "Opinion," hoping to bring out some of the different views held by members of the networking community. We hope you will take issue with some of these columns and send us your own opinion piece. We begin the series with an article by Geoff Huston entitled "The Middleware Muddle." Let us know what you think by sending your comments to **ipj@cisco.com**

Mobile IP

by William Stallings

In response to the increasing popularity of palm-top and other mobile computers, Mobile IP was developed to enable computers to maintain Internet connectivity while moving from one Internet attachment point to another. Although Mobile IP can work with wired connections, in which a computer is unplugged from one physical attachment point and plugged into another, it is particularly suited to wireless connections.

The term "mobile" in this context implies that a user is connected to one or more applications across the Internet, that the user's point of attachment changes dynamically, and that all connections are automatically maintained despite the change. This scenario is in contrast to a user, such as a business traveler, with a portable computer of some sort who arrives at a destination and uses the computer notebook to dial into an *Internet Service Provider* (ISP).

In this latter case, the user's Internet connection is terminated each time the user moves, and a new connection is initiated when the user dials back in. Each time an Internet connection is established, software in the point of attachment (typically an ISP) is used to obtain a new, temporarily assigned IP address. For each application-level connection (for example, *File Transfer Protocol* [FTP], Web connection), this temporary IP address is used by the user's correspondent. A better term for this kind of use is "nomadic."

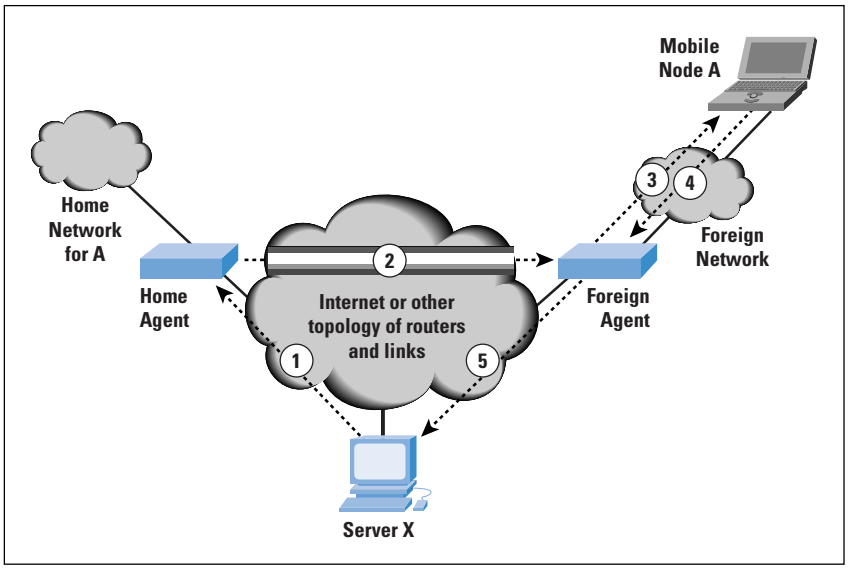
We begin with a general overview of Mobile IP and then look at some of the details.

Operation of Mobile IP

Routers make use of the IP address in an IP datagram to perform routing. In particular, the *network portion* of an IP address is used by routers to move a datagram from the source computer to the network to which the target computer is attached. Then the final router on the path, which is attached to the same network as the target computer, uses the *host portion* of the IP address to deliver the IP datagram to the destination. Further, this IP address is known to the next higher layer in the protocol architecture. In particular, most applications over the Internet are supported by *Transmission Control Protocol* (TCP) connections. When a TCP connection is set up, the TCP entity on each side of the connection knows the IP address of the correspondent host. When a TCP segment is handed down to the IP layer for delivery, TCP provides the IP address. IP creates an IP datagram with that IP address in the IP header and sends the datagram out for routing and delivery. However, with a mobile host, the IP address may change while one or more TCP connections are active.

Figure 1 shows in general terms how Mobile IP deals with the problem of dynamic IP addresses. A mobile node is assigned to a particular network, known as its *home network*. Its IP address on that network, known as its *home address,* is static. When the mobile node moves its attachment point to another network, that is considered a *foreign network* for this host. When the mobile node is reattached, it makes its presence known by registering with a network node, typically a router, on the foreign network known as a *foreign agent*. The mobile node then communicates with a similar agent on the user's home network, known as a *home agent,* giving the home agent the *care-of address* of the mobile node; the care-of address identifies the foreign agent's location. Typically, one or more routers on a network will implement the roles of both home and foreign agents.

Figure 1: Mobile IP Scenario



When IP datagrams are exchanged over a connection between the mobile node (A) and another host (server X in Figure 1), the following operations occur:

1. Server X transmits an IP datagram destined for mobile node A, with A's home address in the IP header. The IP datagram is routed to A's home network.
2. At the home network, the incoming IP datagram is intercepted by the home agent. The home agent encapsulates the entire datagram inside a new IP datagram, which has the A's care-of address in the header, and retransmits the datagram. The use of an outer IP datagram with a different destination IP address is known as *tunneling*.
3. The foreign agent strips off the outer IP header, encapsulates the original IP datagram in a network-level *Protocol Data Unit* (PDU) (for example, a LAN *Logical Link Control* [LLC] frame), and delivers the original datagram to A across the foreign network.

4. When A sends IP traffic to X, it uses X's IP address. In our example, this is a fixed address; that is, X is not a mobile node. Each IP datagram is sent by A to a router on the foreign network for routing to X. Typically, this router is also the foreign agent.
5. The IP datagram from A to X travels directly across the Internet to X, using X's IP address.

To support the operations illustrated in Figure 1, Mobile IP includes three basic capabilities:

- *Discovery:* A mobile node uses a discovery procedure to identify prospective home agents and foreign agents.
- *Registration:* A mobile node uses an authenticated registration procedure to inform its home agent of its care-of address.
- *Tunneling:* Tunneling is used to forward IP datagrams from a home address to a care-of address.

Figure 2 indicates the underlying protocol support for the Mobile IP capability. The registration protocol communicates between an application on the mobile node and an application in the home agent, and hence uses a transport-level protocol. Because registration is a simple request/response transaction, the overhead of the connection-oriented TCP is not required, and, therefore, the *User Datagram Protocol* (UDP) is used as the transport protocol. Discovery makes use of the existing *Internet Control Message Protocol* (ICMP) by adding the appropriate extensions to the ICMP header. ICMP is a connectionless protocol well suited for the discovery operation. Finally, tunneling is performed at the IP level.

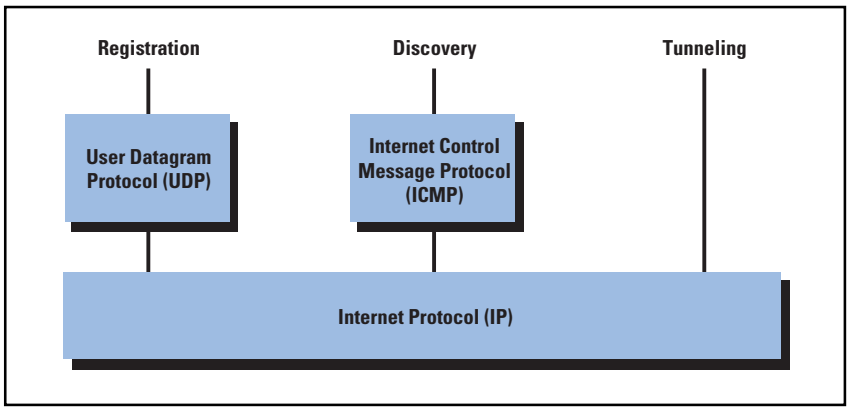


Figure 2: Protocol Support for Mobile IP

Discovery

The discovery process in Mobile IP is very similar to the router advertisement process defined in ICMP. Accordingly, agent discovery makes use of ICMP router advertisement messages, with one or more extensions specific to Mobile IP.

The mobile node is responsible for an ongoing discovery process. It must determine if it is attached to its home network, in which case IP datagrams may be received without forwarding, or if it is attached to a foreign network.

Because handoff from one network to another occurs at the physical layer, a transition from the home network to a foreign network can occur at any time without notification to the network layer (that is, the IP layer). Thus, discovery for a mobile node is a continuous process.

For the purpose of discovery, a router or other network node that can act as an agent periodically issues a router advertisement ICMP message with an advertisement extension. The router advertisement portion of the message includes the IP address of the router. The advertisement extension includes additional information about the role of the router as an agent, as discussed subsequently. A mobile node listens for these *agent advertisement messages*. Because a foreign agent could be on the home network of the mobile node (set up to serve visiting mobile nodes), the arrival of an agent advertisement does not necessarily tell the mobile node that it is on a foreign network. The mobile node must compare the network portion of the router IP address with the network portion of its own home address. If these network portions do not match, then the mobile node is on a foreign network.

The *agent advertisement extension* follows the ICMP router advertisement fields and consists of the following fields:

- *Type:* 16, indicates that this is an agent advertisement.
- *Length:* (6 + 4*N*), where *N* is the number of care-of addresses advertised.
- *Sequence number:* The count of agent advertisement messages sent since the agent was initialized.
- *Lifetime:* The longest lifetime, in seconds, that this agent is willing to accept a registration request from a mobile node.
- *R:* Registration with this foreign agent is required (or another foreign agent on this network). Even those mobile nodes that have already acquired a care-of address from this foreign agent must reregister.
- *B:* Busy. The foreign agent will not accept registrations from additional mobile nodes.
- *H:* This agent offers services as a home agent on this network.
- *F:* This agent offers services as a foreign agent on this network.
- *M:* This agent can receive tunneled IP datagrams that use minimal encapsulation, explained subsequently.
- *G:* This agent can receive tunneled IP datagrams that use *Generic Routing Encapsulation* (GRE), explained subsequently.
- *Y:* This agent supports the use of Van Jacobson header compression, an algorithm defined in RFC 1144 for compressing fields in the TCP and IP headers.
- *Care-of address:* The care-of address or addresses supported by this agent on this network. There must be at least one such address if the F bit is set. There may be multiple addresses.

There may also be an optional *prefix-length extension* following the advertisement extension. This extension indicates the number of bits in the router address that define the network number. The mobile node uses this information to compare the network portion of its own IP address with the network portion of the router. The fields include the following:

- *Type:* 19, indicates that this is a prefix-length advertisement.
- *Length: N,* where *N* is the value of the Num Addrs field in the ICMP router advertisement portion of this ICMP message. In other words, this is the number of router addresses listed in this ICMP message.
- *Prefix length:* The number of leading bits that define the network number of the corresponding router address listed in the ICMP router advertisement portion of this message. The number of prefix length fields matches the number of router address fields (*N*).

Foreign agents are expected to periodically issue agent advertisement messages. If a mobile node needs agent information immediately, it can issue an ICMP router solicitation message. Any agent receiving this message will then issue an agent advertisement.

As was mentioned, a mobile node may move from one network to another because of some handoff mechanism, without the IP level being aware of it. The agent discovery process is intended to enable the agent to detect such a move. The agent may use one of two algorithms for this purpose:

- *Use of Lifetime field:* When a mobile node receives an agent advertisement from a foreign agent that it is currently using or that it is now going to register with, it records the Lifetime field as a timer. If the timer expires before the agent receives another agent advertisement from the agent, then the node assumes that it has lost contact with that agent. If, in the meantime, the mobile node has received an agent advertisement from another agent and that advertisement has not yet expired, the mobile node can register with this new agent. Otherwise, the mobile node should use agent solicitation to find an agent.
- *Use of network prefix:* The mobile node checks whether any newly received agent advertisement is on the same network as the current care-of address of the node. If it is not, the mobile node assumes that it has moved and may register with the agent whose advertisement the mobile node has just received.

The discussion so far has involved the use of a care-of address associated with a foreign agent; that is, the care-of address is an IP address for the foreign agent. This foreign agent will receive datagrams at this care-of address, intended for the mobile node, and then forward them across the foreign network to the mobile node. However, in some cases a mobile node may move to a network that has no foreign agents or on which all foreign agents are busy.

As an alternative, the mobile node may act as its own foreign agent by using a *colocated care-of address*. A colocated care-of address is an IP address obtained by the mobile node that is associated with the current interface to a network of that mobile node.

The means by which a mobile node acquires a colocated address is beyond the scope of Mobile IP. One means is to dynamically acquire a temporary IP address through an Internet service such as *Dynamic Host Configuration Protocol* (DHCP). Another alternative is that the colocated address may be owned by the mobile node as a long-term address for use only while visiting a given foreign network.

Registration

When a mobile node recognizes that it is on a foreign network and has acquired a care-of address, it needs to alert a home agent on its home network and request that the home agent forward its IP traffic. The registration process involves four steps:

1. The mobile node requests the forwarding service by sending a registration request to the foreign agent that the mobile node wants to use.
2. The foreign agent relays this request to the home agent of that mobile node.
3. The home agent either accepts or denies the request and sends a registration reply to the foreign agent.
4. The foreign agent relays this reply to the mobile node.

If the mobile node is using a colocated care-of address, then it registers directly with its home agent, rather than going through a foreign agent.

The registration operation uses two types of messages, carried in UDP segments. The *registration request message* consists of the following fields:

- *Type:* 1, indicates that this is a registration request.
- *S:* Simultaneous bindings. The mobile node is requesting that the home agent retain its prior mobility bindings. When simultaneous bindings are in effect, the home agent will forward multiple copies of the IP datagram, one to each care-of address currently registered for this mobile node. Multiple simultaneous bindings can be useful in wireless handoff situations to improve reliability.
- *B:* Broadcast datagrams. Indicates that the mobile node would like to receive copies of broadcast datagrams that it would have received if it were attached to its home network.
- *D:* Decapsulation by mobile node. The mobile node is using a colocated care-of address and will decapsulate its own tunneled IP datagrams.
- *M:* Indicates that the home agent should use minimal encapsulation, explained subsequently.

- *V:* Indicates that the home agent should use Van Jacobson header compression, an algorithm defined in RFC 1144 for compressing fields in the TCP and IP headers.
- *G:* Indicates that the home agent should use GRE encapsulation, explained subsequently.
- *Lifetime:* The number of seconds before the registration is considered expired. A value of zero is a request for deregistration.
- *Home address:* The home IP address of the mobile node. The home agent can expect to receive IP datagrams with this as a destination address, and must forward those to the care-of address.
- *Home agent:* The IP address of the mobile node home agent. This informs the foreign agent of the address to which this request should be relayed.
- *Care-of address:* The IP address at this end of the tunnel. The home agent should forward IP datagrams that it receives with the mobile node home address to this destination address.
- *Identification:* A 64-bit number generated by the mobile node, used for matching registration requests to registration replies and for security purposes, as explained subsequently.
- *Extensions:* The only extension so far defined is the authentication extension, explained subsequently.

The *registration reply message* consists of the following fields:

- *Type:* 3, indicates that this is a registration reply.
- *Code:* Indicates result of the registration request.
- *Lifetime:* If the code field indicates that the registration was accepted, the number of seconds before the registration is considered expired. A value of zero indicates that the mobile node has been deregistered.
- *Home address:* The home IP address of the mobile node.
- *Home agent:* The IP address of the mobile node home agent.
- *Identification:* A 64-bit number used for matching registration requests to registration replies.

The only extension so far defined is the authentication extension, explained subsequently.

A key concern with the registration procedure is security. Mobile IP is designed to resist two types of attacks:

1. A node may pretend to be a foreign agent and send a registration request to a home agent so as to divert traffic intended for a mobile node to itself.
2. A malicious agent may replay old registration messages, effectively cutting the mobile node from the network.

The technique that is used to protect against such attacks involves the use of message authentication and the proper use of the identification field of the registration request and reply messages.

For purposes of message authentication, each registration request and reply contains an *authentication extension* with the following fields:

- *Type:* Used to designate the type of this authentication extension.
- *Length:* 4 plus the number of bytes in the authenticator.
- *Security parameter index (SPI):* An index that identifies a security context between a pair of nodes. This security context is configured so that the two nodes share a secret key and parameters relevant to this association (for example, authentication algorithm).
- *Authenticator:* A code used to authenticate the message. The sender inserts this code into the message using a shared secret key. The receiver uses the code to ensure that the message has not been altered or delayed. The authenticator protects the entire registration request or reply message, any extensions prior to this extension, and the type and length fields of this extension.

The default authentication algorithm uses keyed MD5 to produce a 128-bit message digest. For Mobile IP, a "prefix+suffix" mode of operation is used. The MD5 digest is computed over the shared secret key, followed by the protected fields from the registration message, followed by the shared secret key again. Three types of authentication extensions are defined:

- *Mobile-home:* This extension must be present and provides for authentication of the registration messages between the mobile node and the home agent.
- *Mobile-foreign:* The extension may be present when a security association exists between the mobile node and the foreign agent. The agent will strip this extension off before relaying a request message to the home agent and add this extension to a reply message coming from a home agent.
- *Foreign-home:* The extension may be present when a security association exists between the foreign agent and the home agent.

Note that the authenticator protects the identification field in the request and reply messages. As a result, the identification value can be used to thwart replay types of attacks. As was mentioned, the identification value enables the mobile node to match a reply to a request. Further, if the mobile node and the home agent maintain synchronization so that the home agent can distinguish a reasonable identification value from a suspicious one, then the home agent can reject suspicious messages. One way to do this is to use a timestamp value. As long as the mobile node and home agent have reasonably synchronized values of time, the timestamp will serve the purpose. Alternatively, the mobile node could generate values using a pseudorandom number generator. If the home agent knows the algorithm, then it knows what identification value to expect next.

Tunneling

When a mobile node is registered with a home agent, the home agent must be able to intercept IP datagrams sent to the mobile node home address so that these datagrams can be forwarded via tunneling. The standard does not mandate a specific technique for this purpose but references *Address Resolution Protocol* (ARP) as a possible mechanism. The home agent needs to inform other nodes on the same network (the home network) that IP datagrams with a destination address of the mobile node in question should be delivered (at the link level) to this agent. In effect, the home agent steals the identity of the mobile node in order to capture packets destined for that node that are transmitted across the home network.

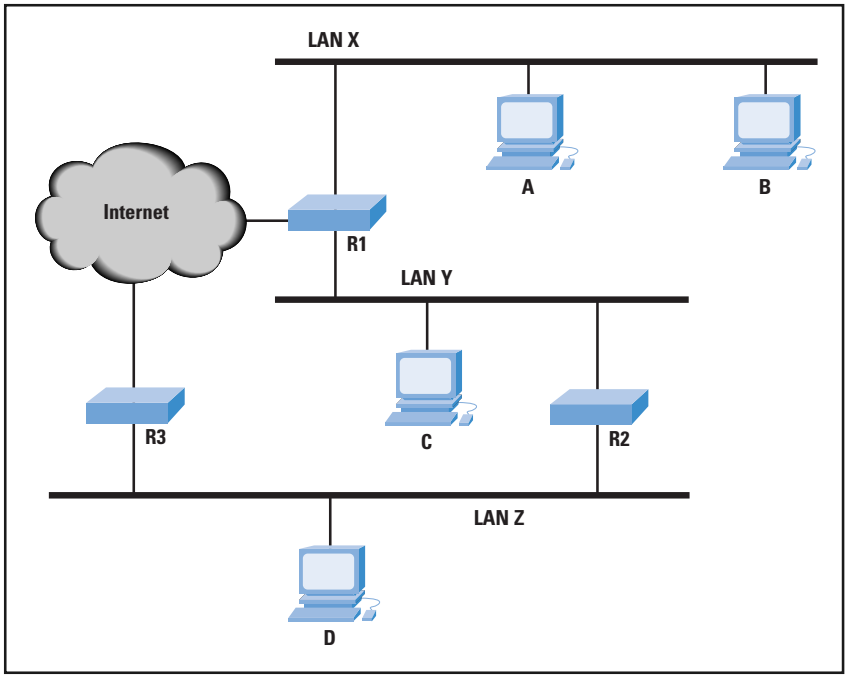

Figure 3: A Simple Internetworking Example

For example, suppose that R3 in Figure 3 is acting as the home agent for a mobile node that is attached to a foreign network elsewhere on the Internet. That is, there is a host H whose home network is LAN Z that is now attached to some foreign network. If host D has traffic for H, it will generate an IP datagram with H's home address in the IP destination address field. The IP module in D recognizes that this destination address is on LAN Z and so passes the datagram down to the link layer with instructions to deliver it to a particular *Media Access Control* (MAC)-level address on Z. Prior to this time, R3 has informed the IP layer at D that datagrams destined for that particular address should be sent to R3. Thus, the MAC address of R3 is inserted by D in the destination MAC address field of the outgoing MAC frame. Similarly, if an IP datagram with the mobile node home address arrives at router R2, it recognizes that the destination address is on LAN Z and will attempt to deliver the datagram to a MAC-level address on Z. Again, R2 has previously been informed that the MAC-level address it needs corresponds to R3.

For traffic that is routed across the Internet and arrives at R3 from the Internet, R3 must simply recognize that for this destination address, the datagram is to be captured and forwarded.

To forward an IP datagram to a care-of address, the home agent puts the entire IP datagram into an outer IP datagram. This is a form of encapsulation, just as placing an IP header in front of a TCP segment encapsulates the TCP segment in an IP datagram. Three options for encapsulation are allowed for Mobile IP and we will review the first two of the following options:

- *IP-within-IP encapsulation:* This is the simplest approach, defined in RFC 2003.
- *Minimal encapsulation:* This approach involves fewer fields, defined in RFC 2004.
- *Generic routing encapsulation (GRE):* This is a generic encapsulation procedure, defined in RFC 1701, that was developed prior to the development of Mobile IP.

In the IP-within-IP encapsulation approach, the entire IP datagram becomes the payload in a new IP datagram (Figure 4a). The inner, original IP header is unchanged except to decrement *Time To Live* (TTL) by 1. The outer header is a full IP header. Two fields (indicated as unshaded in the figure) are copied from the inner header. The version number is 4, the protocol identifier for IPv4, and the type of service requested for the outer IP datagram is the same as that requested for the inner IP datagram.

Figure 4a: Mobile IP Encapsulation

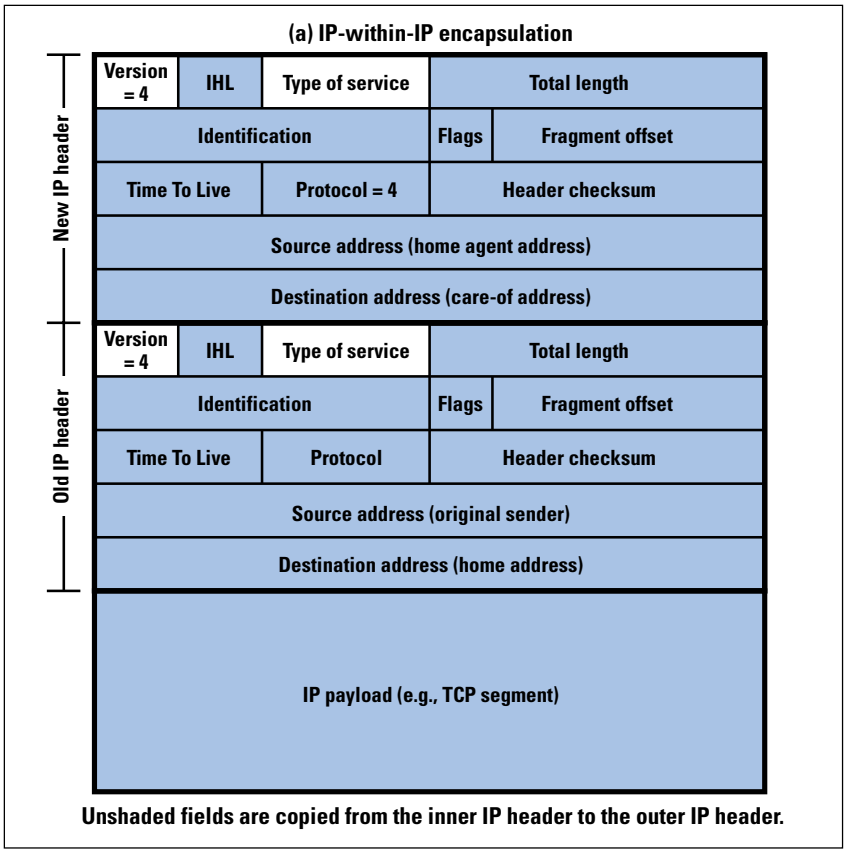

Figure 4b: Mobile IP Encapsulation

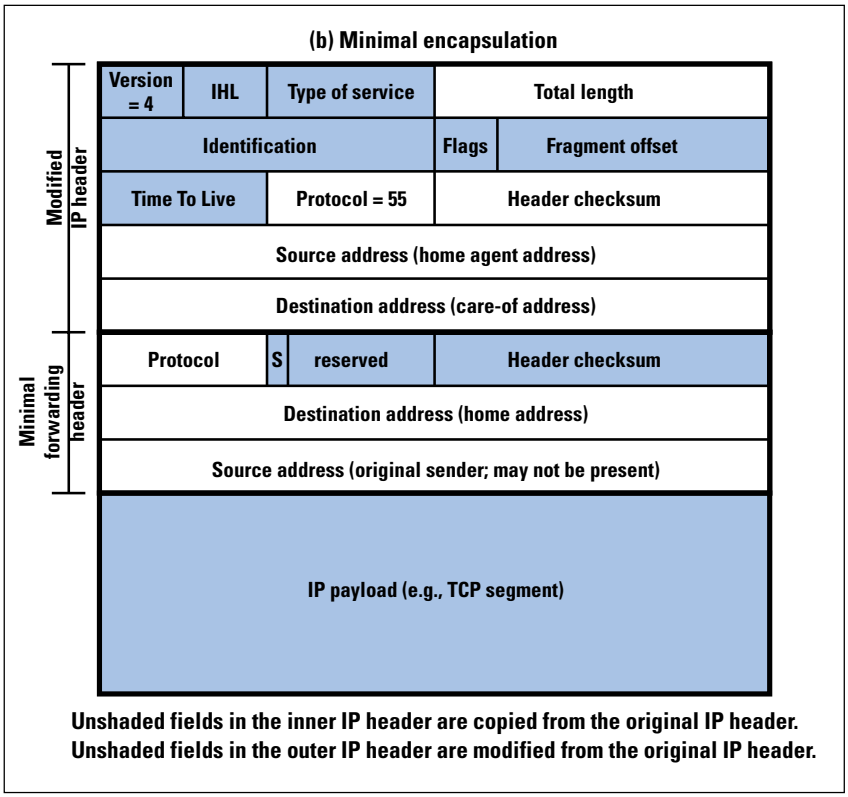

In the inner IP header, the source address refers to the host that is sending the original datagram, and the destination address is the home address of the intended recipient. In the outer IP header, the source and destination addresses refer to the entry and exit points of the tunnel. Thus, the source address typically is the IP address of the home agent, and the destination address is the care-of address for the intended destination.

Example: Consider an IP datagram that originates at server X in Figure 1 and that is intended for mobile node A. The original IP datagram has a source address equal to the IP address of X and a destination address equal to the IP home address of A. The network portion of A's home address refers to A's home network, so the datagram is routed through the Internet to A's home network, where it is intercepted by the home agent. The home agent encapsulates the incoming datagram with an outer IP header, which includes a source address equal to the IP address of the home agent and a destination address equal to the IP address of the foreign agent on the foreign network to which A is currently attached. When this new datagram reaches the foreign agent, it strips off the outer IP header and delivers the original datagram to A.

Minimal encapsulation results in less overhead and can be used if the mobile node, home agent, and foreign agent all agree to do so. With minimal encapsulation, the new header is inserted between the original IP header and the original IP payload (Figure 4b). It includes the following fields:

- *Protocol:* Copied from the Destination Address field in the original IP header. This field identifies the protocol type of the original IP payload and thus identifies the type of header that begins the original IP payload.
- *S:* If 0, the original source address is not present, and the length of this header is 8 octets. If 1, the original source address is present, and the length of this header is 12 octets.
- *Header checksum:* Computed over all the fields of this header.
- *Original destination address:* Copied from the Destination Address field in the original IP header.
- *Original source address:* Copied from the Source Address field in the original IP header. This field is present only if the S bit is 1. The field is not present if the encapsulator is the source of the datagram (that is, the datagram originates at the home agent).

The following fields in the original IP header are modified to form the new outer IP header:

- *Total length:* Incremented by the size of the minimal forwarding header (8 or 12).
- *Protocol:* 55; this is the protocol number assigned to minimal IP encapsulation.
- *Header checksum:* Computed over all the fields of this header; because some of the fields have been modified, this value must be recomputed.
- *Source address:* The IP address of the encapsulator, typically the home agent.
- *Destination address:* The IP address of the exit point of the tunnel. This is the care-of address and may be either the IP address of the foreign agent or the IP address of the mobile node (in the case of a colocated care-of address).

The processing for minimal encapsulation is as follows. The encapsulator (home agent) prepares the encapsulated datagram with the format of Figure 4b. This datagram is now suitable for tunneling and is delivered across the Internet to the care-of address. At the care-of address, the fields in the minimal forwarding header are restored to the original IP header and the forwarding header is removed from the datagram. The total length field in the IP header is decremented by the size of the minimal forwarding header (8 or 12) and the header checksum field is recomputed.

Goodbye DES, Welcome AES

by Edgar Danielyan

Much has changed since introduction of the *Data Encryption Standard* (DES)[2] in 1977. Our hardware is faster, we have more memory, and the use of computer networks in all areas of human activity is increasing. The widely used DES has, on several occasions, been proven to be inadequate for many applications—especially those involving the transmission of sensitive information over public networks such as the Internet, where the entire transmission may be intercepted and cryptanalyzed. Specialized hardware has been built that can determine the 56-bit DES key in a few hours. These considerations, and others, have signaled that a new standard algorithm and longer keys are necessary.

Fortunately, in January 1997, the U.S. *National Institute of Standards and Technology* (NIST) announced that it's time for a new encryption standard: the *Advanced Encryption Standard* (AES). They formalized their requirements and issued a call for candidate algorithm nominations in September 1997. The deadline for submissions was June 1998, when a total of 15 algorithms were submitted for consideration. This article shows why DES is outdated and should not be used for any purposes that require serious encryption. It also provides a brief description of the soon-to-come replacement of DES, the Advanced Encryption Standard.

Data Encryption Standard

Published as the U.S. Federal Information Processing Standard 46 in 1977, DES is still widely used, despite being proven inadequate for use in many applications. It is a symmetric block cipher (shared secret key), with its block size fixed at 64 bits. There are four defined modes of operation, with the *Electronic Code Book* (ECB) mode being the most widely used[1]. Additionally, DES has been incorporated into numerous other standards, such as American Bankers Association's *Protection of Personal Identification Numbers in Interchange Standard, Management and Use of Personal Identification Numbers Standard, Key Management Standard,* and three ANSI standards, *Data Encryption Algorithm* (DEA), *Standard for Personal Identification Number (PIN) Management and Security,* and *Standard for Financial Institution Message Authentication*[3]. In particular, DES is also specified as an approved algorithm in the *IP Security Architecture* (IPSec) standard[9], which is used in the equipment from many different suppliers.

Key Length

Key length is one of the two most important security factors of any encryption algorithm—the other one being the design of the algorithm itself. DES uses a 64-bit block for the key; however, 8 of these bits are used for odd parity and are, therefore, not counted in the key length. The effective key length is then calculated as 56 bits, giving 2^{56} possible keys. A true 64-bit key has 256 times as many keys, whereas a 128-bit key is 2^{72} times "better" than a 56-bit key. As if this was not enough, DES also has so-called *weak* and semi-*weak* keys. During the encryption process, the key is used to generate two values that are used for separate purposes during the process. These 16 weak and semi-weak keys will produce values that don't appear to be random. They will give outputs of all-ones, all-zeros, or distinguishable patterns of ones and zeros. It is generally recognized that these 16 key values should not be used. The key length was known to be a factor in trusting DES soon after DES was published. For this reason, people started exploring the use of multiple encryption passes and multiple keys. *Triple DES* (3DES) is a way of using DES encryption three times.

The most common method is to first encrypt the data block with one key. The output of this operation is run through the decryption process with a second key, and the output of that operation is run through the encryption process again with the first key. This process makes the effective key length 112 bits long. Again, the problem with weak and semi-weak keys remains. The disadvantage of Triple DES is that it is about one-third as fast as DES when processing data. This effort just slightly extended the life of DES while a suitable alternative could be found.

Breaking the DES

In addition to the brute-force key search (for example, trying every possible key in order to recover the plaintext—for DES that would be 2^{56} keys), there is also a technique known as *cryptanalysis*, which may be used to find the key or the plaintext. Essentially, there are two publicized ways to cryptanalyze DES: *differential* and *linear*. Discovered by Biham and Shamir in 1990, differential cryptanalysis was previously unknown to the public. In short, differential cryptanalysis looks at the difference between pairs of ciphertext and uses the information about these differences to find the key. Linear cryptanalysis, discovered by M. Matsui, on the other hand, uses a method called *linear approximations* to analyze block ciphers (not only DES). Because some internal structures used in DES are not designed to be strong against linear cryptanalysis, it is quite effective when used against DES. To show that the DES is inadequate and should not be used in important systems anymore, RSA Data Security[7] sponsored a challenge to see how long it would take to decrypt successively more difficult algorithms (see **`http://www.rsasecurity.com/rsalabs/challenges`** for more information). Two organizations played key roles in breaking the DES: the distributed.net and the *Electronic Frontier Foundation* (EFF).

distributed.net

distributed.net[6] is a worldwide distributed computing network. Started in 1997, the company now has thousands of participants who are contributing their idle computing power to provide an equivalent of about 160,000 Pentium II computers working in parallel. The company's mission statement says, in particular:

"We will deploy our software to form an immense, globally distributed computer that solves large-scale problems and provides an accessible pool of computational power to projects that need it. This deployment will also demonstrate the real-world utility of both distributed computing in general and our software in particular."

It may be said that they are doing well: projects undertaken and successfully completed by distributed.net include the CS Cipher, DES III, DES II 2, and RC5-56 challenges. At the time of writing, distributed.net is working on two projects: breaking RC5 with a 64-bit key and finding *Optimal Golomb Rulers* (OGRs). The idea behind distributed.net is that it is possible to distribute chunks of data over the Internet to be processed in parallel by participating computers during their idle time. The results of these calculations are then sent to a central computer that coordinates the distributed computation. The same principle is used by the SETI (Search for Extraterrestrial Intelligence) @ Home project.

Electronic Frontier Foundation

The EFF's DES cracking computer was designed by Cryptography Research, Advanced Wireless Technologies, and the EFF[5]. The design was based upon theoretical work by Michael Wiener[10]. It checked 90 billion keys per second, was assembled in six Sun 2 cabinets, and had 27 boards and 1800 custom chips. Built for less than $250,000, it found the key in approximately 56 hours of brute-force search.

DES I

The DES I contest was the first attempt to prove that DES is no longer fit for any serious use. It was completed on June 17, 1997, by R. Verser in a collaborative effort, after checking about 14 percent (10,178,478,175,420,416 keys) of the key space. It took 84 days.

DES II

There were, in fact, two DES II challenges. distributed.net participated in the first one, which began on January 13, 1998, and completed it on February 23, 1998. About 63 quadrillion keys were checked. At the end, the participants of distributed.net were checking 28 gigakeys per second. The decrypted text was "The unknown message is: Many hands make light work." The EFF won the second challenge on July 15, 1998, in less than three days, with distributed.net coming in second. This time the plaintext read "It's time for those 128-, 192-, and 256-bit keys."

DES III

The DES III contest, announced by RSA Data Security on December 12, 1998, to start on January 18, 1999, was also a success. In an official press release, RSA said:

> "First adopted by the federal government in 1977, the 56-bit DES algorithm is still widely used by financial services and other industries to protect sensitive on-line applications, despite growing doubts about its vulnerability to hackers. It has been widely known that 56-bit keys, such as those offered by the government's DES standard, offer marginal protection against a committed adversary."

It took 22 hours and 15 minutes for Electronic Frontier Foundation's Deep Crack computer and distributed.net's worldwide distributed computing network to find out the 56-bit DES key, decipher the message, and win the $10,000 contest. The decrypted message read "See you in Rome (Second AES Conference, March 22–23, 1999)" and was found after checking about 30 percent of the key space. This latest exercise finally proved that DES belongs to the past.

AES Timeline

In April 1997, NIST organized a workshop to consider criteria and submission guidelines of candidate algorithms; later in September, an official call for nominations was published in the U.S. Federal Register. By June 1998, 15 algorithms were submitted to the NIST for consideration:

- CAST-256 (Entrust Technologies)
- CRYPTON (Future Systems)
- DEAL (Richard Outerbridge, Lars Knudsen)
- DFC (National Centre for Scientific Research, France)
- E2 (NTT)
- FROG (TecApro Internacional)
- HPC (Rich Schroeppel)
- LOKI97 (Lawrie Brown, Josef Pieprzyk, Jennifer Seberry)
- MAGENTA (Deutsche Telekom)
- Mars (IBM)
- RC6 (RSA)
- Rijndael (Joan Daemen, Vincent Rijmen)
- Safer+ (Cylink)
- Serpent (Ross Anderson, Eli Biham, Lars Knudsen)
- Twofish (Bruce Schneier, John Kelsey, Doug Whiting, David Wagner, Chris Hall, Niels Ferguson)

NIST asked for public comments on these 15 algorithms and set the date for the second AES candidate conference to March 1999, to be held in Rome, Italy. The candidate algorithms were tested from both cryptological and performance viewpoints. One of the original NIST requirements for the algorithm was that it had to be efficient both in software and hardware implementations. (DES was originally practical only in hardware implementations.) Java and C reference implementations were used to do performance analysis of the algorithms. A few months later, a NIST press release announced the selection of 5 out of 15 algorithms that survived rigorous testing and cryptanalysis. This fact is not to say that the algorithms that were not selected were broken or were without merit. Those algorithms either were not as efficient, or were not as practical to implement.

The selected algorithms were Mars, RC6, Rijndael, Serpent, and Twofish. These algorithms were accepted as cryptologically strong and flexible, as well as able to be efficiently implemented in software and hardware. In August 2000, the National Security Agency published the VHDL model for performance testing of algorithms when implemented in hardware. Finally, in October 2000, a NIST press release announced the selection of Rijndael as the proposed Advanced Encryption Standard.

Rijndael

Rijndael[4] (pronounced "Reign Dahl," "Rain Doll," or "Rhine Dahl") was designed by Joan Daemen, PhD (Proton World International, Belgium) and Vincent Rijmen (Catholic University of Leuven, Belgium). Both authors are internationally known cryptographers. Rijndael is an efficient, symmetric block cipher. It supports key and block sizes of 128, 192, and 256 bits. The main design goals for the algorithm were simplicity, performance, and strength (that is, resistance against cryptanalysis). When used in *Cipher Block Chaining Message Authentication Code* (CBC MAC) mode, Rijndael can be used as a MAC algorithm; it also may be used as a hash function and as a pseudo random number generator (both are special mathematical functions widely used in cryptography; an example of a hash function is *Message Digest 5* (MD5)—a popular message digest algorithm by Ron Rivest). In their specification of the algorithm, the authors specifically state the strength of Rijndael against differential, truncated differential, linear, interpolation, and Square attacks. Although Rijndael is not based on Square[8], some ideas from the Square algorithm design are used in Rijndael.

Square is a 128-bit symmetric iterated block cipher designed by Daemen, Rijnmen, and Knudsen. Its primary design goal was strength against both linear and differential cryptanalyses; the high degree of parallelism of the Square algorithm allows efficient implementation on parallel computers.

Of course, the length of the key is also very important, especially because the most efficient known attack against Rijndael is an exhaustive key search. It would take 2^{255} runs of Rijndael to find a key 256 bits long. To the credit of the authors, Rijndael does not use "parts" or tables from other algorithms, making it easy to implement alone.

Table 1: Comparing DES and AES

	DES	AES
Key Length	56 bits	128, 192, or 256 bits
Cipher Type	Symmetric block cipher	Symmetric block cipher
Block Size	64 bits	128, 192, or 256 bits
Developed	1977	2000
Cryptanalysis resistance	Vulnerable to differential and linear cryptanalysis; weak substitution tables	Strong against differential, truncated differential, linear, interpolation and Square attacks
Security	Proven inadequate	Considered secure
Possible Keys	2^{56}	2^{128}, 2^{192}, or 2^{256}
Possible ASCII printable character keys*	95^{7}	95^{16}, 95^{24}, or 95^{32}
Time required to check all possible keys at 50 billion keys per second**	For a 56-bit key: 400 days	For a 128-bit key: 5 x 10^{21} years

* When a text password input by a user is used for encryption (there are 95 printable characters in ASCII).

** In theory, the key may be found after checking 1/2 of the key space. The time shown is 100% of the key space.

Summary

It is expected that AES will be officially published as a *Federal Information Processing Standard* (FIPS) in April–June 2001, and implementations of AES in various security systems probably will surface shortly thereafter. In the meantime, authoritative information on AES developments may be found on NIST's Web site at **`http://csrc.nist.gov/encryption/aes/`**. The full mathematical specification of the algorithm and reference implementations in C and Java are also available from the same Web site.

Opinion: The Middleware Muddle

by Geoff Huston

[This occasional column is an individual soapbox on views of various aspects of the Internet. The views stated here are intended to be mildly provocative, and, if backed to the wall, the author will rapidly disclaim any responsibility for them whatsoever!]

It is not often that an entire class of technology can generate an emotive response. But, somehow, middleware has managed to excite many strong reactions. For some *Internet Service Providers* (ISPs), middleware—in the form of *Web caches*—is not only useful, it's critical to the success of their enterprise. For many corporate networks, middleware—in the form of *firewalls*—is the critical component of their network security measures. For such networks, middleware is an integral part of the network. Other networks use middleware, in the form of *Network Address Translators* (NATs), as a means of stretching a limited number of Internet public addresses to provide connectivity services to a much larger local network. For others, middleware is seen as something akin to network heresy. For them, not only does middleware often break the basic semantics of the Internet Protocol, it is also in direct contravention to the end-to-end architecture of the Internet. Middleware, they claim, breaks the operation of entire classes of useful applications, and this makes the Internet a poorer network as a result.

Emotions have run high in the middleware debate, and middleware has been portrayed as being everything from absolutely essential to the operation of the Internet as we know it, to being immoral and deceptive. Strong stuff indeed from an engineering community, even one as traditionally opinionated as Internet engineers.

So what is middleware all about and why the fuss?

It may be helpful to start with a definition of middleware. One definition of middleware is that of anything in the network that functions at a level in a network reference model above that of end-to-end transport (TCP/IP), and below that of the application environment (the *Application Programming Interface* [API])[1]. Of course, this definition encompasses a very broad class of services that covers everything from *Authentication, Authorization, and Accounting* (AAA) servers and *Domain Name System* (DNS) servers through to various forms of information discovery services and resource management.

Another possible definition of middleware adopts the perspective of the integrity of the end-to-end model of Internet architecture[2]. From this perspective, middleware is a class of network devices that do something other than forward or discard an IP packet onward along the next hop to the destination address of the packet—in other words, anything other than a packet-switching element that sits in the transmission path of the packet.

With such an end-to-end definition of middleware, these middleware units may intercept the packet and alter the header or payload of the packet, redirect the packet to be delivered to somewhere other than its intended destination, or process the packet as if it were addressed to the middleware device itself. From this perspective, AAA, the DNS, and related services from our first definition are simply applications that traverse the network.

There's nothing like confusion over definitions to fuel a debate, and this area is no exception. However, a debate over definitions is too often a dry one. So, in the interest of adding a little more incendiary material to the topic, let's simply use this second definition of middleware to look further at the issues.

Why would a network go to all this bother to trap and process certain packets? Surely it's easier and cheaper to simply forward the packet onward to its intended destination? The answer can be "yes" or "no," depending on how you feel about the role of middleware in TCP/IP.

An Example: Cache Middleware

Let's look at this in a bit more detail, using a specific flavor of middleware to illustrate the middleware dilemma. A common form of middleware is the *Transparent Web Cache*. Such a Web cache is constructed using two parts, an *interceptor* and a *cache system*. The interceptor is placed into the network, either as a software module added to a router or as a device, which is spliced into a point-to-point link. The interceptor takes all incoming TCP traffic addressed to port 80 (a *Hypertext Transfer Protocol* [HTTP] session) and redirects it across to the cache system. All other traffic is treated normally. The cache system accepts all such redirected packets as if they were directly addressed to the cache itself. It responds to the HTTP requestor as if it were the actual intended destination, using a source address that matches the destination address of the original request, assuming the identity of the actual intended content server. If the requested Web object is located in the local cache, it will deliver the object to the requestor immediately. If it is not in the cache, it will set up its own session with the original destination, send it the original request, and feed the response back to the requestor, while also keeping a copy for itself in its cache.

Caching of content works well in the Web world simply because so much Web traffic today is movement of the same Web page to different recipients. It is commonly reported that up to one half of all Web traffic in the Internet is a duplicate transmission of content. If an ISP locally caches all Web content as it is delivered, and checks the cache before passing through a content request, then the ISP's upstream Web traffic volume may be halved. Even a moderately good cache will be able to service about one quarter of the Web content from the cache. That amount of local caching can be translated into a significant cost saving for the ISP.

The cached Web content is traffic that is not purchased as transit traffic from an upstream ISP, representing a potential saving on the cost of upstream transit services. This saving, in turn, can allow the ISP to operate at a lower price point in the retail market. The cache is also located closer to the ISP's customers, and with appropriate tuning, the cache can also deliver cached content to the customer at a consistently much faster rate than a request to the original content server. For very popular Web sites the originating server may be operating more slowly under extreme load, while the local cache continues to operate at a more consistent service level. The combination of the potential for improved performance and lower overall cost is certainly one that looks enticing: the result is the same set of Web transactions delivered to customers, but cheaper and faster.

End-to-End Issues with Cache Middleware

But not everything is perfect in this transparent caching world. What if the Web server used a security model that served content only to certain requestors, and the identity of the requestor was based on their IP address? This is not a very good security model, admittedly, but it's simple, and because of its simplicity this practice enjoys very common usage. With the introduction of a transparent cache, the Web client sees something quite strange. The Web client can ping the Web server, the client can communicate with any other port on the server, and if the client were to query the status of the server, the Web server would be seen to be functioning quite normally. But, mysteriously, the client cannot retrieve any Web content from the server, and the server does not see any such request from the client. The middleware cache is sitting inside a network somewhere on the path between the client and the service, but it may well be the case that neither the end client or the end server are aware of the deployment of the middleware unit. It is not surprising that this is a remarkably challenging operational problem for either the client or the server to correctly diagnose.

A similar case is where a Web server wishes to deliver different content to different requestors, based on some inference gained from the source IP address of the requestor, or the time of day, or some other variable derived from the circumstances of the request. A transparent cache will not detect such variations in the response of the server and will instead deliver the same version of the cached content to all clients whose requests pass through the transparent cache. Variations of this situation of perceived abnormal service behavior abound, all clustered around the same concept that it is unwise in such an environment for a server to assume that it is always communicating with the end client. Indeed the situation is common enough that the Web application has explicit provision for instructing cache servers about whether the content can be cached and replayed in response to similar subsequent requests.

More subtle vulnerabilities also are present in such a middleware environment. A client can confidently assert that packets are being sent to a server, and the server appears to be responding, but the data appears to have been corrupted. Has the server been compromised? It may look like this is the case, but when middleware is around, looks can be deceiving. If the integrity of the cache is compromised, and different pages are substituted in the cache, then to the clients of the cache it appears that the integrity of original server has been compromised. The twist with transparent cache middleware is that the clients of the cache may be unaware that the cache exists, let alone that their requests are being redirected to the cache server. Any abnormalities in the responses they receive are naturally attributed to problems with the security of the server and the integrity of the associated service.

The common theme of these issues is that there are sets of inconsistent assumptions at play here. On the one hand, the assumption of an end-to-end architecture leads an application designer to assume that an IP session opened with a remote peer will indeed be with that remote peer, and not with some intercepting network-level proxy agent attempting to mimic the behavior of that remote peer. On the other hand, is the assumption that transactions adhere to a consistent and predictable protocol, and transactions may be intercepted and manipulated by middleware as long as the resultant interaction behaves according to the defined protocol.

Middleware Architecture

Are transparent caches good or bad? Is the entire concept of middleware good or bad?

There is no doubt that middleware can be very useful. Cache systems can create improved service quality and reduced cost. NATs can reduce the demand for public IP address space. Firewalls can be effective as security policy agents. Middleware can perform load balancing across multiple service points for a particular class of applications, such as a Web server farm. Middleware can dynamically adjust the Internal Protocol parameters of a TCP session to adapt to particular types of networks, or various forms of network service policies. Middleware can provide services within the network that relieve the end user of a set of tasks and responsibilities, and middleware can improve some aspects of the service quality. Middleware can make an Internet service faster, cheaper, more flexible, and more secure, although probably not all at the same time. But middleware comes at a steep long-term price.

The advantage of the Internet lies in its unique approach to network architecture. In a telephone network, the end device—a telephone handset—is a rather basic device consisting of a pair of transducers and a tone generator. All the functionality of the telephone service is embedded within the network itself.

The architecture of the Internet is the complete opposite. The network consists of a collection of packet switches with basic functionality. The service is embedded within the protocol stack and the set of applications that are resident on the connected device. Within this architecture, adding new services to the network is as simple as distributing new applications among those end systems that want to use the application. The network makes no assumptions about the services it supports, and network services can be added, refined, and removed without requiring any change to the network itself. This results in a cheap, flexible, and basic network, and it passes the entire responsibility for service control to the network users. The real strength of the Internet lies in its architectural simplicity and lack of complex interdependencies within the network.

Middleware cuts across this model by inserting directly into the network functionality that alters the behavior of the network. IP or TCP Packet Header fields may be altered on the fly, or, as with a transparent cache, middleware may intercept user traffic, use an application level interpreter to interpret the upper-level service request associated with the traffic, and generate a response, acting as an unauthorized proxy for the intended recipient. With middleware present in an IP network, sending a packet to an addressed destination and receiving a response with a source address of that destination is no guarantee that you have actually communicated with the addressed remote device. You may instead be communicating with a middleware box, or have had the middleware box alter your traffic in various ways that are not directly visible to the sender.

In such an environment, it's not just the end-user applications that define an Internet-deployed service, because middleware is also part of the Internet service architecture. Services may be deployed that are reliant on the existence of middleware to be effective. Streaming video services, for example, become far more viable as a scalable Internet service when the streaming video server content is replicated across a set of middleware streaming systems deployed close to end users of the service. To change the behavior of a service that has supporting middleware deployed requires the network middleware to be changed. A new service may not be deployed until the network middleware is altered to permit its deployment. Any application requiring actual end-to-end communications may have to have additional functionality to detect if there is network middleware deployed along the path, and then explicitly negotiate with this encountered middleware to ensure that its actual communication will not be intercepted and proxied or otherwise altered.

Conclusion

The cumulative outcome is that such a middleware-modified Internet service model is not consistent with an end-to-end architecture. It represents the introduction of a more muddled service architecture where the network may choose to selectively intervene in the interaction between one device and another. Such a network architecture may not have stable scaling properties. Such an architecture may not readily support entire classes of new applications and new services. Such an architecture may not be sufficiently flexible and powerful to underpin a ubiquitous global data communications system. All this middleware overhead makes applications more complex, makes the network more complex, and makes networking more expensive, more limited, and less flexible.

From this perspective, middleware is an unglamorous hack. To adapt a 350-year-old quote from Thomas Hobbes, middleware is nasty, brutish, and short-sighted. It is, hopefully, a temporary imposition on an otherwise elegant, simple, and adequate Internet architecture.[3, 4]

Book Review

Internetworking with TCP/IP

Internetworking with TCP/IP (Vol. 1): Principles, Protocols, and Architectures, Douglas E. Comer, ISBN 0-13-018380-6, Prentice Hall, 2000.

Internetworking With TCP/IP (Vol. 1): Principles, Protocols, and Architectures (fourth edition) is the latest update to Comer's landmark work containing *Internetworking With TCP/IP (Vol. 2): Design, Implementation, and Internals* and *Internetworking With TCP/IP (Vol. 3): Client-Server Programming and Applications/BSD Socket Version.* As a recent engineering graduate, I wish I had read this book sooner; it is very concise and would have saved me a lot of time early in my studies.

Comer imparts Volume 1 in four sections. The first section provides a basic introduction to general networking including descriptions of typical network components. This section is most helpful for the entry-level student or casual reader. Advanced readers may want to skip right to the next section of the text, which continues with coverage of the TCP/IP networking environment from the host's point of view. Here, the organization and operation of local host protocols, addressing, and routing are thoroughly discussed. After reading this portion of the book, you will definitely understand how your desktop computer communicates on the network. Next, the global Internet architecture is laid out in a very comprehensible format. The reader is introduced to router-to-router protocols and algorithms that don't seem so complicated after this treatment. Lastly, application-level services and the client-server model of networking are covered in the final portion of the book.

Classic Reference

When reviewing one of the eminent texts in the field, it is of limited use to comment on the work chapter by chapter. However, I am compelled to comment on the quality of Chapter 11, Protocol Layering. This chapter is particularly interesting because Comer directly compares the ISO 7-layer reference model to the TCP/IP 5-layer model. As is par for this book, the comparison is clear and concise. Furthermore, the advantages and disadvantages of protocol layering are discussed in general and a realistic perspective is provided with reference to actual software implementation practices which may result in layer blurring. This is a very cogent presentation of the interaction between theory and reality in engineering. Although covering a specific topic, it could easily serve as an object lesson in a discussion of "real world" engineering techniques. In addition to Chapter 11, the chapters covering Internet routing (14 through 16) really shine as mainstays of this book. The Internet is viewed from the top down and "big network" protocols such as the *Border Gateway Protocol* (BGP) are given good coverage. This is an area where very few people are completely comfortable and Comer once more brings the important material forward in an easily understandable fashion. In the following paragraphs, I will highlight some of the new material included in the fourth edition.

New TCP/IP Concepts

The book's handling of *Classless Inter-Domain Routing* (CIDR) is very informative. In addition to explaining the inner-workings of the address space, Comer points out the requirement for new routing algorithms. This is an associated cost of adopting this new concept that is often overlooked when CIDR is presented.

Two new and important IP topics are also well-presented. Comer begins his treatment of IP Version 6 (IPv6) with a quick history of the protocol and a review of the logic behind this change. The new address space notation and allocation by type are explained very well. New advantages provided under IPv6 protocol structures are then discussed. Additionally, Mobile IP concepts and practicalities are introduced. Comer does a good job of bringing out both good news and bad news of this crucial new networking technology.

Coverage of *Random Early Drop* (RED) was rather brief and really needs more detail before readers can thoroughly grasp the concept. However, this would require greater mathematical sophistication on the part of the reader. Accordingly, depth of coverage is forgone in the interest of readability.

The section on *Network Address Translation* (NAT) does not adequately explain the dynamic nature of IP address assignment across hosts and data flows. An additional detailed example would help here.

Multimedia

In the application-level services section of the book, Comer offers a hasty explanation of how voice and video are sent over IP internets and how IP Telephony operates. The H.323 protocol is briefly mentioned as the low-bandwidth videoconferencing standard. However, it is not presented in its full importance as an umbrella recommendation from the *International Telecommunications Union* (ITU). A chapter explaining the roles of subordinate H.320 protocols in general would be a welcome addition to this section. *Quality of Service* (QoS) concepts such as *Resource Reservation Protocol* (RSVP), *Differentiated Services* (DiffServ), and *Real Time Protocol* (RTP) are likewise given short rift. However, IP Multicast is given significant treatment in one of the book's longest chapters; its concepts, mechanics, and implementation choices are thoroughly addressed.

Security

The book provides clear introductions to *Virtual Private Networks* (VPNs) and the IPSec set of protocols. The actual mechanics of IPSec are detailed thoroughly. Various required algorithms are introduced and pertinent RFC references are pointed out. Finally, firewall basics and implementation issues are covered. Overall, these sections clearly define the pertinent security concepts and make them simple.

Prerequisite Knowledge

This book thoroughly covers the fundamental principles of network design including implementation trade-offs and their associated foibles. However, understanding this text requires little more than a modest understanding of basic computer and networking concepts. An introductory programming course that covers computer organization, the binary number system, and basic data structures should suffice. From this point, the student can use the text for initial network familiarization as well as a future reference to ground the more abstract topics in network design.

A Must-Have Reference

An extensive, concept-based overview of the TCP/IP internetworking protocols makes Comer's Volume 1 the classic introduction to TCP/IP. He makes this an enjoyable read by breaking the topic into short, digestible chapters. Additionally, Comer pauses throughout the text to intersperse review material. Recurrent, italicized summaries provide a significant advantage to the student. These asides concisely summarize key points and provide a coherent set of landmarks for quick review and study.

By itself, Volume 1 is broad enough to be complete as an introduction to IP networking protocols. Comer further extends the work by pointing the reader to very specific resources for in-depth information including web pages and specific RFC numbers for applicable topics at the end of each chapter. One of life's simple treasures is found in the *Guide to RFCs* (Appendix 1). Here, the first 2728 RFCs are organized by major categories and subtopics. At last, a navigable index of RFCs has been incorporated with a superb text from which the beginner can delve the body of networking knowledge.

Would You Like to Review a Book for IPJ?

We receive numerous books on computer networking from all the major publishers. If you've got a specific book you are interested in reviewing, please contact us and we will make sure a copy is mailed to you. The book is yours to keep if you send us a review. We accept reviews of new titles, as well as some of the "networking classics." Contact us at **ipj@cisco.com** for more information.

Fragments

Jonathan B. Postel Service Award for 2001 Presented to Daniel Karrenberg

Internet Society (ISOC) Chairman Brian Carpenter presented the *2001 Jonathan Postel Service Award* to Mr. Daniel Karrenberg, one of the pioneers of the Internet's development in Europe, during the opening ceremony of the 2001 INET Conference. His early work was at the University of Dortmund creating a basic networked e-mail and USENET service. The success of this initiative was the seed on which the first pre-commercial network, EUnet, was built. As the Internet came to Europe in the late 1980s, Mr. Karrenberg was active in organizing the first RIPE meeting and in creating the RIPE NCC to serve as secretariat for the Internet community in Europe. The RIPE NCC became the first *Regional Internet Registry* as we know them, taking on address allocation as one of its core services. Daniel headed the effort from the start, working hard to maximize the benefit for the community.

Mr. Karrenberg humbly accepted the award, thanking the Internet community for this recognition and pledging to continue his work guided by the spirit of Jon Postel.

The Jonathan B. Postel Service Award was established by the Internet Society to honor a person who has made outstanding contributions in service to the data communications community. It is named for Dr. Jonathan B. Postel to recognize and commemorate the extraordinary stewardship exercised by Jon over the course of a thirty year career in networking. The Award consists of an engraved crystal globe and US $20,000.00. The first award was presented posthumously to Jon Postel himself, accepted by his mother, Lois Postel at INET '99. Scott Bradner received the second award during INET 2000. For additional information on Jon Postel's life and contributions, please visit:
http://www.isoc.org/postel/

RFC 1149 Implemented

The Internet Engineering Task Force (IETF) has a long tradition of publishing humorous *Request For Comments* (RFCs) each year on April 1st. One of the more famous such RFCs is "A Standard for the Transmission of IP Datagrams on Avian Carriers," RFC 1149, by David Waitzman, published on April 1, 1990. This "carrier pigeon" RFC was recently implemented by a group in Bergen, Norway. For details see:
http://www.blug.linux.no/rfc1149/

Jon Crowcroft Joins IPJ Editorial Advisory Board

We are pleased to announce that Dr. Jon Crowcroft of University College London has joined the Editorial Advisory Board for the *Internet Protocol Journal* (IPJ). Dr. Crowcroft has been working in the field of internetworking and protocol design since the early days of the ARPANET. For more information, see:
http://www.cs.ucl.ac.uk/staff/J.Crowcroft/

We would also like to thank Edward Kozel, the creator of IPJ, for his support and advice over the last three years. Mr. Kozel has left Cisco to pursue other interests.

From The Editor

Multiprotocol Label Switching (MPLS) is a technology that has received a great deal of attention in recent years. The IETF alone has produced over 300 Internet Drafts and numerous RFCs related to MPLS and continues its work on refining the standards. So, what is MPLS all about? We asked Bill Stallings to give us a basic tutorial.

The tragic events of September 11, 2001 have focused attention on the stability and robustness of the Internet. The Internet played an important role in the aftermath of the terrorist attacks. While popular news Web sites initially appeared overloaded, a great deal of private traffic in the form of instant messaging and e-mail took place. Companies directly or indirectly affected by the events in New York and Washington were quick to use the Web as a way to disseminate important information to their clients as well as to their employees. In many cases, the Internet was used in place of an overloaded telephone network. With this in mind, The *Internet Corporation for Assigned Names and Numbers* (ICANN) has decided to re-focus its next meeting to address issues of Internet stability and security, particularly with regard to naming and addressing. (See "Fragments," page 32.) To provide some background information, we bring you the article "A Unique, Authoritative Root for the DNS," by M. Stuart Lynn, the president and CEO of ICANN. Since this article has been posted for public comment, you are encouraged to address your feedback to: **comments@icann.org**

We would like to remind our readers to send us postal address updates. The computer-communications industry is one where people change jobs and locations often. While we do receive some address changes automatically when mail is returned to us, it is much more reliable to send us e-mail with the new information. In the near future, readers will be able to make address changes and select delivery options through a Web interface which will be deployed at **http://www.cisco.com/ipj**. Until then, please send your updates to **ipj@cisco.com**

MPLS

by William Stallings

Multiprotocol Label Switching (MPLS) is a promising effort to provide the kind of traffic management and connection-oriented *Quality of Service* (QoS) support found in *Asynchronous Transfer Mode* (ATM) networks, to speed up the IP packet-forwarding process, and to retain the flexibility of an IP-based networking approach.

Background

The roots of MPLS go back to numerous efforts in the mid-1990s to combine IP and ATM technologies. The first such effort to reach the marketplace was IP switching, developed by Ipsilon. To compete with this offering, numerous other companies announced their own products, notably Cisco Systems (Tag Switching), IBM (aggregate route-based IP switching), and Cascade (IP Navigator). The goal of all these products was to improve the throughput and delay performance of IP, and all took the same basic approach: Use a standard routing protocol such as *Open Shortest Path First* (OSPF) to define paths between endpoints; assign packets to these paths as they enter the network; and use ATM switches to move packets along the paths. When these products came out, ATM switches were much faster than IP routers, and the intent was to improve performance by pushing as much of the traffic as possible down to the ATM level and using ATM switching hardware.

In response to these proprietary initiatives, the *Internet Engineering Task Force* (IETF) set up the MPLS working group in 1997 to develop a common, standardized approach. The working group issued its first set of Proposed Standards in 2001. Meanwhile, however, the market did not stand still. The late 1990s saw the introduction of many routers that are as fast as ATM switches, eliminating the need to provide both ATM and IP technology in the same network.

Nevertheless, MPLS has a strong role to play. MPLS reduces the amount of per-packet processing required at each router in an IP-based network, enhancing router performance even more. More significantly, MPLS provides significant new capabilities in four areas that have ensured its popularity: QoS support, traffic engineering, *Virtual Private Networks* (VPNs), and multiprotocol support. Before turning to the details of MPLS, we briefly examine each of these.

Connection-Oriented QoS Support

Network managers and users require increasingly sophisticated QoS support for numerous reasons. The following are key requirements:

- Guarantee a fixed amount of capacity for specific applications, such as audio/video conference
- Control latency and jitter and ensure capacity for voice
- Provide very specific, guaranteed, and quantifiable service-level agreements, or traffic contracts
- Configure varying degrees of QoS for multiple network customers

A connectionless network, such as in IP-based internetwork, cannot provide truly firm QoS commitments. A *Differentiated Service* (DS) framework works in only a general way and upon aggregates of traffic from numerous sources. An *Integrated Services* (IS) framework, using the *Resource Reservation Protocol* (RSVP), has some of the flavor of a connection-oriented approach, but is nevertheless limited in terms of its flexibility and scalability. For services such as voice and video that require a network with high predictability, the DS and IS approaches, by themselves, may prove inadequate on a heavily loaded network. By contrast, a connection-oriented network has powerful traffic-management and QoS capabilities. MPLS imposes a connection-oriented framework on an IP-based internet and thus provides the foundation for sophisticated and reliable QoS traffic contracts.

Traffic Engineering

MPLS makes it easy to commit network resources in such a way as to balance the load in the face of a given demand and to commit to differential levels of support to meet various user traffic requirements. The ability to dynamically define routes, plan resource commitments on the basis of known demand, and optimize network utilization is referred to as *traffic engineering*.

With the basic IP mechanism, there is a primitive form of automated traffic engineering. Specifically, routing protocols such as OSPF enable routers to dynamically change the route to a given destination on a packet-by-packet basis to try to balance load. But such dynamic routing reacts in a very simple manner to congestion and does not provide a way to support QoS. All traffic between two endpoints follows the same route, which may be changed when congestion occurs. MPLS, on the other hand, is aware of not just individual packets, but flows of packets in which each flow has certain QoS requirements and a predictable traffic demand. With MPLS, it is possible to set up routes on the basis of these individual flows, with two different flows between the same endpoints perhaps following different routers. Further, when congestion threatens, MPLS paths can be rerouted intelligently. That is, instead of simply changing the route on a packet-by-packet basis, with MPLS, the routes are changed on a flow-by-flow basis, taking advantage of the known traffic demands of each flow. Effective use of traffic engineering can substantially increase usable network capacity.

VPN Support

MPLS provides an efficient mechanism for supporting VPNs. With a VPN, the traffic of a given enterprise or group passes transparently through an internet in a way that effectively segregates that traffic from other packets on the internet, proving performance guarantees and security.

Multiprotocol Support

MPLS, which can be used on many networking technologies, is an enhancement to the way a connectionless IP-based internet is operated, requiring an upgrade to IP routers to support the MPLS features. MPLS-enabled routers can coexist with ordinary IP routers, facilitating the introduction of evolution to MPLS schemes. MPLS is also designed to work in ATM and Frame Relay networks. Again, MPLS-enabled ATM switches and MPLS-enabled Frame Relay switches can be configured to coexist with ordinary switches. Furthermore, MPLS can be used in a pure IP-based internet, a pure ATM network, a pure Frame Relay network, or an internet that includes two or even all three technologies. This universal nature of MPLS should appeal to users who currently have mixed network technologies and seek ways to optimize resources and expand QoS support.

For the remainder of this discussion, we focus on the use of MPLS in IP-based internets, with brief comments about formatting issues for ATM and Frame Relay networks.

MPLS Operation

An MPLS network or internet consists of a set of nodes, called *Label Switched Routers* (LSRs), that are capable of switching and routing packets on the basis of a label which has been appended to each packet. Labels define a flow of packets between two endpoints or, in the case of multicast, between a source endpoint and a multicast group of destination endpoints. For each distinct flow, called a *Forwarding Equivalence Class* (FEC), a specific path through the network of LSRs is defined. Thus, MPLS is a connection-oriented technology. Associated with each FEC is a traffic characterization that defines the QoS requirements for that flow. The LSRs do not need to examine or process the IP header, but rather simply forward each packet based on its label value. Therefore, the forwarding process is simpler than with an IP router.

Figure 1: MPLS Operation

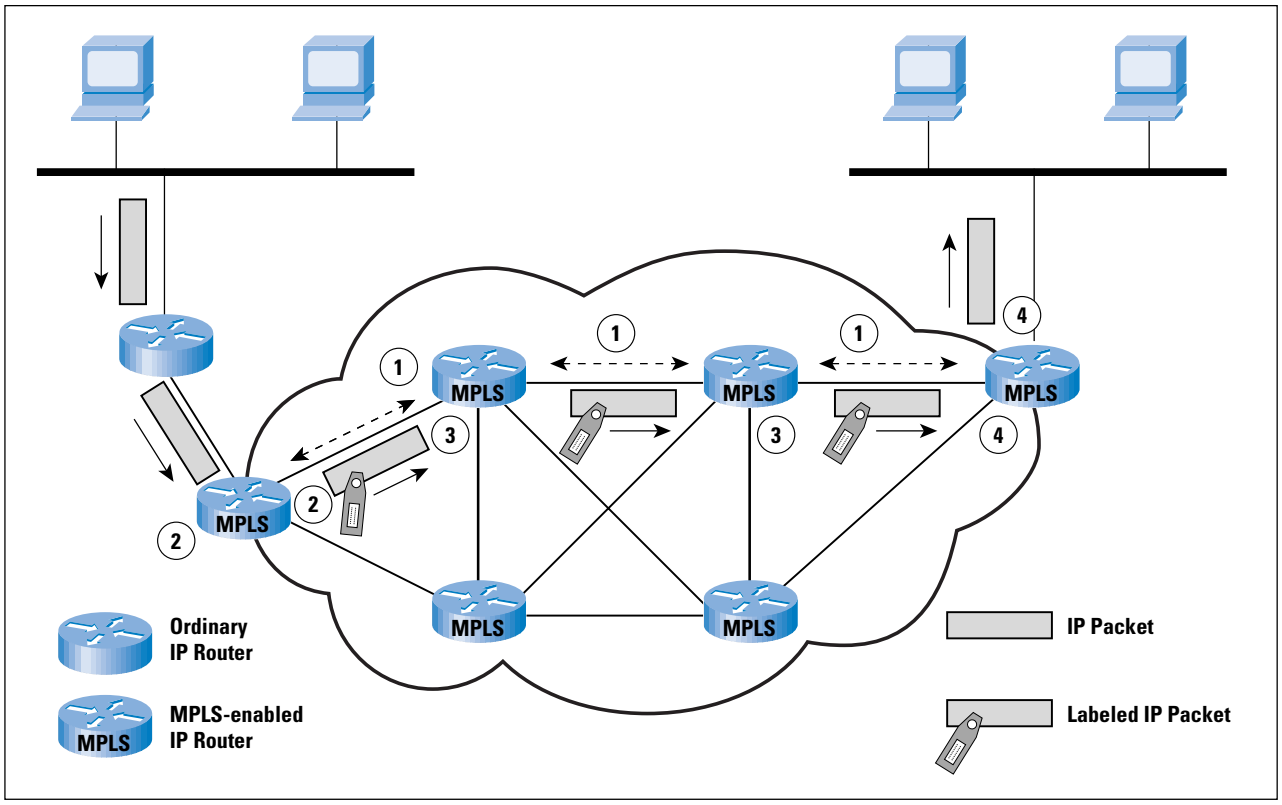

Figure 1, based on one in[4], depicts the operation of MPLS within a domain of MPLS-enabled routers. The following are key elements of the operation.

1. Prior to the routing and delivery of packets in a given FEC, a path through the network, known as a *Label Switched Path* (LSP), must be defined and the QoS parameters along that path must be established. The QoS parameters determine (1) how many resources to commit to the path, and (2) what queuing and discarding policy to establish at each LSR for packets in this FEC. To accomplish these tasks, two protocols are used to exchange the necessary information among routers:
   (a) An interior routing protocol, such as OSPF, is used to exchange reachability and routing information.
   (b) Labels must be assigned to the packets for a particular FEC. Because the use of globally unique labels would impose a management burden and limit the number of usable labels, labels have local significance only, as discussed subsequently. A network operator can specify explicit routes manually and assign the appropriate label values. Alternatively, a protocol is used to determine the route and establish label values between adjacent LSRs. Either of two protocols can be used for this purpose: the *Label Distribution Protocol* (LDP) or an enhanced version of RSVP.

2. A packet enters an MPLS domain through an ingress edge LSR where it is processed to determine which network-layer services it requires, defining its QoS. The LSR assigns this packet to a particular FEC, and therefore a particular LSP, appends the appropriate label to the packet, and forwards the packet. If no LSP yet exists for this FEC, the edge LSR must cooperate with the other LSRs in defining a new LSP.
3. Within the MPLS domain, as each LSR receives a labeled packet, it:
   (a) Removes the incoming label and attaches the appropriate outgoing label to the packet.
   (b) Forwards the packet to the next LSR along the LSP.
4. The egress edge LSR strips the label, reads the IP packet header, and forwards the packet to its final destination.

Several key features of MLSP operation can be noted at this point:

1. An MPLS domain consists of a contiguous, or connected, set of MPLS-enabled routers. Traffic can enter or exit the domain from an endpoint on a directly connected network, as shown in the upper-right corner of Figure 1. Traffic may also arrive from an ordinary router that connects to a portion of the internet not using MPLS, as shown in the upper-left corner of Figure 1.
2. The FEC for a packet can be determined by one or more of a number of parameters, as specified by the network manager. Among the possible parameters:
   - Source or destination IP addresses or IP network addresses
   - Source or destination port numbers
   - IP protocol ID
   - Differentiated services codepoint
   - IPv6 flow label
3. Forwarding is achieved by doing a simple lookup in a predefined table that maps label values to next-hop addresses. There is no need to examine or process the IP header or to make a routing decision based on destination IP address.
4. A particular *Per-Hop Behavior* (PHB) can be defined at an LSR for a given FEC. The PHB defines the queuing priority of the packets for this FEC and the discard policy.
5. Packets sent between the same endpoints may belong to different FECs. Thus, they will be labeled differently, will experience different PHB at each LSR, and may follow different paths through the network.

Figure 2: MPLS Packet Forwarding

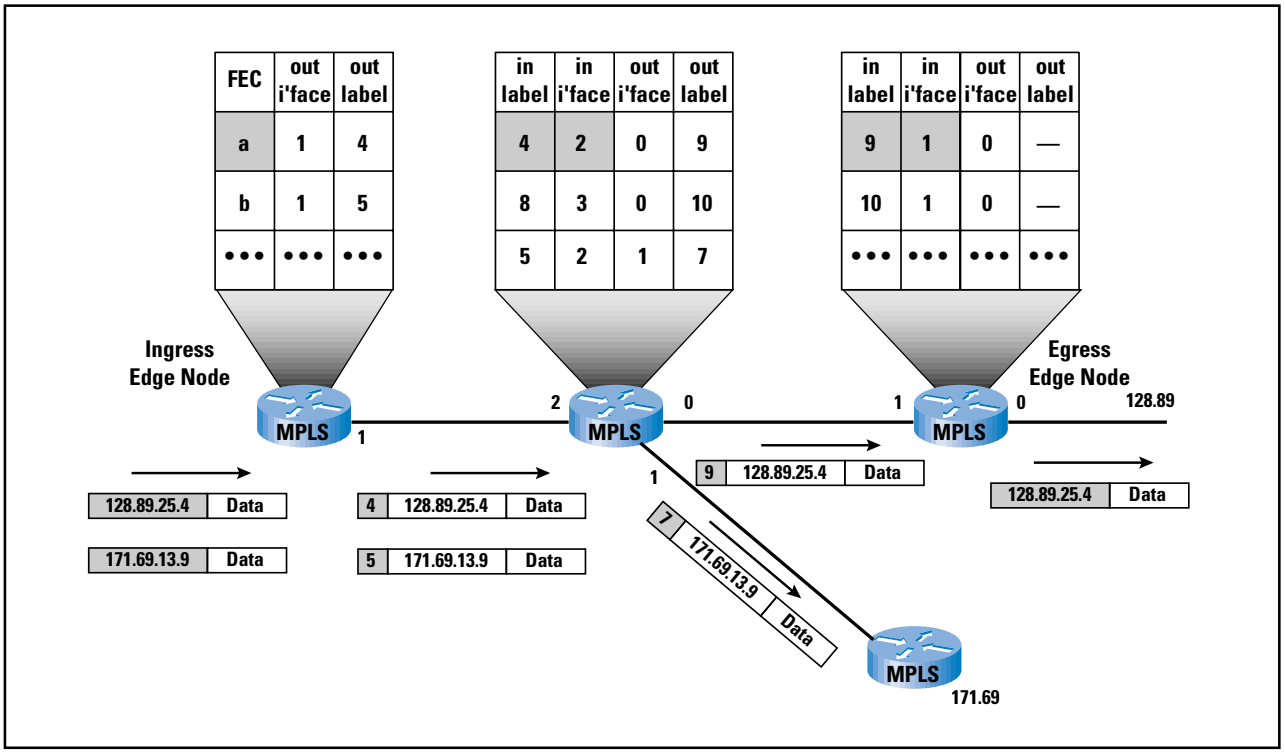

Figure 2 shows the label-handling and label-forwarding operation in more detail. Each LSR maintains a forwarding table for each LSP passing through the LSR. When a labeled packet arrives, the LSR indexes the forwarding table to determine the next hop. For scalability, as was mentioned, labels have local significance only. Thus, the LSR removes the incoming label from the packet and attaches the matching outgoing label before forwarding the packet. The ingress-edge LSR determines the FEC for each incoming unlabeled packet and, on the basis of the FEC, assigns the packet to a particular LSP, attaches the corresponding label, and forwards the packet.

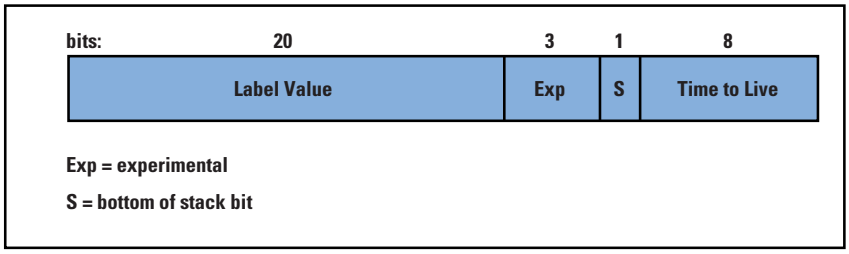
Label Stacking

One of the most powerful features of MPLS is *label stacking*. A labeled packet may carry many labels, organized as a last-in-first-out stack. Processing is always based on the top label. At any LSR, a label may be added to the stack (push operation) or removed from the stack (pop operation). Label stacking allows the aggregation of LSPs into a single LSP for a portion of the route through a network, creating a *tunnel*. At the beginning of the tunnel, an LSR assigns the same label to packets from a number of LSPs by pushing the label onto the stack of each packet. At the end of the tunnel, another LSR pops the top element from the label stack, revealing the inner label. This is similar to ATM, which has one level of stacking (virtual channels inside virtual paths), but MPLS supports unlimited stacking.

Label stacking provides considerable flexibility. An enterprise could establish MPLS-enabled networks at various sites and establish numerous LSPs at each site. The enterprise could then use label stacking to aggregate multiple flows of its own traffic before handing it to an access provider. The access provider could aggregate traffic from multiple enterprises before handing it to a larger service provider. Service providers could aggregate many LSPs into a relatively small number of tunnels between points of presence. Fewer tunnels means smaller tables, making it easier for a provider to scale the network core.

Figure 3: MPLS Label Format



Label Format and Placement

An MPLS label is a 32-bit field consisting of the following elements (Figure 3):

- *Label value*: locally significant 20-bit label
- *Exp:* 3 bits reserved for experimental use; for example, these bits could communicate DS information or PHB guidance
- *S*: set to one for the oldest entry in the stack, and zero for all other entries
- *Time To Live* (TTL): 8 bits used to encode a hop count, or time to live, value

Time-to-Live Processing

A key field in the IP packet header is the TTL field (IPv4), or Hop Limit (IPv6). In an ordinary IP-based internet, this field is decremented at each router and the packet is dropped if the count falls to zero. This is done to avoid looping or having the packet remain too long in the internet because of faulty routing. Because an LSR does not examine the IP header, the TTL field is included in the label so that the TTL function is still supported. The rules for processing the TTL field in the label are as follows:

1. When an IP packet arrives at an ingress edge LSR of an MPLS domain, a single label stack entry is added to the packet. The TTL value of this label stack entry is set to the value of the IP TTL value. If the IP TTL field needs to be decremented, as part of the IP processing, it is assumed that this has already been done.

   When an MPLS packet arrives at an internal LSR of an MPLS domain, the TTL value in the top label stack entry is decremented.

Then:

(a) If this value is zero, the MPLS packet is not forwarded. Depending on the label value in the label stack entry, the packet may be simply discarded, or it may be passed to the appropriate "ordinary" network layer for error processing (for example, for the generation of an *Internet Control Message Protocol* [ICMP] error message).

(b) If this value is positive, it is placed in the TTL field of the top label stack entry for the outgoing MPLS packet, and the packet is forwarded. The outgoing TTL value is a function solely of the incoming TTL value, and is independent of whether any labels are pushed or popped before forwarding. There is no significance to the value of the TTL field in any label stack entry that is not at the top of the stack.

2. When an MPLS packet arrives at an egress edge LSR of an MPLS domain, the TTL value in the single label stack entry is decremented and the label is popped, resulting in an empty label stack. Then:

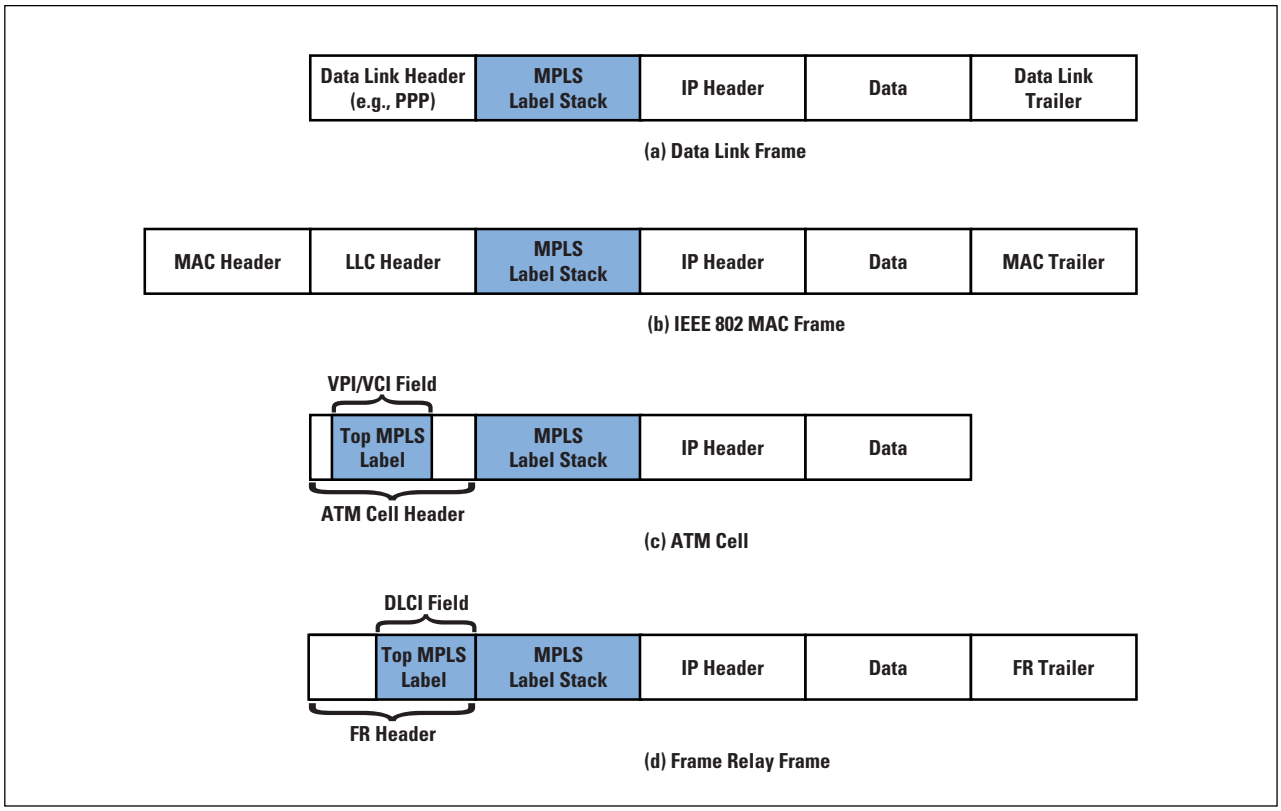
(a) If this value is zero, the IP packet is not forwarded. Depending on the label value in the label stack entry, the packet may be simply discarded, or it may be passed to the appropriate "ordinary" network layer for error processing.

(b) If this value is positive, it is placed in the TTL field of the IP header, and the IP packet is forwarded using ordinary IP routing. Note that the IP header checksum must be modified prior to forwarding.

Label Stack

The label stack entries appear after the data link layer headers, but before any network layer headers. The top of the label stack appears earliest in the packet (closest to the network layer header), and the bottom appears latest (closest to the data link header). The network layer packet immediately follows the label stack entry that has the *S* bit set. In a data link frame, such as for the *Point-to-Point Protocol* (PPP), the label stack appears between the IP header and the data link header (Figure 4a). For an IEEE 802 frame, the label stack appears between the IP header and the *Logical Link Control* (LLC) header (Figure 4b).

Figure 4: Position of MPLS Label



If MPLS is used over a connection-oriented network service, a slightly different approach may be taken, as shown in Figure 4c and d. For ATM cells, the label value in the topmost label is placed in the *Virtual Path/Channel Identifier* (VPI/VCI) field in the ATM cell header. The entire top label remains at the top of the label stack, which is inserted between the cell header and the IP header. Placing the label value in the ATM cell header facilitates switching by an ATM switch, which would, as usual, need to look only at the cell header. Similarly, the topmost label value can be placed in the *Data Link Connection Identifier* (DLCI) field of a Frame Relay header. Note that in both these cases, the TTL field is not visible to the switch and so is not decremented. The reader should consult the MPLS specifications for the details of the way this situation is handled.

FECs, LSPs, and Labels

To understand MPLS, it is necessary to understand the operational relationship among FECs, LSPs, and labels. The specifications covering all the ramifications of this relationship are lengthy. In the remainder of this section, we provide a summary.

The essence of MPLS functionality is that traffic is grouped into FECs. The traffic in an FEC transits an MPLS domain along an LSP. Individual packets in an FEC are uniquely identified as being part of a given FEC by means of a *locally significant label*.

At each LSR, each labeled packet is forwarded on the basis of its label value, with the LSR replacing the incoming label value with an outgoing label value.

The overall scheme described in the previous paragraph imposes numerous requirements. Specifically:

1. Traffic must be assigned to a particular FEC.
2. A routing protocol is needed to determine the topology and current conditions in the domain so that a particular LSP can be assigned to an FEC. The routing protocol must be able to gather and use information to support the QoS requirements of the FEC.
3. Individual LSRs must become aware of the LSP for a given FEC, must assign an incoming label to the LSP, and must communicate that label to any other LSR that may send it packets for this FEC.

The first requirement is outside the scope of the MPLS specifications. The assignment needs to be done either by manual configuration, by means of some signaling protocol, or by an analysis of incoming packets at ingress LSRs. Before looking at the other two requirements, let us consider the topology of LSPs. We can classify these in the following manner:

- *Unique ingress and egress LSR:* In this case a single path through the MPLS domain is needed.
- *Unique egress LSR, multiple ingress LSRs:* If traffic assigned to a single FEC can arise from different sources that enter the network at different ingress LSRs, then this situation occurs. An example is an enterprise intranet at a single location but with access to an MPLS domain through multiple MPLS ingress LSRs. This situation would call for multiple paths through the MPLS domain, probably sharing a final few hops.
- *Multiple egress LSRs for unicast traffic:* RFC 3031 states that most commonly, a packet is assigned to a FEC based (completely or partially) on its network layer destination address. If not, then it is possible that the FEC would require paths to multiple distinct egress LSRs. However, more likely, there would be a cluster of destination networks, all of which are reached via the same MPLS egress LSR.
- *Multicast:* RFC 3031 lists multicast as a subject for further study.

Route Selection

Route selection refers to the selection of an LSP for a particular FEC. The MPLS architecture supports two options: hop-by-hop routing and explicit routing.

With *hop-by-hop routing,* each LSR independently chooses the next hop for each FEC. The RFC implies that this option makes use of an ordinary routing protocol, such as OSPF.

This option provides some of the advantages of MPLS, including rapid switching by labels, the ability to use label stacking, and differential treatment of packets from different FECs following the same route. However, because of the limited use of performance metrics in typical routing protocols, hop-by-hop routing does not readily support traffic engineering or policy routing (defining routes based on some policy related to QoS, security, or some other consideration).

With *explicit routing*, a single LSR, usually the ingress or egress LSR, specifies some or all of the LSRs in the LSP for a given FEC. For strict explicit routing, an LSR specifies all of the LSRs on an LSP. For loose explicit routing, only some of the LSRs are specified. Explicit routing provides all the benefits of MPLS, including the ability to do traffic engineering and policy routing.

Explicit routes can be selected by configuration, that is, set up ahead of time, or dynamically. Dynamic explicit routing would provide the best scope for traffic engineering. For dynamic explicit routing, the LSR setting up the LSP would need information about the topology of the MPLS domain as well as QoS-related information about that domain. An MPLS traffic engineering specification[2] suggests that the QoS-related information falls into two categories:

- A set of attributes associated with an FEC or a collection of similar FECs that collectively specify their behavioral characteristics
- A set of attributes associated with resources (nodes, links) that constrain the placement of LSPs through them

A routing algorithm that accounts for the traffic requirements of various flows and the resources available along various hops and through various nodes is referred to as a *constraint-based routing algorithm*. In essence, a network that uses a constraint-based routing algorithm is aware of current utilization, existing capacity, and committed services at all times. Traditional routing algorithms, such as OSPF and the *Border Gateway Protocol* (BGP), do not employ a sufficient array of cost metrics in their algorithms to qualify as constraint-based.

Furthermore, for any given route calculation, only a single cost metric (for instance, number of hops, delay) can be used. For MPLS, it is necessary either to augment an existing routing protocol or to deploy a new one. For example, an enhanced version of OSPF has been defined[1] that provides at least some of the support required for MPLS. Examples of metrics that would be useful to constraint-based routing include the following:

- Maximum link data rate
- Current capacity reservation
- Packet loss ratio
- Link propagation delay

Label Distribution

Route selection consists of defining an LSP for an FEC. A separate function is the actual setting up of the LSP. For this purpose, each LSR on the LSP must:

1. Assign a label to the LSP to be used to recognize incoming packets that belong to the corresponding FEC.
2. Inform all potential upstream nodes (nodes that will send packets for this FEC to this LSR) of the label assigned by this LSR to this FEC, so that these nodes can properly label packets to be sent to this LSR.
3. Learn the next hop for this LSP and learn the label that the downstream node (LSR that is the next hop) has assigned to this FEC. This process will enable this LSR to map an incoming label to an outgoing label.

The first item in the preceding list is a local function. Items 2 and 3 must be done either by manual configuration or by using some sort of label distribution protocol. Thus, the essence of a label distribution protocol is that it enables one LSR to inform others of the label/FEC bindings it has made. In addition, a label distribution protocol enables two LSRs to learn each other's MPLS capabilities. The MPLS architecture does not assume a single label distribution protocol but allows for multiple such protocols. Specifically, RFC 3031 refers to a new label distribution protocol and to enhancements to existing protocols, such as RSVP and BGP, to serve the purpose.

The relationship between label distribution and route selection is complex. It is best to look at in the context of the two types of route selection.

With hop-by-hop route selection, no specific attention is paid to traffic engineering or policy routing concerns, as we have seen. In such a case, an ordinary routing protocol such as OSPF is used to determine the next hop by each LSR. A relatively straightforward label distribution protocol can operate using the routing protocol to design routes.

With explicit route selection, a more sophisticated routing algorithm must be implemented, one that does not employ a single metric to design a route. In this case, a label distribution protocol could make use of a separate route selection protocol, such as an enhanced OSPF, or incorporate a routing algorithm into a more complex label distribution protocol.

References

The two most important defining documents for MPLS are [5] and [6]. Reference [3] provides a thorough treatment of MPLS; [8] covers not only MPLS but other Internet QoS concepts; it includes an excellent chapter on MPLS traffic engineering. Reference [7] includes a concise overview of the MPLS architecture and describes the various proprietary efforts that preceded MPLS.

A Unique, Authoritative Root for the DNS

by M. Stuart Lynn, ICANN

The following *Internet Coordination Policy* (ICP) is being posted for the information of the Internet community by the *Internet Corporation for Assigned Names and Numbers* (ICANN) and is a statement of policy currently followed in administering the authoritative root of the Domain Name System. Comments on this article are welcome and should be directed to **comments@icann.org**

Abstract

This article reaffirms ICANN's commitment to a single, authoritative public root for the Internet *Domain Name System* (DNS) and to the management of that unique root in the public interest according to policies developed through community processes. This commitment is founded on the technical and other advice of the community and is embodied in existing ICANN policy.

The DNS is intended to provide a convenient means of referring to sites available on the Internet. By offering users an easy-to-use and reliable means of unambiguously referring to Web sites, e-mail servers, and the Internet's many other services, the DNS has helped the Internet achieve its promise as a global communications medium for commerce, research, education, and cultural and other expressive activities.

The DNS is a globally distributed database of domain name (and other) information. One of its core design goals is that it reliably provides the same answers to the same queries from any source on the public Internet, thereby supporting predictable routing of Internet communications. Achievement of that design goal requires a globally unique public name space derived from a single, globally unique DNS *root*.

Although the Internet allows a high degree of decentralized activities, coordination of the assignment function by a single authority is necessary where unique parameter values are technically required. Because of the uniqueness requirement, the content and operation of the DNS root must be coordinated by a central entity.

Where central coordination is necessary, it should be performed by an organization dedicated to serving the public interest and that acts according to policies developed through processes that are developed through the participation of affected stakeholders. Traditionally, the responsibility for performing the central coordinating functions of the global Internet for the public good, including management of the unique public DNS root, has been carried out by the *Internet Assigned Numbers Authority* (IANA)[12]. ICANN's core mission is to continue the work of the IANA in a more formalized and globally representative framework, to ensure the views of all the Internet's stakeholders are taken into account in carrying out this public trust.

Over the past several years, some private organizations have established DNS roots as alternates to the authoritative root. Some uses of these alternate roots do not jeopardize the stability of the DNS. For example, some are purely private roots operating inside institutions and are carefully insulated from the DNS. Others are purely experimental in the best traditions of the Internet and are carefully managed so as not to interfere with the operation of the DNS. These both operate within community-established norms.

Frequently, however, these alternate roots have been established to support top-level or pseudo-top-level domain name registries that are operated for profit. Yet other alternate roots have been established by certain individuals to protest the policies developed by the broader community processes for management of the authoritative root, or to express their disinterest in participating in those processes. These alternate roots have not been launched through any ICANN consensus processes, so they have not been entered into the authoritative root managed by the IANA or ICANN.

These alternate roots typically substitute insular concerns in place of the community-based processes that govern the management of the authoritative root. Their operators decide to include particular top-level domains in these alternate roots that have not been subjected to the tests of community support and conformance with consensus processes—coordinated by ICANN—that would allow their inclusion in the authoritative root. These decisions of the alternate-root operators have been made without any apparent regard for the fundamental public-interest concern of Internet stability. The widespread use of active domain names in these alternate roots could in fact impair the uniqueness of the authoritative name-resolution mechanism and hence the stability of the DNS.

ICANN's mandate to preserve stability of the DNS requires that it avoid encouraging the proliferation of these alternate roots that could cause conflicts and instability. This means that ICANN continues to adhere to community-based processes in its decisions regarding the content of the authoritative root. Within its current policy framework, ICANN can give no preference to those who choose to work outside of these processes and outside of the policies engendered by this public trust.

None of this precludes experimentation done in a manner that does not threaten the stability of name resolution in the authoritative DNS. Responsible experimentation is essential to the vitality of the Internet. Nor does it preclude the ultimate introduction of new architectures that may ultimately obviate the need for a unique, authoritative root. But the translation of experiments into production and the introduction of new architectures require community-based approaches, and are not compatible with individual efforts to gain proprietary advantage.

The Technical Need for a Single Authoritative Root

The DNS was originally deployed in the mid-1980s[13] as an improved means of mapping easy-to-remember names (i.e., **example.com)** to the IP addresses (i.e., **128.9.176.32**) by which packets are routed on the Internet. It is a distributed database that holds this mapping information (as well as various other types of technical information regarding computers on the Internet) in *resource records*. The DNS provides these resource records in response to queries it receives from programs called *resolvers* on individual computers throughout the Internet. The resolvers translate domain names into the corresponding IP addresses.

From the inception of the DNS, its most fundamental design goal has been to provide the same answers to the same queries issued from any place on the Internet. As stated in RFC 1034, the basic specification of the DNS's "Concepts and Facilities,"[16], "The primary (design) goal is a consistent name space which will be used for referring to resources." And as reiterated in RFC 2535, "Domain Name System Security Extensions,"[15] "It is part of the design philosophy of the DNS that the data in it is public and that the DNS gives the same answers to all inquirers."

The DNS is hierarchical. By design, the hierarchy begins with a group of *root nameservers* (often called simply *root servers*), which are specially-designated computers operated under common coordination that provide information about which other computers are authoritative regarding the top-level domains in the DNS naming structure. These set of root servers house the *authoritative root*. Thus, a resolver seeking information concerning a domain name such as **www.example.com** obtains one of the root servers' resource records about **.com**, which tells the resolver which computers have authoritative information about names within the **.com** top-level domain. The resolver then queries one of those authoritative **.com** nameservers about example.com, to locate the nameservers for **example.com**. A query is then made to one of those nameservers obtain the IP address of the computer designated by the name **www.example.com**.

The principal advantage of this hierarchical structure is that it allows different parts of the naming database to be maintained by different entities. According to the DNS's design, each domain was intended to be administered by a single entity.[19]

When the DNS was deployed in the mid-1980s, a set of root nameservers was designated and several top-level domains were established. These root nameservers (there are now 13 of them distributed around the world) are intended to provide authoritative information about which nameservers hold the naming information for each of the top-level domains. Since the authoritative root nameservers operate at the top of the hierarchy, resolvers find them by referring to IP addresses prestored at local computers throughout the Internet.

Over the past several years, some groups have established alternate root nameservers on the public Internet that distribute different information than the information distributed by the authoritative root nameservers. These groups then seek to persuade ISPs and Internet users to replace the pre-stored IP addresses of the authoritative root nameservers with those of their alternate servers. For a variety of reasons, these alternate roots have not to date achieved a significant level of usage on the public Internet.

Fortunately, the rare usage of alternate roots has thus far limited their practical effect on the Internet. If these alternate roots were to become prevalent, however, they would have the potential for seriously disrupting the reliable functioning of the DNS. Some of the consequences include:

- *Providing the Wrong Location:* The presence of alternate public DNS roots can result in different answers being given to the same DNS query issued from different computers on the Internet, depending on whether the inquiring computer is programmed to access the authoritative root or a particular one of the alternate roots (or more precisely a domain-name resolver associated with one or the other of these). The fundamental DNS design goal of providing consistent answers to DNS queries is therefore frustrated.[1]
- *Reaching the Wrong Computer:* The main consequence of such inconsistent data is that the same domain name can identify different computers depending on where the name is used. Put another way, *Uniform Resource Locators* (URLs) are no longer uniform. Thus, typing in a Web site address at two different computers configured to reference different roots can result in reaching different Web sites—a particularly disturbing possibility if, for example, money is to change hands or privacy or security concerns are violated. Similarly, the same piece of e-mail sent to the same address from the two computers can be directed to different recipients. The return of inconsistent DNS data defeats the globally consistent resolution of domain names that is vital to the Internet achieving its promise as a universal communications and applications medium for commerce, research, education, cultural exchange, expressive activities, and other uses.
- *Consequences Unpredictable to Most Users:* The set of DNS answers that will be received (from the authoritative root or one of the several alternate roots) is not predictable by most end users. Most users on the Internet employ a local DNS resolver that is configured by another person. Few users are likely to appreciate the significance of the resolver's DNS configuration; even fewer are likely to have detailed knowledge of that configuration. As the number of users on the Internet has grown, the proportion of users knowledgeable about technical concepts such as DNS resolvers and root servers has diminished. Yet these non-technical users are precisely those for whom the Internet in general—and the DNS in particular—hold the greatest potential benefits.

- *Intermediate Hosts Add to Confusion:* Moreover, some Internet services depend on the actions of DNS resolvers employed by intermediate hosts. Alternate roots introduce the possibility that the DNS answer obtained by the intermediate host alters the character of the service in an unexpected way. A similar phenomenon can occur where one user sends another a reference to a URL, such as an e-mail reply address or a link on a Web site. If the recipient of an e-mail or the visitor to the Web site is using a computer that employs a different DNS root than intended by the sender of the e-mail or the designer of the Web site, unexpected results are likely to occur. For example, the e-mail could end up with the wrong person.
- *Cache Poisoning:* Alternate roots also introduce the possibility of misdirected Internet activities due to the phenomenon known as cache poisoning. For performance reasons, the DNS design calls for resource records to be passed around among the nameservers on the Internet, so that a resolver can obtain quicker access to a local copy of the resource record. Because the DNS assumes a single-root system, resource records are not marked to distinguish them according to the root from which they emanate. Thus, the presence of alternate roots introduces the possibility that Internet activities by those intending to use the authoritative root could be misdirected by a stray resource record emanating from an alternate root. Indeed, some malicious hacking attacks have been based on this principle, prompting the *Internet Engineering Task Force* (IETF) to propose a series of not-yet-fully-implemented improvements known as *DNS-Security* or *DNSSec*.

(It should be noted that the original design of the DNS provided a way to operate alternate roots in a way that does not imperil stability. See "Experimentation" below for details.)

These potentially destructive effects of alternate roots have long been accepted by the vast majority of Internet engineers. Despite this broad-based recognition, some have sought to justify the alternate roots by downplaying these effects. In response, and to document what it referred to as "some of the problems inherent in a family of recurring technically naive proposals," in May 2000 the *Internet Architecture Board* (IAB)[14] issued RFC 2826, entitled "IAB Technical Comment on the Unique DNS Root." The IAB summarized its comments (in relevant part) as follows:

"Summary: To remain a global network, the Internet requires the existence of a globally unique public name space. The DNS name space is a hierarchical name space derived from a single, globally unique root. This is a technical constraint inherent in the design of the DNS. Therefore it is not technically feasible for there to be more than one root in the public DNS. That one root must be supported by a set of coordinated root servers administered by a unique naming authority.

> "Put simply, deploying multiple public DNS roots would raise a very strong possibility that users of different ISPs who click on the same link on a Web page could end up at different destinations, against the will of the Web page designers."

For some concrete examples of potential failures and instabilities that would likely result from alternate roots prevalently used on the public Internet, see the draft "Alt-Roots, Alt-TLDs."[17]

In the face of the destabilizing consequences of alternate roots, as articulated by the IAB and others, ICANN's prime directive of preserving the stability of the Internet and DNS requires an unwavering commitment to promote the continued prevalence of a single authoritative root for the public DNS. Any other course of action by ICANN would be irresponsible.

The Public Trust in Coordinated Assignment Functions

The Internet's proper operation requires assignment of unique values to various identifiers for different computers or services on the Internet. To be effective, these assigned values must be made broadly available and their significance must be respected by the many people responsible for the Internet's operation. For example, every computer on the public Internet is assigned a unique IP address; this address is made known to routers throughout the Internet to cause TCP/IP packets with that destination address to be routed to the intended computer. Without common agreement to respect the assignment, the Internet would not reliably route communications to their intended destinations.

Beginnings to 1998: Central Coordination as a Public Trust

From the very beginnings of the Internet, the technical community has recognized the need for central coordination of the unique assignment of the values of identifiers. The IANA, now operated by ICANN was created to fill this need; it now makes assignments of unique values for approximately 120 different identifier types. This responsibility has always been understood to be a public trust, and the IANA long ago adopted the motto: "Dedicated to preserving the central coordinating functions of the global Internet for the public good."

The most commonly known of the Internet's uniquely assigned identifiers, of course, are domain names. From the time the DNS was deployed, the Internet community made the IANA "responsible for the overall coordination and management of the Domain Name System (DNS), and especially the delegation of portions of the name space called top-level domains."[18] As in its other assignment responsibilities, the IANA's role is to act in the public interest, neutrally, and without proprietary motives.

Competition as a Value Guiding the Internet's Technical Management

In the Internet's early years, with limited exceptions day-to-day registration activities for domain names were done by a single company (first SRI International and later Network Solutions) under the IANA's guidance.

By the mid-1990s, however, the growth and increasing commercialization of the Internet led the U.S. Government's Green[2] and White[3] Papers to note the emergence of "widespread dissatisfaction about the absence of competition in domain name registration." This dissatisfaction prompted the Green and White Papers to include the promotion of competition in registration services as one of the four values (stability; competition; private, bottom-up coordination; and representation) that should guide the Internet's technical management. Both documents made clear that, of these four values, preservation of stability was to be paramount.

Building on the IANA model of a non-profit entity carrying the public trust to perform the vital central coordination functions, the U.S. Government reconciled the need to ensure Internet stability with the desire to introduce competitive domain-name registration services as follows:

> "In keeping with these principles, we divide the name and number functions into two groups, those that can be moved to a competitive system and those that should be coordinated. We then suggest the creation of a representative, not-for-profit corporation to manage the coordinated functions according to widely accepted objective criteria. We then suggest the steps necessary to move to competitive markets in those areas that can be market driven." [4]

This dichotomy recognizes that the Internet is, after all, a network (albeit a network of networks), and networks require coordination among their participants to operate in a stable and efficient manner. It also reflects the phenomenal success of the Internet's tradition of cooperatively developed open and non-proprietary standards. Those standards have provided an environment of highly interoperable systems that has allowed competition and innovation to flourish.

ICANN Assumes the Public Trust

After public comment on the Green Paper, the United States Government issued the White Paper, which laid out the basic charter on which ICANN was founded and continues to operate. The White Paper re-emphasized the prime directive of stability and, to that end, the need to avoid creation of alternate roots:

> "The introduction of a new management system should not disrupt current operations or create competing root systems. During the transition and thereafter, the stability of the Internet should be the first priority of any DNS management system." [5]

The United States Government then invited the Internet community to form a not-for-profit corporation to perform the "coordinated functions" that should be handled as a matter of public trust, rather than according to a competitive regime that would not be conducive to stability. Among the "coordinated functions" were management of the root-server system and decisions to introduce new TLDs:

> "Similarly, coordination of the root server network is necessary if the whole system is to work smoothly. While day-to-day operational tasks, such as the actual operation and maintenance of the Internet root servers, can be dispersed, *overall policy guidance and control of the TLDs and the Internet root server system should be vested in a single organization* that is representative of Internet users around the globe.
>
> "Further, changes made in the administration or the number of gTLDs contained in the authoritative root system will have considerable impact on Internet users throughout the world. In order to promote continuity and reasonable predictability in functions related to the root zone, the *development of policies for the addition, allocation, and management of gTLDs and the establishment of domain name registries and domain name registrars to host gTLDs should be coordinated.*" [6]

In response to this invitation for the formation of a non-profit, Internet-community-based organization, ICANN was established in 1998. ICANN was subsequently selected by the United States Government from among several proposals submitted precisely because it was open, consensus-based, and rooted in the Internet community. The establishment of ICANN had followed extensive dialogs among different constituencies of the Internet community to ensure that ICANN could be responsive to the needs of these various constituencies.

ICANN, among its other responsibilities, now acts as the coordinator for operation of the authoritative root-server system and the policy forum for decisions about the policies governing what TLDs are to be included in the authoritative DNS root. [7]

In linking the formation of ICANN to the global Internet community, the White Paper established a public trust that required that the DNS be administered in the public interest as the unique-rooted,[8] authoritative database for domain names that provides a stable addressing system for use by the global Internet community. This commitment to a unique and authoritative root is a key part of the broader public trust—to carry out the Internet's central coordination functions for the public good—that is ICANN's reason for existence.

The Public Trust and the Introduction of New TLDs

It is essential that the centrally coordinated functions be performed in the public interest, not out of proprietary or otherwise self-interested motives. For this reason, ICANN was founded as a not-for-profit public-benefit organization, accountable to the Internet community. Longstanding Internet principles also require that the policies guiding the coordinated functions be established openly based on community deliberation and input. For these reasons ICANN's structure is representative of the geographic and functional diversity of the Internet, and relies to the extent possible on private-sector, bottom-up methods.

As the White Paper emphasized, the decisions about the introduction of new TLDs are appropriately done within this open, non-proprietary, and broadly representative framework, rather than by individuals or entities not accountable to the community and that ordinarily act for their own proprietary motives:

> "As Internet names increasingly have commercial value, the decision to add new top-level domains cannot be made on an ad hoc basis by entities or individuals that are not formally accountable to the Internet community." [9]

Within the framework of its commitment to a unique root system and to the stability of the Internet, last year ICANN launched a process for carefully introducing several new generic TLDs to the DNS. This introduction was fashioned as a proof of concept of the technical and business feasibility of introducing more TLDs into the DNS. Proceeding with an initial proof of concept was in response to the advice of ICANN's *Protocol Supporting Organization* (PSO) and its *Domain Name Supporting Organizatio*n (DNSO) to proceed cautiously and in an orderly fashion. The PSO and the DNSO represent the consensus views of the technical and the user/business/other institutional communities, respectively. Generic TLDs had not been introduced for many years, and there were and still are serious questions as to what the effect of introducing new TLDs will be on the stability and reliability of the DNS; and many questions about what should be the appropriate contractual and business context.

In response to an issued RFP, forty-seven institutions and groups submitted proposals for the establishment of new TLDs. They chose to work within the community-based ICANN process, even though they knew that only a "limited number" of TLDs would be selected—at least in the first round. In fact, seven were selected, and, following a methodology which allowed for considerable community input, contracts have or will shortly be signed with these initial seven. ICANN looks forward to the successful introduction of these new TLDs and will work with the community to monitor their performance so that a community decision can be made on moving forward with the introduction of more TLDs, should this be the conclusion of the proof of concept.

Outside the Process

Some private organizations have established DNS roots as alternates to the authoritative root. Some uses of these alternate roots do not jeopardize the stability of the DNS. For example, many are purely private roots operating inside institutions and are carefully insulated from the DNS. Others are purely experimental in the best traditions of the Internet and are carefully managed so as not to interfere with the operation of the DNS. These both operate within community-established norms.

Frequently, however, these alternate roots have been established to support top-level or pseudo-top-level domain name registries that are operated for profit. Yet other alternate roots have been established by certain individuals to protest the policies developed by the broader community processes for management of the authoritative root, or to express their disinterest in participating in those processes. These alternate roots have not been launched through any ICANN consensus processes, so they have not been entered into the authoritative root managed by the IANA or ICANN.

These alternate roots typically substitute insular concerns in place of the community-based processes that govern the management of the authoritative root. Their operators decide to include particular top-level domains in these alternate roots that have not been subjected to the tests of community support and conformance with consensus processes—coordinated by ICANN—that would allow their inclusion in the authoritative root. These decisions of the alternate root operators have been made with no apparent regard for the fundamental public-interest concern of Internet stability. The widespread introduction of active domain names into these alternate roots could in fact impair the uniqueness of the authoritative name resolution mechanism and hence the stability of the DNS.

In fact, some of the operators of these alternate roots state that stability is not an important attribute for the DNS. This thesis, for reasons already stated, is at fundamental variance with ICANN policy as embodied in its founding documents. Some of these operators and their supporters assert that their very presence in the marketplace gives them preferential right to TLDs to be authorized in the future by ICANN. They work under the philosophy that if they get there first with something that looks like a TLD and invite many registrants to participate, then ICANN will be required by their very presence and force of numbers to recognize in perpetuity these pseudo TLDs, inhibiting new TLDs with the same top-level name from being launched through the community's processes.

No current policy allows ICANN to grant such preferential rights. To do so would effectively yield ICANN's mandate to introduce new TLDs in an orderly manner in the public interest to those who would simply grab all the TLD names that seem to have any marketplace value, thus

circumventing the community-based processes that ICANN is required to follow. For ICANN to yield its mandate would be a violation of the public trust under which ICANN was created and under which it must operate. Were it to grant such preferential rights, ICANN would abandon this public trust, rooted in the community, to those who only act for their own benefit. Indeed, granting preferential rights could jeopardize the stability of the DNS, violating ICANN's fundamental mandate.

Alternate roots inherently endanger DNS stability—that is, they create the real risk of name resolvers being unable to determine to which numeric address a given name should point. This violates the fundamental design of the DNS and impairs the Internet's utility as a ubiquitous global communications medium. Some of these alternate systems also employ special technologies that—ingenious as they may be—may conflict with future generations of community-established Internet standards. Indeed, can there be any guarantee that these proprietary technologies can or will be adapted to future changes in Internet standards?

Experimentation

Experimentation has always been an essential component of the Internet's vitality. Working within the system does not preclude experimentation, including experimentation with alternate DNS roots. But these activities must be done responsibly, in a manner that does not disrupt the ongoing activities of others and that is managed according to experimental protocols.

DNS experiments should be encouraged. Experiments, however, almost by definition have certain characteristics to avoid harm: (a) they are clearly labeled as experiments, (b) it is well understood that these experiments may end without establishing any prior claims on future directions, (c) they are appropriately coordinated within a community-based framework (such as the IETF), and (d) the experimenters commit to adapt to consensus-based standards when they emerge through the ICANN and other community-based processes. This is very different from launching commercial enterprises that lull users into a sense of permanence without any sense of the foregoing obligations or contingencies.

Moreover, it is essential that experimental operations involving alternate DNS roots be conducted in a controlled manner, so that they do not adversely affect those who have not consented to participate in them. Given the design of the DNS, and particularly the intermediate-host and cache poisoning issues described earlier, special care must be taken to insulate the DNS from the alternate roots' effects. For example, alternate roots are commonly operated by large organizations within their private networks without harmful effects, since care is taken to prevent the flow of the alternate resource records onto the public Internet.

It should be noted that the original design of the DNS provides a facility for future extensions that accommodates the possibility of safely deploying multiple roots on the public Internet for experimental and other purposes. As noted in RFC 1034, the DNS includes a "class" tag on each resource record, which allows resource records of different classes to be distinguished even though they are commingled on the public Internet. For resource records within the authoritative root-server system, this class tag is set to "IN"; other values have been standardized for particular uses, including 255 possible values designated for "private use" that are particularly suited to experimentation.[10]

As described in a recent proposal within the IETF,[11] this "class" facility allows an alternate DNS namespace to be operated from different root servers in a manner that does not interfere with the stable operation of the existing authoritative root-server system. To take advantage of this facility, it should be noted, requires the use of client or applications software developed for the alternate namespace (presumably deployed after responsible testing), rather than the existing software that has been developed to interoperate with the authoritative root. Those who operate alternate roots for global commercial purposes, however, have not followed this course.

In an ever-evolving Internet, ultimately there may be better architectures for getting the job done where the need for a single, authoritative root will not be an issue. But that is not the case today. And the transition to such an architecture, should it emerge, would require community-based approaches. In the interim, responsible experimentation should be encouraged, but it should not be done in a manner that affects those who do not consent after being informed of the character of the experiment.

Conclusion

The success of the Internet and the guarantee of Internet stability rest on the cooperative activities of thousands, even millions, of people and institutions collaborating worldwide towards a common end. This extraordinary—even unprecedented—community effort has served to impel the incredible growth of the Internet. Many of these people and institutions compete intensely among themselves yet agree to do so within a common framework for the overall public good. Their collective efforts provide a policy framework for technical and entrepreneurial innovation, and the advancement of economic, social, and educational goals.

Most members of the global community and most institutions with which they are associated recognize that it is in their best long-term interests to work within these community-based processes, even if that means foregoing short-term advantages to particular individuals or groups. The over-arching principles outlined in this document override exclusive and narrowly focused self-interest.

Community-based policy development is not perfect. It may proceed slower than some would wish. The introduction of new TLDs has proceeded at deliberate speeds. Impatience in the context of Internet timescales is perfectly understandable. The outcome of orderly processes based on the wishes of the community, however, is assurance that the Internet will continue to function in a stable and holistic manner that benefits the global community, and not become captured by the self-interests of the few. That, in the minds of most, is a price worth paying.

ICANN—in deference to its public trust—will continue to collaborate with these citizens of the Internet community to advance the notions of a unique root system as a prerequisite to Internet stability, and to ensure that community-based policies take precedence. ICANN encourages responsible experimentation designed to further advance the Internet as a useful, stable, and accessible medium for the public good.

References

[1] Ironically, to avoid name conflicts in a multi-root system, a single-root system would need to be created-adding a higher level to the hierarchy.

Book Review

Web Protocols and Practice

Web Protocols and Practice: HTTP/1.1, Networking Protocols, Caching, and Traffic Measurement, by Balachander Krishnamurty and Jennifer Rexford, ISBN 0-201-71088-9, Addison-Wesley, 2001.

If you want to know something about the underlying workings of the Web, you can find it somewhere out there on the Web itself. But, as we all know, it is not always easy to find the page you want, and particularly not if you are in a hurry and don't want to have to wade through documentation hierarchies or download PDF files. In these cases a real book is unbeatable, if one is available. Sadly, for information about the lower reaches of Web protocols there has been no single useful printed reference source available.

Organisation

This book fills that gap. It provides a detailed look at all the low level protocol issues as well as many other things; the book's subtitle sums it up admirably. The first section provides a brief history of the Web and its development which introduces all the important terminology and, most importantly, also says what the book is *not* about: nothing on XML (hurrah!), HTML, scripting languages, administration of Web servers, or specific products.

Section two moves on to more technical matters looking at Web clients, proxies and servers. The client chapter has a particularly useful section on spiders with an excellent table showing the names and calling hosts of the commonest spider programs. The information about proxies and servers is also of high quality and provide a solid grounding in how they interact with each other and the potential problems that can arise.

The third section looks at the protocols involved when using the Web. Starting with a concise run through TCP and the use of the DNS, the authors then glance at FTP, SMTP and NNTP, before going to a detailed examination of HTTP/1.1. In my personal experience, information on HTTP/1.1 has always been particularly inaccessible, both from the point of view of discoverability and readability, and this chapter explained several things that I had been puzzled about, especially about cache control which is rather a black art. (Also featured is a comprehensive table of HTTP return codes to which I shall turn quite often.) To finish this section of the book, there is a chapter on how HTTP interacts with TCP—a whole area that I had never really thought about before and which is much more complex that I would have thought it to be.

Next is a short section devoted to measuring and characterizing Web traffic. This a hugely contentious area and the discussion is well balanced and sensible. Following this the authors look in more detail at caching and at multimedia streaming, and manage to cover the latter topic without going into much unnecessary details about the actual bits that get sent whilst still giving a good coverage of the important material.

To round off the book, there are three chapters devoted to research topics, looking again at caching, measurement and protocol issues. Much of the material here is not directly of relevance to someone who is dealing with Web protocols on a daily basis, but there is still much here that will be of interest as the authors draw attention to places where improvements can be expected and how these might be realised.

Excellent Book

As you might expect, there is also a comprehensive bibliography and index. All in all an excellent book that is well researched, well written, and clearly set out without the excess of white space that is so common in computing books today. The price is perhaps rather high (I certainly could not recommend this as a textbook to my students—they simply could not afford it), but for people working in the industry it would be a worthwhile purchase and I think that they would soon find it an indispensable source of reference.

Would You Like to Review a Book for IPJ?

We receive numerous books on computer networking from all the major publishers. If you've got a specific book you are interested in reviewing, please contact us and we will make sure a copy is mailed to you. The book is yours to keep if you send us a review. We accept reviews of new titles, as well as some of the "networking classics." Contact us at **ipj@cisco.com** for more information.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

Next ICANN Meeting, Marina del Rey, November 13–15, 2001

Many members of the *Internet Corporation for Assigned Names and Numbers* (ICANN) community wrote in response to a call for input as to whether the events of September 11 would affect their plans to travel to Los Angeles in November to attend the scheduled ICANN meetings. Almost without exception the respondents emphatically encouraged ICANN to hold its meetings and stated unequivocally that they planned to attend unless the international situation deteriorated to where travel was not practical.

Given this response and given the need to address emerging priorities, ICANN is planning to proceed with its November meeting, subject to any further serious change in the international situation that would affect travel conditions. However, as discussed below, the format of the meeting will differ significantly from what had previously been announced.

The events of September 11 have caused institutions worldwide to rethink their priorities and plans. As an international institution, ICANN is not immune. Although those events raise logistical and other concerns for holding meetings, they also underscore the need to address Internet stability issues, and security as a key component of stability. ICANN is not responsible for the overall security of the Internet. However, given ICANN's global responsibilities for the stability of the Internet's naming and addressing systems and under the new circumstances facing the international community, it would be irresponsible for ICANN not to conduct an in depth assessment of the robustness and security of these systems, and to take steps, if necessary, to strengthen the Internet in these regards. These are urgent matters and of worldwide importance.

The Internet is global in reach, as are the threats of terrorism. The events of September 11 offered a stark and tragic reminder of the incalculable importance of a reliable and secure naming and addressing system to support emergency response, personal and other communications, and information sharing. E-mail, instant messaging, and the Web, for example, all played essential roles.

Accordingly, the November ICANN meetings will focus on stability and security of the Internet's naming and addressing systems and of their operational implementation globally. This will be the overriding imperative for the meeting. As such, this will be a very different kind of meeting than previous ICANN meetings and will not follow the usual format.

At this meeting, ICANN will be seeking to promote discussion throughout the community on how to reassess areas of potential threats that could affect services within the scope of ICANN's responsibilities, how to improve readiness to meet these threats, and what additional policies or other actions should be considered and implemented to facilitate such improvements.

Clearly not all these questions will be answered in one meeting, but ICANN must now devote its energies as members of the global Internet community towards obtaining answers. Every constituency and supporting organization will be asked to report on its efforts to ensure the stability of the Internet's naming and addressing systems and what additional steps it proposes to take to improve that stability and security among its member organizations. Agenda items will be assessed for inclusion by what they contribute to the overall focus of the meeting.

Although a precise schedule has not yet been mapped out, these meetings will last three days from November 13 through 15, inclusive. Constituencies and supporting organizations will be asked to meet during this time to focus on the topic of the meeting. There will be a Board meeting at the end of the meeting to address essential business. The Board agenda will concentrate on topics where time is of the essence.

The focus of the meetings may well delay progress on some of the worthy and important initiatives that are currently underway. The effects of such delays have to be measured against the importance of ensuring the stability and security of the Internet itself. This will require patience on the part of those who may experience delays in matters of importance to them so that the ICANN community can bear down on the issue at hand.

This is only a preliminary announcement to enable attendees to firm up their travel plans. Details of the meeting will be announced as soon as possible. Please visit the ICANN Web site (**`http://www.icann.org`**) for further updates.

Van Jacobson Receives 2001 ACM SIGCOMM Award

Van Jacobson, the man widely credited with saving the Internet from an otherwise inevitable congestion collapse in the late 1980s, has been named the 2001 recipient of the ACM SIGCOMM Award. Jacobson is chief scientist at networking startup Packet Design, LLC.

The award is given annually by the *Association for Computing Machinery's Special Interest Group in Data Communications* (ACM SIGCOMM) to a recipient with a long and distinguished history of contributing to the field of data communications. Jacobson began his career in data communications developing control systems for the Department of Energy in the 1970s. He is best known for redesigning the TCP/IP protocol's flow-control algorithms to better handle congestion, preventing the Internet's collapse from traffic congestion in 1988–89. He is also widely recognized for his work on network synchronization effects, scalable multimedia protocols and applications, IP operations tools (for example *traceroute* and *pathchar*) and high-performance TCP implementations.

Prior to joining Packet Design as a member of the founding team, Jacobson was chief scientist at Cisco Systems, and before that had been group leader for Lawrence Berkeley Laboratory's Network Research Group.

The SIGCOMM Award has been presented every year since 1989. Prior recipients include Paul Baran, Vinton G. Cerf, David Farber and Leonard Kleinrock. ACM SIGCOMM is the world's largest professional society devoted to data communications. For more information, see: **http://www.acm.org/sigcomm/**

Useful Links

- The *Internet Engineering Task Force* (IETF). The primary standards-setting body for Internet technologies. **http://www.ietf.org**
- *Internet-Drafts* are working documents of the IETF, its areas, and its working groups. Note that other groups may also distribute working documents as Internet-Drafts. Internet-Drafts are not an archival document series. These documents should not be cited or quoted in any formal document. Unrevised documents placed in the Internet-Drafts directories have a maximum life of six months. After that time, they must be updated, or they will be deleted. Some Internet-Drafts become RFCs (see below). **http://www.ietf.org/ID.html**
- The *Request For Comments* (RFC) document series. The RFCs form a series of notes, started in 1969, about the Internet (originally the ARPANET). The notes discuss many aspects of computer communication, focusing on networking protocols, procedures, programs, and concepts but also including meeting notes, opinion, and sometimes humor. The specification documents of the Internet protocol suite, as defined by IETF and its steering group the IESG, are published as RFCs. Thus, the RFC publication process plays in important role in the Internet standards process. **http://www.rfc-editor.org/**
- The *Internet Society* (ISOC) is a non-profit, non-governmental, international, professional membership organization. **http://www.isoc.org**
- The *Internet Corporation for Assigned Names and Numbers* (ICANN) "... is the non-profit corporation that was formed to assume responsibility for the IP address space allocation, protocol parameter assignment, domain name system management, and root server system management functions previously performed under U.S. Government contract by IANA and other entities." **http://www.icann.org**

- The *North American Network Operators' Group* (NANOG) "...provides a forum for the exchange of technical information, and promotes discussion of implementation issues that require community cooperation. Coordination among network service providers helps ensure the stability of overall service to network users."
  http://www.nanog.org
- The *Regional Internet Registries* (RIRs) provide IP address block assignments for Internet Service Providers and others. Currently, there are three active RIRs:
  - The *Asia Pacific Network Information Centre* (APNIC):
    http://www.apnic.net
  - *RIPE Network Coordination Centre*—the RIR responsible for Europe and Northern Africa: **http://www.ripe.net**
  - *American Registry for Internet Numbers* (ARIN)—the RIR responsible for the Americas and Sub-Saharan Africa:
    http://www.arin.net

  Two more RIRs are in the process of formation: *AfriNIC* for Africa and *LACNIC* for Central- and Latin America.
- The *World Wide Web Consortium* (W3C) " ... develops interoperable technologies (specifications, guidelines, software, and tools) to lead the Web to its full potential as a forum for information, commerce, communication, and collective understanding."
  http://www.w3.org/
- The *International Telecommunication Union* (ITU) "... is an international organization within which governments and the private sector coordinate global telecom networks and services."
  http://www.itu.int
- The *International Organization for Standardization* (ISO) " ... is a worldwide federation of national standards bodies from some 140 countries, one from each country. The mission of ISO is to promote the development of standardization and related activities in the world with a view to facilitating the international exchange of goods and services, and to developing cooperation in the spheres of intellectual, scientific, technological and economic activity. ISO's work results in international agreements which are published as International Standards." **http://iso.org**

This is by no means intended to be a complete list of organizations that are related to Internet development in one way or another, but this list should give you a good starting point.

From The Editor

In a previous article entitled "Analyzing the Internet BGP Routing Table," Geoff Huston examined many issues relating to the operation of today's Internet. In this issue he goes a step further and suggests ways in which the fundamental routing architecture could be changed to solve problems related to routing-table growth. The article is called "Scaling Inter-Domain Routing—A View Forward."

The IP address space is administered by three entities, namely APNIC, ARIN and RIPE NCC. Collectively referred to as the *Regional Internet Registries* (RIRs), these organizations are responsible for address allocation to their member organizations (typically national registries or large Internet Service Providers). Since the IPv4 address space is a limited resource, this allocation has to be done with care, while accounting for the needs of the adress space consumers. We asked the RIRs for an overview of the work they perform. What we received was a joint effort that not only describes the RIR structure, but also gives some historical background on the evolution of IP addressing and routing.

We were pleased to receive a couple of Letters to the Editor recently, both in response to articles in our previous issue. This kind of feedback is most welcome and we encourage you to send your comments and suggestions to **ipj@cisco.com**

We'd like to remind you that all back issues of *The Internet Protocol Journal* can be downloaded from **www.cisco.com/ipj**. Click on "IPJ Issues" and you will be taken to the appropriate section.

By the time you read this, our online subscription system should be operational. You will find it at our Web site: **www.cisco.com/ipj**. Please let us know if you encounter any difficulties by sending e-mail to **ipj@cisco.com**

Scaling Inter-Domain Routing—A View Forward

by Geoff Huston,Telstra

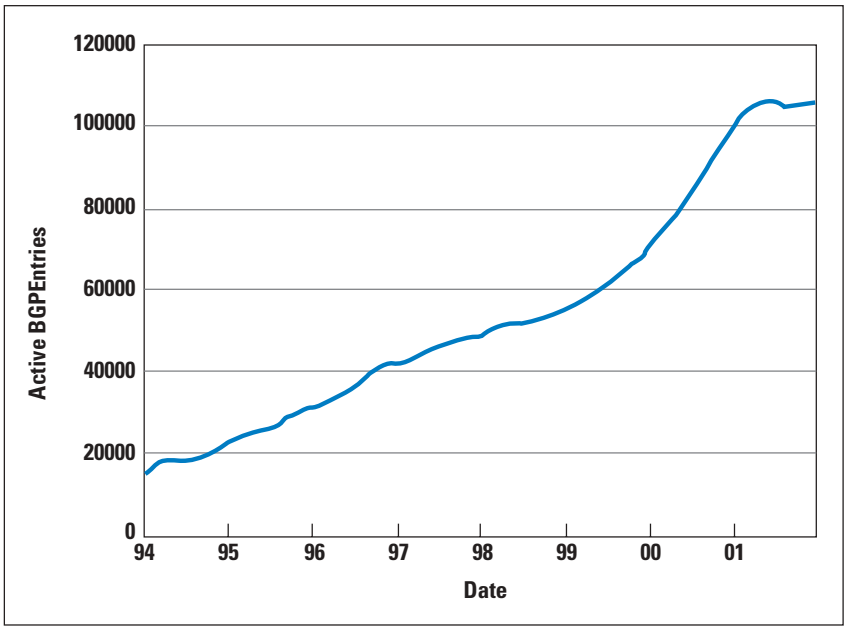
In the previous IPJ article, "Analyzing the Internet BGP Routing Table," (Vol. 4, No. 1, March 2001) we looked at the characteristics of the growth of the routing table in recent years. The motivation for this work is to observe aspects of the Internet routing table in order to understand the evolving structure of the Internet and thereby attempt to predict some future requirements for routing technology for the Internet.

The conclusions drawn in the previous article included the observation that multihomed small networks appeared to be a major contributor to growth of the Internet routing system. It also observed that there was a trend toward a denser mesh of inter-Autonomous System connectivity within the Internet. At the same time there has been an increase of various forms of policy-based constraints imposed upon this connectivity mesh, probably associated with a desire to undertake various forms of inter-domain traffic engineering through manipulation of the flow of routing information.

Taken together, these observations indicate that numerous strong growth pressures are being exerted simultaneously on the inter-domain routing space. Not only is the network itself growing in size, but also the internal interconnectivity of the network is becoming more densely meshed. The routing systems that are used to maintain a description of the network connectivity are being confronted with having to manipulate smaller route objects that describe finer levels of network detail. This is coupled with lengthening lists of qualifying attributes that are associated with each route object. The question naturally arises as to whether the *Border Gateway Protocol* (BGP) and the platforms used to support BGP in the Internet today can continue to scale at a pace that matches the growth in demands that are being placed upon it.

The encouraging news is that there appears to be no immediate cause for concern regarding the capability of BGP to continue to support the load of routing the Internet. The processor and memory capacity in current router platforms is easily capable of supporting the load associated with various forms of operational deployment models, and the protocol itself is not in imminent danger of causing network failure through any internal limitation within the protocol itself. Also, numerous network operators have exercised a higher level of care as to how advertisements are passed into the Internet domain space and, as a result, the growth rates for the routing table over 2001 shows a significant slowdown over the rates of the previous two years (Figure 1).

Figure 1: BGP Table Size 1994–2001



However, the observed trends in inter-domain routing of an increasingly detailed and highly qualified view of a more densely interconnected and still-growing network provide adequate grounds to examine the longer-term routing requirements. It is useful, therefore, to pose the question as to whether we can continue to make incremental changes to the BGP protocol and routing platforms, or whether the pace of growth will, at some point in time, mandate the adoption of a routing architecture that is better attuned to the evolving requirements of the Internet.

This article does not describe the operation of an existing protocol, nor does it describe any current operational practice. Instead it examines those aspects of inter-domain routing that are essential to today's Internet, and the approaches that may be of value when considering the evolution of the Internet inter-domain routing architecture. With this approach, the article illustrates one of the initial phases in any technology development effort—that of an examination of various requirements that could or should be addressed by the technology.

Attributes of an Inter-Domain Routing Architecture

Let's start by looking at those aspects of the inter-domain routing environment that could be considered a base set of attributes for any inter-domain routing protocol.

Accuracy

For a routing system to be of any value, it should accurately reflect the forwarding state of the network. Every routing point is required to have a consistent view of the routing system in order to avoid forwarding loops and black holes (points where there is no relevant forwarding information and the packet must be discarded). Local changes in underlying physical network, or changes in the policy configuration of the network at any point, should cause the routing system to compute a new distributed routing state that accurately reflects the changes.

This requirement for accuracy and consistency is not, strictly speaking, a requirement that every node in a routing system has global knowledge, nor a requirement that all nodes have precisely the same scope of information. In other words, a routing system that detects and avoids routing loops and inconsistent black holes does not necessarily need to use routing systems that rely on uniform distribution of global knowledge frameworks.

Scalability

Scalability can be expressed in many ways, including the number of routing entries, or prefixes, carried within the protocol, the number of discrete routing entities within the inter-domain routing space, the number of discrete connectivity policies associated with these routing entries, and the number of protocols supported by the protocol. Scalability also needs to encompass the dynamic nature of the network, including the number of routing updates per unit of time, time to converge to a coherent view of the connectivity of the network following changes, and the time taken for updates to routing information to be incorporated into the network forwarding state. In expressing this ongoing requirement for scalability in the routing architecture, there is an assumption that we will continue to see an Internet that is composed of a large number of providers, and that these providers will continue to increase the density of their interconnection.

The growth trends in the inter-domain routing space do not appear to have well-defined upper limits, so placing bounds on various aspects of the routing environment is impractical. The only practical way to describe this attribute is that it is essential to use a routing architecture that is scalable to a level well beyond the metrics of today's Internet.

In the absence of specific upper bounds to quantify this family of requirements, the best we conclude here is that at present we are working in an inter-domain environment that manipulates some 10^5 distinct routing entries, and at any single point of interconnection there may be of the order of 10^6 routing protocol elements being passed between routing domains. Experience in scaling transmission systems for the Internet indicates that an improvement of a single order of magnitude in the capacity of a technology has a relatively short useful lifetime. It would, therefore, be reasonable to consider that a useful attribute is to be able to operate in an environment that is between two to three orders of magnitude larger than today's system.

Policy Expressiveness

Routing protocols perform two basic tasks: first, determining if there is at least one viable path between one point in the network and another, and secondly, where there is more than one such path, determining the "best" such path to use. In the case of interior routing protocols, "best" is determined by the use of administratively assigned per-link metrics, and a "best" path is one that minimizes the sum of these link metrics.

In the case of the inter-domain routing protocols, no such uniformly interpreted metric exists, and "best" is expressed as a preference using network paths that yield an optimal price and performance outcome for each domain.

The underlying issue here is that the inter-domain routing system must straddle a collection of heterogeneous networks, and each network has a unique set of objectives and constraints that reflect the ingress, egress, and transit routing policies of a network. Ingress routing policies reflect how a network learns information, and which learned routes have precedence when selecting a routing entry from a set of equivalent routes. In a unicast environment, exercising control over how routes are learned by a domain has a direct influence over which paths are taken by traffic leaving the domain. Egress policies reflect how a domain announces routes to its adjacent neighbors. A domain may, for example, wish to announce a preferential route to a particular neighbor, or indicate a preference that the route not be forwarded beyond the adjacent neighbor. In a unicast environment, egress routing policies have a bearing on which paths are used for traffic to reach the domain. Transit routing policies control how the routes learned from an adjacent domain are advertised to other adjacent domains. If a domain is a transit provider for another domain, then a typical scenario for the transit provider would be to announce all learned routes to all other connected domains. For a multi-homed transit customer, routes learned from one transit provider would normally not be announced to any other transit provider.

This requirement for policy expressiveness implies that the inter-domain routing protocol should be able to attach various attributes to protocol objects, allowing a domain to communicate its preferences relating to handling of the route object to remote domains.

Robust Predictable Operational Characteristics

A routing system should operate in such a way that it achieves predictable outcomes. The inference here is that under identical initial conditions a routing system should always converge to the same routing state, and that with knowledge of the rules of operation of the protocol and the characteristics of the initial environment, an observer can predict what this state will be. Predictability also implies stability of the routing environment, such that a routing state should remain constant for as long as the environment itself remains constant.

The routing protocol should operate in a way that tends to damp propagation of dynamic changes to the routing system rather than amplify such changes. This implies that minor variations in the state of the network should not cause large-scale instability across the entire network while a new stable routing state is reached. Instead, routing changes should be propagated only as far as necessary to reach a new stable state, so that the global requirement for stability implies some degree of locality in the behavior of the system.

The routing system should have robust convergence properties. A change in the physical configuration or policy environment in any part of the network causes a distributed computation of the routing state. Convergence implies that this distributed computation reaches a conclusion at some point. The requirement for a robust convergence property implies that the distributed computation should always halt, that the halting point be reached quickly, and the system should avoid generating transitory incorrect intermediate routing states. The interpretation of "quickly" in this context is variable. Currently, this value for BGP convergence time is of the order of tens to hundreds of seconds. In order to support increasingly time-critical applications, there appears to be an emerging requirement to reduce the median convergence time for the inter-domain routing protocol to a small number of seconds.

Efficiency

The routing system should be efficient, in that the amount of network resources, in terms of bandwidth and processing capacity of the network switching elements, should not be disproportionately large. This is an area of trade-off in that the greater the amount of information passed within the routing system and the greater the frequency of such information exchanges, the greater the level of expectation that the routing system can continuously maintain an accurate view of the connectivity of the network, but at a cost of higher overhead. It is necessary to pass enough information across the system to allow each routing element to have a sufficiently accurate view of the network, yet ensure that the total routing overhead is low.

Evolving Requirements of Inter-Domain Routing

Layered on top of the base set of routing requirements listed above are a second set of requirements that can be seen as reflecting current directions in the deployed Internet, and are not necessarily well integrated into the existing routing architecture.

Multi-Homing of Edge Networks

Multi-homing refers to the practice of using more than one upstream transit provider. The common motivation for such a configuration is that if service from one transit provider fails, the customer can use the other provider as a means of service restoration. It may also allow some form of traffic balancing across multiple services. With careful use of route policies, the customer can direct traffic to each provider to minimize delay and loss, achieving some improved application performance.

The issue presented by multi-homing is that the multi-homed network is now not wholly contained within a service hierarchy of any particular provider. This implies that routing information describing reachability to the multi-homed customer cannot readily be aggregated into any single provider's routing advertisements, and the usual outcome is that the multi-homed customer must independently announce its reachability to each transit provider, who in turn must propagate this information across the routing system.

The evolving requirement here is one that must be able to integrate the demands of an increasing use of multi-homing into the overall network design. Two basic forms of approach can be used here—one is to use a single address block across the customer network and announce this block to all transit providers as an unaggregatable routing advertisement into the inter-domain routing system, and the other is to use multiple address blocks drawn from each provider's address block, and use either host-based software or some form of dynamic address translation within the network in order to use a source address drawn from a particular provider's block for each network transaction (Figure 2). The second approach is not widely used, and for the immediate future the requirement for multi-homing is normally addressed by using unique address blocks for the multi-homed network that are not part of any provider's aggregated address blocks. The consequence of this is that widespread use of multi-homing as a means of service resiliency will continue to have an impact on the inter-domain routing system.

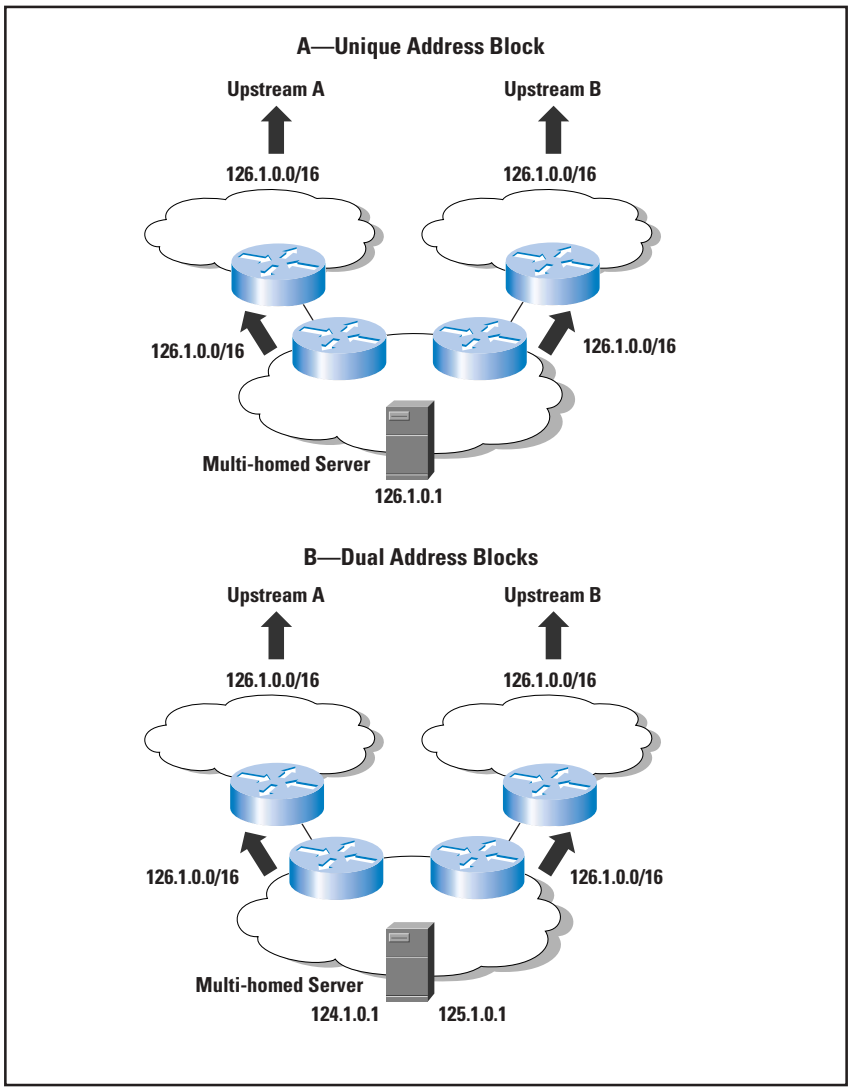


Figure 2: Routing Approaches to Multi-Homing

Inter-Domain Traffic Engineering

In an increasingly densely interconnected network, selecting and using just one path between two points is not an optimal outcome of a routing architecture. Of more importance is the ability to identify a larger set of viable paths between these points and distribute the associated traffic flows in such a way that each individual transaction uses a single path, but the total set of flows is distributed across the set of paths.

To achieve this outcome, more information must be placed into the routing system, allowing a route originator to describe the policy-based preferences of which sets of paths should be preferred for traffic destined to the route originator, allowing a transit service operator to add information regarding current preferences associated with using particular transit paths, and allowing the traffic originator the ability to use local traffic egress policies to reach the destination. These traffic engineering-related preferences are not necessarily represented by static values of routing attributes. One of the requirements of traffic engineering is to allow the network to dynamically respond to shifting traffic load patterns, and this implies that there is a component of dynamic information update that is associated with such traffic engineering-related aspects of the routing system.

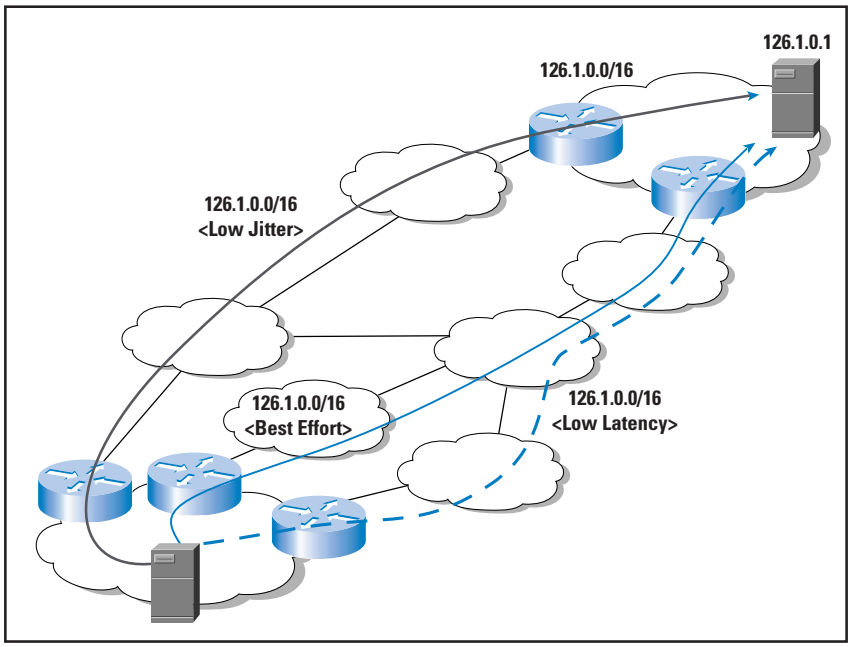
At an abstract level, this greater volume of routing information is needed in order to address the dual role of the routing system as both an inter-domain connectivity maintenance protocol and as a traffic-engineering tool.

Inter-Domain Quality of Service

Quality of Service (QoS) is a term that encompasses a wide variety of mechanisms. In the case of routing, the term is used to describe the process of modifying the normal routing response of associating a single forwarding action with a destination address prefix in such a way that there may be numerous forwarding decisions for a particular address prefix. Each forwarding decision is associated with a particular service response, so that a "best-effort" path to a particular destination address may differ from a "low-latency" path, which in turn may differ from a "high-bandwidth" path, and so on.

As with inter-domain traffic engineering, this requirement is one which would be expected to place greater volumes of information into the routing domain. At an abstract level this requirement can be seen as the association of a service quality attribute with an address prefix, and passing the paired entity into the routing domain as a single routing object. The inference is that multiple quality attributes associated with a path to a particular prefix would require the routing system to independently manipulate multiple route objects, because it would be reasonable to anticipate that the routing system would select different paths to reach the same address prefix if different QoS service attributes were used as a path qualifier (Figure 3).

Figure 3: Inter-Domain Routing with QoS



Approaches to Inter-Domain Routing

Let's now take this set of requirements and attempt to match them to various approaches to routing protocols.

Routing is a distributed computation wherein each element of the computation set must reach an outcome that is consistent with all other computations undertaken by other members of the set. There are two major approaches to this form of distributed computation, namely *serial* or *parallel* computation. Serial computation involves each element of the set undertaking a local computation and then passing the outcomes of this computation to its adjacent elements. This approach is used in various forms of distance-vector routing protocols where each routing node computes a local set of selected paths, and then propagates the set of reachable prefixes and the associated path metric to its neighbors. Parallel computation involves rapid flooding of the current state of connectivity within the set to all elements, and all set elements simultaneously compute forwarding decisions using the same base connectivity data. This approach is used in various forms of link-state routing protocols, where the protocol uses a flooding technique to rapidly propagate updated link-status information and then relies on each routing node to perform a local path selection computation for each reachable address prefix. Is one of these approaches substantially better suited than the other to the inter-domain routing environment?

Open or Closed Routing Policies

One of the key issues behind consideration of this topic is that of the role of *local policy*. Using a distance-vector protocol, a routing domain gathers selected path information from its neighbors, applies local policy to this information, and then distributes this updated information in the form of selected paths to its neighbor domains.

In this model the nature of the local policy applied to the routing information is not necessarily visible to the domain neighbors, and the process of converting received route advertisements into advertised route advertisements uses a local policy process whose policy rules are not visible externally. This scenario can be described as *policy opaque*. The side effect of such an environment is that a third party cannot remotely compute which routes a network may accept and which may be readvertised to each neighbor.

In link-state protocols, a routing domain effectively broadcasts its local domain adjacencies, and the policies it has with respect to these adjacencies, to all nodes within the link-state domain. Every node can perform an identical computation upon this set of adjacencies and associated policies in order to compute the local inter-domain forwarding table. The essential attribute of this environment is that the routing node has to announce its routing policies in order to allow a remote node to compute which routes will be accepted from which neighbor, and which routes will be advertised to each neighbor and what, if any, attributes are placed on the advertisement. Within an interior routing domain the local policies are in effect metrics of each link, and these polices can be announced within the routing domain without any consequent impact.

In the exterior routing domain it is not the case that interconnection policies between networks are always fully transparent. Various permutations of supplier/customer relationships and peering relationships have associated policy qualifications that are not publicly announced for business competitive reasons. The current diversity of interconnection arrangements appears to be predicated on policy opaqueness, and to mandate a change to a model of open interconnection policies may be contrary to operational business imperatives. An inter-domain routing tool should be able to support models of interconnection where the policy associated with the interconnection is not visible to any third party. If the architectural choice is a constrained one between distance vector and link state, then this consideration would appear to favor the continued use of a distance-vector approach to inter-domain routing. This choice, in turn, has implications on the convergence properties and stability of the inter-domain routing environment. If there is a broader spectrum of choice, the considerations of policy opaqueness would still apply.

Separation of Functions

The inter-domain routing function undertakes many roles simultaneously. First, it maintains the current view of inter-domain connectivity. Any changes in the adjacency of a domain are reflected in a distributed update computation that determines if the adjacency change implies a change in path selection and in address reachability. Secondly, it maintains the set of currently reachable address prefixes. And finally, the protocol binds the first two functions together by associating each prefix with a path through the inter-domain space.

This association uses a policy framework to allow each domain to select a path that optimizes local policy constraints within the bounds of existing constraints applied by other domains. This policy may be related to traffic-engineering objectives, QoS requirements, local cost optimization, or related operational or business objectives.

An alternative approach to inter-domain routing is to separate the functions of connectivity maintenance, address reachability, and policy negotiation. As an example of this approach, a connectivity protocol can be used to identify all viable paths between a source and a destination domain. A policy negotiation protocol can be used to ensure that there are a consistent sequence of per-domain forwarding decisions that will pass traffic from the source domain to the destination domain. An address reachability protocol can be used to associate a collection of address prefixes with each destination domains. This framework is illustrated in Figure 4.

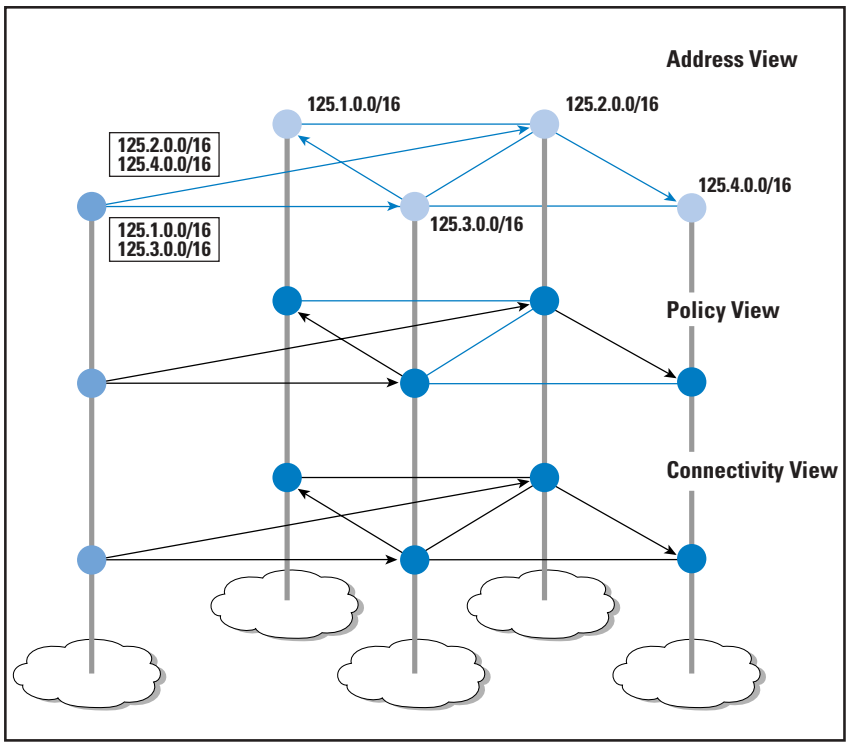


Figure 4: A Multi-Tiered Approach to Inter-Domain Routing

Address Prefixes and Autonomous System Numbers

One observation about the current inter-domain routing system is that it uses a view of the network based on computing the optimal path to each address prefix. This view is translated into an inter-domain routing protocol that uses the address prefix as the basic protocol element and attaches various attributes to each address prefix as they are passed through the network

As of late 2001, the routing system had some 100,000 distinct address prefixes and 11,500 origin domains. This implies that each origin domain is responsible for an average of 8 to 9 address prefixes. If each domain advertised its prefixes with a consistent policy, then each address prefix would be advertised with identical attributes. If the routing protocol were to be inverted such that the routing domain identifier, or *Autonomous System* number, were the basic routing object and the set of prefixes and associated common set of route attributes were attributes of the Autonomous System object, then the number of routing objects would be reduced by the same factor of between 8 and 9.

The motivation in this form of approach is that seeking clear hierarchical structure in the address space as deployed is no longer feasible, and that no further scaling advantage can be obtained by various forms of address aggregation within the routing system. This approach replaces this address-based hierarchy with a two-level hierarchy of routing domains. Within a routing domain, routing is undertaken using the address prefix. Between routing domains, routing is undertaken using domain identifiers and associated sets of domain attributes.

Although this approach appears to offer some advantage in creating a routing domain, one-tenth of the size of the address prefix-based routing domain, it is interesting to note that since late 1996 the average number of address prefixes per Autonomous System has fallen from 25 to the current value of 9. In other words, the number of distinct routing domains is growing at a faster rate than the number of routed address prefixes. While the adoption of a domain-based routing protocol offers some short-term advantages in scaling, the longer-term prospects are not so attractive, given these relative growth rates.

Routing Hierarchies of Information

The scaling properties of an inter-domain routing protocol are related on the ability of the protocol to remove certain specific items of information from the routing domain at the point where it ceases to have any differentiating impact. For example, it is important for a routing protocol to carry information that a particular domain has multiple adjacencies and that there are a number of policies associated with each adjacency, and propagate this information to all local domains. At a suitably distant point in the network, the forwarding decision remains the same regardless of the set of local adjacencies, and propagation of the detail of the local environment to points where the information ceases to have any distinguishing outcome is unproductive.

From this perspective, scaling the routing system is not a case of determining what information can be added into the routing domain, but instead it's a case of determining how much information can be removed from the routing domain, and how quickly.

One way of removing information is through the use of *hierarchies*. Within a hierarchical structure, a set of objects with similar properties are aggregated into a single object with a set of common properties. One way to perform such aggregation is by increasing the amount of information contained in each aggregate route object. For example, if single route objects are to be used that encompass a set of address prefixes and a collection of Autonomous Systems, then it would be necessary to define additional attributes within the route object to further qualify the policies associated with the object in terms of specific prefixes, specific Autonomous Systems, and specific policy semantics that may be considered as policy exceptions to the overall aggregate. This approach would allow aggregation of routing information to occur at any point in the network, allowing the aggregator to create a compound object with a common set of attributes, and a set of additional attributes that apply to a particular subset of the aggregate.

Another approach to using hierarchies to reduce the number of route objects is to reduce the scope of advertisement of each routing object, allowing the object to be removed and proxy aggregated into some larger object when the logical scope of the object is reached. This approach would entail the addition of route attributes that could be used to define the circumstances where a specific route object would be subsumed by an aggregate route object without impacting the policy objectives associated with the original set of advertisements. This approach places control of aggregation with the route object originator, allowing the originator to specify the extent to which a specific route object should be propagated before being subsumed into an aggregate object.

It is not entirely clear that the approach of exploiting hierarchies in an address space is the most appropriate response to scaling pressures. Viewed from a more general perspective, scaling of the routing system requires the systematic removal of information from the routing domain. The way this is achieved is by attempting to align the structure of deployment with some structural property of the syntax of the protocol elements that are being used as routing objects. Information can then be eliminated through systematic aggregation of the routing objects at locations within the routing space that correspond to those points in the topology of the network where topology aggregation is occurring. The maintenance of this tight coupling of the structure of the deployed network to the structure of the identifier space is the highest cost of this approach. Alterations to the topology of the network through the relocation or reconfiguration of networks requires renumbering of the protocol element if hierarchical aggregation is to be maintained. If the address space is the basis of routing, as at present, then this becomes a large-scale exercise of renumbering networks that in turn implies an often prohibitively disruptive and expensive exercise of renumbering collections of host systems and associated services.

One view of this is that the connectivity properties of the Internet are already sufficiently meshed that there is no readily identifiable hierarchical structure, and that this trend is becoming more pronounced, not less. In that case, the most appropriate course of action may be to reexamine the routing domain and select some other attribute as the basis of the routing computation that does not have the same population, complexity, and growth characteristics as address prefixes, and base the routing computation on this attribute. One such alternative approach is to consider Autonomous System numbers as routing "atoms" where the routing system converges to select an Autonomous System path to a destination Autonomous System, and then uses this information to add the associated set of prefixes originated by this Autonomous System, and next-hop forwarding decision to reach this Autonomous System into the local forwarding table.

Extend or Replace BGP

A final consideration is to consider whether these requirements can best be met by an approach of a set of upward-compatible extensions to BGP, or by a replacement to BGP.

The rationale for extending BGP would be to increase the number of commonly supported transitive route attributes, and, potentially, allow a richer syntax for attribute definition which in turn would allow the protocol to use a richer set of semantic definitions in order to express more complex routing policies.

This direction may sound like a step backward, in that it proposes an increase in the complexity of the route objects carried by the protocol and potentially increases the amount of local processing capability required to generate and receive routing updates. However, this can be offset by potential benefits that are realizable through the greater expressive capability for the policy attributes associated with route objects. It can allow a route originator an ability to specify the scope of propagation of the route object, rather than assuming that propagation will be global. The attributes can also describe intended service outcomes in terms of policy and traffic engineering. It may also be necessary to allow BGP sessions to negotiate additional functionality intended to improve the convergence behavior of the protocol. Whether such changes can produce a scalable and useful outcome in terms of inter-domain routing remains, at this stage, an open question.

An alternative approach is that of a replacement protocol. Use of a parallel-processing approach to the distributed computation of routing, such as that used in the link-state protocols, can offer the benefits of faster convergence times and avoidance of unstable transient routing states. On the other hand, link-state protocols present issues relating to policy opaqueness, as described above. Another major issue with such an approach is the need to address the efficiency of inter-domain link-state flooding.

The inter-domain space would need some further levels of imposed structure similar to intra-domain areas in order to ensure that individual link updates are rapidly propagated across the relevant subset of the network. The use of such an area structure may well imply the need for an additional set of operator relationships, such as mutual transit. Such inter-domain relationships may prove challenging to adapt to existing operator practices.

Another approach could be based on the adoption of a multi-layer approach of separate protocols for separate functions, as described above. A base inter-domain connectivity protocol could potentially be based on a variant of a link-state protocol, using the rapid convergence properties of such protocols to maintain a coherent view of the current state of connectivity within the network. The overlay of a policy protocol would be intended as a signaling mechanism to allow each domain to make local forwarding decisions that are consistent with those adopted by adjacent domains, thereby maintaining a collection of coherent inter-domain paths from source to destination. Traffic engineering can also be envisaged as an overlay mechanism, allowing a source to make a forwarding decision that selects a path to the destination where the characteristics of the path optimize the desired service outcomes.

Directions for Further Activity

Although short-term actions based on providing various incentives for network operators to remove redundant or inefficiently grouped entries from the BGP routing table may exist, such actions are short-term palliative measures, and will not provide long-term answers to the need for a scalable inter-domain routing protocol. One approach to the longer-term requirements may be to preserve many of the attributes of the current BGP protocol, while refining other aspects of the protocol to improve its scaling and convergence properties. A minimal set of alterations could retain the Autonomous System concept to allow for administrative boundaries of information summarization, as well as retaining the approach of associating each prefix advertisement with an originating Autonomous System. The concept of policy opaqueness would also be retained in such an approach, implying that each Autonomous System accepts a set of route advertisements, applies local policy constraints, and readvertises those advertisements permitted by the local policy constraints. It could be feasible to consider alterations to the distance-vector path-selection algorithm, particularly as it relates to intermediate states during processing of a route withdrawal. It is also feasible to consider the use of compound route attributes, allowing a route object to include an aggregate route, and numerous specifics of the aggregate route, and attach attributes that may apply to the aggregate or a specific address prefix. Such route attributes could be used to support multi-homing and inter-domain traffic-engineering mechanisms. The overall intent of this approach is to address the major requirements in the inter-domain routing space without using an increasing set of globally propagated specific route objects.

Another approach is to consider the feasibility of decoupling the requirements of inter-domain connectivity management with the applications of policy constraints and the issues of sender- and receiver-managed traffic-engineering requirements. Such an approach may use a link-state protocol as a means of maintaining a consistent view of the topology of inter-domain network, and then use some form of overlay protocol to negotiate policy requirements of each Autonomous System, and use a further overlay to support inter-domain traffic-engineering requirements. The underlying assumption of such an approach is that if the functional role of inter-domain routing is divided into distinct components, each component will have superior scaling and convergence properties which in turn will result in superior properties for the entire routing system. Obviously, this assumption requires some testing.

Research topics with potential longer-term application include the approach of drawing a distinction between the identity of a network, its location relative to other networks, and maintenance of a feasible path set between a source and destination network that satisfies various policy and traffic-engineering constraints. Again the intent of such an approach would be to divide the current routing function into numerous distinct scalable components rather than using a single monolithic routing protocol.

Development of the Regional Internet Registry System

by Daniel Karrenberg, RIPE-NCC; Gerard Ross, APNIC; Paul Wilson, APNIC; Leslie Nobile, ARIN

The current system of managing Internet address space involves *Regional Internet Registries* (RIRs), which together share a global responsibility delegated to them by the *Internet Assigned Numbers Authority* (IANA). This regime is now well established, but it has evolved over ten years from a much simpler, centralized system. Internet number spaces were originally managed by a single individual "authority," namely the late Jon Postel, co-inventor of some of the most important technical features of today's Internet.

It is important to understand that the evolution of the RIR system was not simply the result of Internet growth and the natural need to refine and decentralize a growing administrative task. On the contrary, it arose from, and closely tracked, the technical evolution of the Internet Protocol, in particular the development of today's IP addressing and routing architecture.

In a relatively short time, the Regional Internet Registry system has evolved into a stable, robust environment for Internet address management. It is maintained today through self-regulatory practices that are well established elsewhere in the Internet and other industries, and it maintains its legitimacy and relevance by firmly adhering to open, transparent, participatory decision-making processes.

Before the RIRs:

IP Address Architecture

An important feature of the Internet Protocol (IP) is the ability to transparently use a wide variety of underlying network architectures to transport IP packets. This is achieved by encapsulating IP packets in whatever packet or frame structure the underlying network uses. Routers connecting different networks forward IP traffic by decapsulating incoming IP packets and then re-encapsulating them as appropriate for the next network to carry them.

To achieve this task with full transparency, the IP needed an addressing structure, which developed as a two-level hierarchy in both addressing and routing. One part of the address, the *network* part, identifies the particular network a host is connected to, while the other part, the *local* part, identifies the particular end system on that network.

Internet routing, then, has to deal only with the network part of the address, routing the packet to a router directly connected to the destination network. The local part is not used at all in Internet routing itself; rather it is used to determine the intended address within the addressing structure of the destination network.

The method by which the local part of an IP address is translated to a local network address depends on the architecture of the destination network—static tables, simple conversions, or special-purpose protocols are used as appropriate.

The original Internet addresses comprised 32 bits, the first 8 bits providing the network part and the remaining 24 bits the local part. These addresses were used for many years. However, in June 1978, in Internet Engineering Note (IEN) 46 "A proposal for addressing and routing in the internet," Clark and Cohen observed:

> "The current internet header has space to name 256 networks. The assumption, at least for the time being, is that any network entering the internet will be assigned one of these numbers. While it is not likely that a great number of large nets, such as the ARPANET, will join the internet, the trend toward local area networking suggests that a very large number of small networks can be expected in the internet in the not too distant future. We should thus begin to prepare for the day when there are more than 256 networks participating in the internet."

Classful Addressing

As predicted, it soon became necessary to adapt the address architecture to allow more networks to be connected. By the time the Internet Protocol itself was comprehensively specified (in RFC 790, published in 1981, edited by Jon Postel), the IP address could be segmented in numerous ways to provide three classes of network address.

In Class A, the high-order bit is zero, the next 7 bits are the network, and the last 24 bits are the local address. In Class B, the high-order 2 bits are one-zero, the next 14 bits are the network, and the last 16 bits are the local address. In Class C, the high-order 3 bits are one-one-zero, the next 21 bits are the network, and the last 8 bits are the local address.

This so-called "classful" architecture served the Internet for the next 12 years, during which time it grew from a small U.S.-based research network to a global academic network showing the first signs of commercial development.

Early Registration Models

In the 1980s, the American *National Science Foundation's* (NSF's) high-speed network, NSFNET, was connected to the ARPANET, a U.S. *Defense Advanced Research Projects Agency* (ARPA, now DARPA) wide-area network, which essentially formed the infrastructure that we now know as the Internet.

From these early days of the Internet, the task of assigning addresses was a necessary administrative duty, to ensure simply that no two networks would attempt to use the same network address in the Internet.

At first, the elementary task of maintaining a list of assigned network addresses was carried out voluntarily by Jon Postel, using (according to legend) a paper notebook.

As the Internet grew, and particularly as classful addressing was established, the administrative task grew accordingly. The IANA was established, and within it the Internet Registry (IR). But as the task of the IR outgrew Postel's notebook, it was passed to SRI International in Menlo Park, California, under a NSF contract, and was called the *Defense Data Network* (DDN) *Network Information Center* (NIC).

During this time, under the classful address architecture, networks were allocated liberally and to any organization that fulfilled the simple request requirements. However, with the accelerating growth of the Internet during the late 1980s, two problems loomed: the rapid depletion of address space, due to the crude classful divisions; and the uncontrolled growth of the Internet routing table, due to unaggregated routing information.

Conservation vs. Aggregation

The problems of "three sizes fit all" highlight the basic dilemma of address space assignment: conservation versus aggregation. On the one hand, one wants to conserve the address space by assigning as little as possible; on the other hand, one wants to ease routing-table pressures by aggregating as many addresses as possible in one routing-table entry.

This can be illustrated by looking at a typical networking setup of the time. Within organizations having a single Internet connection, buildings, departments, or campuses would have their own local networks. Often the use of multiple networks was dictated by distance limitations inherent in the emerging local-area networking technologies, such as Ethernet.

These networks typically had to accommodate more than the 254 hosts addressable by a Class C address, but would rarely exceed 1000 hosts. Using pure classful addressing, one could either subdivide networks artificially to remain below the 254 host limit, or use a Class B address for each local network, possibly wasting more than 60,000 addresses in each. Whereas the latter solution is obviously wasteful in terms of address space, the former is obviously cumbersome. Less obviously, the former also puts an additional burden on the Internet routing system, because each of these networks would require a separate route propagated throughout the whole Internet.

This basic dilemma persists to this day. Assigning address space generously tends to reduce the routing-table size, but wastes address space. Assigning conservatively will waste less, but cause more stress for the routing system.

Subnetting

In order to address some of the problems of classful addressing, the technique of *subnetting* was invented. Described in RFC 791 in 1984, subnetting provided another level of addressing hierarchy by inserting a *subnet* part into the IP address between the network and local parts. Global routing remained the same using the *network* part of the address (Class A, B, or C) until traffic reached a router on the network identified by the network part of the address. This router, configured for subnetting, would interpret a statically configured number of bits from the local part of the address (the subnet part) to route the packet further among a set of similarly configured routers. When the packet reached a router connected to the destination subnet, the remaining bits of the local part would be used to determine the local address of the destination as usual. So, in the previous example, the organization could have used a Class B address with 6-bit subnetting, a setup that would allow for 62 networks of 1022 hosts each.

Subnetting nicely solved the routing-table problem, because now only one global routing-table entry was needed for the organization. It also helped address space conservation somewhat because it provided an obvious alternative to using many sparsely populated Class B networks.

Because the boundary between the subnet part and the local part of an address could not be determined from the address itself, this local knowledge needed to be configured into the routers. At first this was done by static configuration. Later, interior routing protocols carried that information. Refer to RFC 791 for numerous historically interesting case studies.

Supernetting

Within seven years, however, it was becoming clear that subnetting was no longer sufficient to keep up with Internet growth. RFC 1338 stated the problem:

"As the Internet has evolved and grown ... in recent years, it has become painfully evident that it is soon to face several serious scaling problems. These include:

1. Exhaustion of the Class-B network address space. One fundamental cause of this problem is the lack of a network class of a size that is appropriate for a midsized organization; Class C, with a maximum of 254 host addresses, is too small while Class B, which allows up to 65534 addresses, is too large to be widely allocated.
2. Growth of routing tables in Internet routers beyond the ability of current software (and people) to effectively manage.
3. Eventual exhaustion of the 32-bit IP address space.

It has become clear that the first two of these problems are likely to become critical within the next one to three years."

The solution proposed was to extend the subnetting technique beyond the local organization, into the Internet itself. In other words, RFC 1338 proposed abolishing classful addressing, and replacing it with *supernetting*. The proposal was summarized as follows:

"The proposed solution is to hierarchically allocate future IP address assignment, by delegating control of segments of the IP address space to the various network service providers."

CIDR

In 1993, the supernetting technique was published as a standards track RFC under the name *Classless Inter-Domain Routing* (CIDR), by which it is known and used today. Two main ingredients were necessary to make CIDR work: routing system changes and new address allocation and assignment procedures.

Under CIDR, routers could no longer determine the network part of an address from the address itself. This information now needed to be conveyed by Internet routing protocols. Fortunately, there was only one such protocol in widespread use at the time, and it was quickly extended by the major router vendor of the time. According to legend, the necessary extensions of the *Border Gateway Protocol* (BGP)-3 to BGP-4 were designed on a napkin, with all implementors of significant routing software present. The changes were implemented in a matter of days, but only much later described by the Internet standards track RFC 1654.

CIDR also required that forwarding decisions of routers be changed slightly. The network part of an address, now more generally called the *prefix,* can be of any length. This means that a router can have multiple valid routes covering a specific 32-bit destination address. Routers need to use the most specific of these routes—*the longest prefix*—when forwarding packets.

In additional to technical changes, the success of CIDR also relied on the development of administrative procedures to allocate and assign address space in such a way that routes could be aggregated as much as possible. Because the Internet was evolving toward the current state of arbitrarily interconnected networks of *Internet Service Providers* (ISPs), it was obvious that ISPs should play a role in address space distribution. In the new technique, ISPs would now, as much as possible, assign address space to their customers in contiguous blocks, which could be aggregated into single routes to the rest of the Internet.

Emergence of the RIRs:

Internationalization

While the engineering-driven need for topological address space assignment was becoming clear, there was also an emerging recognition that the administrative mechanisms of address space distribution needed further development. A central system just would not scale for numerous reasons, including:

- Sheer volume
- Distance from the address space consumers
- Lack of an appropriate global funding structure
- Lack of local community support

The need to change administrative procedures was formally recognized by August 1990, when the Internet Activities Board published a message it had sent to the U.S. Federal Networking Council, stating "it is timely to consider further delegation of assignment and registration authority on an international basis" (RFC 1174).

The increasing cultural diversity of the Internet also posed administrative challenges for the central IR. In October 1992, the *Internet Engineering Task Force* (IETF) published RFC 1366, which described the "growth of the Internet and its increasing globalization" and set out the basis for an evolution of the registry process, based on a regionally distributed registry model. This document stressed the need for a single registry to exist in each geographical region of the world (which would be of "continental dimensions"). Registries would be "unbiased and widely recognized by network providers and subscribers" within their region. Each registry would be charged with allocating remaining address space in a manner "compatible with potential address aggregation techniques" (or CIDR).

RIPE NCC

While in the United States the Government continued to support and fund registry functions, this was not the case in other parts of the world. In Europe, IP network operators cooperating in *Réseaux IP Européens* (RIPE) realized the need for professional coordination and registration functions. Establishment of the RIPE *Network Coordination Centre* (NCC) was proposed in the same month that RFC 1174 was published. The RIPE NCC was to "function as a 'Delegated Registry' for IP numbers in Europe, as anticipated and defined in RFC 1174" (RIPE-19).

Although consensus among IP network operators was quickly established, it took almost two years of organizing and fund-raising before the first RIR was fully operational in May 1992. The RIPE NCC was organized as a highly independent part of RARE, the organization of European research networks. It was to be funded by contributions from those networks, as well as a small number of emerging commercial networks. The RIPE NCC published its first regional address distribution policy in July 1992 (RIPE-65).

During the following months, European regional policies were refined and, for the first time, global guidelines were published as RFCs (RFC 1366, RFC 1466).

The RIPE NCC is presently organized as a membership association, performing the essential coordination and administration activities required by the RIPE community. Located in Amsterdam, Netherlands, the RIPE NCC service region incorporates 109 countries covering Europe, the Middle East, Central Asia, and African countries located north of the equator. The RIPE NCC currently consists of more than 2700 members. At the time of publication, RIPE NCC is performing the secretariat function for the *Address Supporting Organization* (ASO) of The *Internet Corporation for Assigned Names and Numbers* (ICANN). More information about RIPE NCC is available at **`http://www.ripe.net`**

APNIC

Asia Pacific Network Information Centre (APNIC), the second RIR, was established in Tokyo in 1993, as a pilot project of APCCIRN (Asia Pacific Coordination Committee for Intercontinental Research Networks, now *Asia Pacific Networking Group* [APNG]).

The project was an intended as a trial model for servicing the Internet addressing needs of national *Network Information Centres* (NICs) and other networks throughout the region.

After a successful ten-month trial period, APNIC was established as a permanent organization to serve the Asia Pacific region (which includes 62 economies from Central and South Asia to the Islands of Oceania and the Western Pacific).

Originally, APNIC relied on the support of networking organizations and national NICs. However, in 1996, APNIC implemented a tiered membership structure.

APNIC relocated to Brisbane, Australia, in mid-1998. It currently services approximately 700 member organizations, across 39 economies of the region. Within the APNIC membership, there are also five *National Internet Registries* (NIRs), in Japan, China, Taiwan, Korea, and Indonesia. The NIRs perform analogous functions to APNIC at a national level and together represent the interests of more than 500 additional organizations.

In 2000, APNIC hosted the secretariat functions of the ASO in its inaugural year. More information about APNIC is available at:
`http://www.apnic.net`

ARIN

In 1991, the contract to perform the IR function was awarded to Network Solutions, Inc. in Herndon, Virginia. This included the transition of services including IP address registration, domain name registration and support, *Autonomous System Number* (AS) registration, user registration, online information services, help-desk operations, and RFC and Internet-Draft archive and distribution services (RFC 1261).

With explosive Internet growth in the early 1990s, the U.S. Government and the NSF decided that network support for the commercial Internet should be separated from the U.S. Department of Defense. The NSF originated a project named InterNIC under a cooperative agreement with *Network Solutions, Inc*. (NSI) in 1993 to provide registration and allocation of domain names and IP address numbers for Internet users.

Over time, after lengthy consultation with the IANA, the IETF, RIPE NCC, APNIC, the NSF, and the *Federal Networking Council* (FNC), a further consensus was reached in the general Internet community to separate the management of domain names from the management of IP numbers. This consensus was based on the recognition that the stability of the Internet relies on the careful management of IP address space.

Following the examples of RIPE NCC and APNIC, it was recommended that management of IP address space then administered by the InterNIC should be under the control of, and administered by, those that use it, including ISPs, end-user organizations, corporate entities, universities, and individuals.

As a result, ARIN (*American Registry for Internet Numbers*) was established in December 1997, as an independent, nonprofit corporation, with a membership structure open to all interested entities or individuals.

ARIN is located in Chantilly, Virginia, United States. Its service region incorporates 70 countries, covering North America, South America, the Caribbean, and African countries located south of the equator. ARIN currently consists of more than 1500 members. Within the ARIN region, there are two national delegated registries, located in Mexico and Brazil.

Until now, ARIN has carried the responsibility for maintaining registration of resources allocated before the inception of the RIRs. However, a major project is now under way to transfer these legacy records to the relevant RIRs. More information about ARIN is available at:
`http://www.arin.net`

Emerging RIRs

The existing RIRs currently serve countries outside their core regions to provide global coverage; however, new RIRs are expected to emerge, necessitating changes to the existing service regions. Because the regions are defined on continental dimensions, the number of new RIRs will be low.

Currently, two groups have made significant progress in seeking to establish new RIRs. *AfriNIC* (for the Africa region) and *LACNIC* (for Latin America and the Caribbean) have each conducted public meetings, published documentation, and participated in the activities of the

existing RIRs. In recognition of the regional support they have so far obtained, each organization has been granted observer status at ICANN ASO meetings. The existing RIRs have also sought to provide as much assistance and support as possible to these emerging organizations.

More information about AfriNIC is available at;
http://www.afrinic.org/

More information about LACNIC is available at:
http://lacnic.org/

The RIR System:

Goals of the RIRs

RFC 2050, published in November 1996, represented a collaboration of the global Internet addressing community to describe a set of goals and guidelines for the RIRs. Although IANA was to retain ultimate responsibility for the entire address pool, RFC 2050 recognizes that RIRs operate under the consensus of their respective regional Internet community. This document, along with a history of RIR coordination, has helped to form the basis for a set of consistent global policies.

The three primary goals of the RIR system follow:

- *Conservation:* to ensure efficient use of a finite resource and to avoid service instabilities due to market distortions (such as stockpiling or other forms of manipulation);
- *Aggregation (routability):* to assist in maintenance of Internet routing tables at a manageable size, by supporting CIDR techniques to ensure continued operational stability of the Internet;
- *Registration:* to provide a public registry documenting address space allocations and assignments, necessary to ensure uniqueness and provide information for Internet troubleshooting at all levels.

The Open Policy Framework

It was always recognized that these goals would often be in conflict with each other and with the interests of individuals and organizations. It was also recognized that legitimate regional interests could justify varying approaches in balancing these conflicts. Therefore, within the global framework, each regional community has always developed its own specific policies and procedures.

However, whereas the specific approaches may differ across the RIRs, all operate on a basic principle of open, transparent, consensus-based decision-making, following self-regulatory practices that exist elsewhere in the Internet and other industries. Furthermore, the RIRs all maintain not-for-profit cost-recovery systems and organizational structures that seek to be inclusive of all interested stakeholders.

The activities and services of each of the RIRs are defined, performed, discussed, and evaluated in open forums, whose participants are ultimately responsible for decision-making.

To facilitate broad participation, open policy meetings are hosted by RIRs regularly in each of the regions. Ongoing discussions are carried out on the public mailing lists of each RIR, which are open to both the RIR constituents and the broader community. The RIRs also participate actively in other Internet conferences and organizations and, importantly, each RIR has a strong tradition of participating in the public activities of the others.

A current example of the coordinated efforts of the RIRs is the Provisional IPv6 Assignment and Allocation Policy Document, a joint effort of the RIRs with the assistance of the IETF, The *Internet Architecture Board* (IAB), and the *Internet Engineering Steering Group* (IESG) to describe the allocation and assignment policies for the first release of IPv6 address numbers.

Also, the RIRs recently published the RIR Comparative Policy Overview, which is available at: **`http://www.ripe.net/ripencc/mem-services/registration/rir-comp-matrix-rev.html`**

These documents help illustrate that the well-established combination of bottom-up decision-making and global cooperation of the RIRs has created a stable, robust environment for Internet address management.

RIR Functions

The primary function of each RIR is to ensure the fair distribution and responsible management of IP addresses and the related numeric resources that are required for the stable and reliable operation of the Internet. In particular, the resources allocated, assigned, and registered by RIRs are Internet address numbers (IPv4 and IPv6) and AS numbers. RIRs are also responsible for maintaining the reverse delegation registrations of the parent blocks within their respective ranges.

Complementing their registry function, the RIRs have an important role in educating and informing their communities. The activities carried out by the individual RIRs vary, but include open policy meetings, training courses, seminars, outreach activities, statistical reporting, and research.

Additionally, a crucial role for the RIRs is to represent the interests of their communities by participating in global forums and providing support to other organizations involved in Internet addressing issues.

RIRs and The Global Internet Community:

Formation of ICANN and the ASO

The global Internet governance landscape began to undergo radical changes in mid-1998, with the publication of a U.S. Government white paper outlining the formation of a "not-for-profit corporation formed by private sector Internet stakeholders to administer policy for the Internet name and address system." ICANN was formed later that year.

At the heart of the ICANN structure are "supporting organizations" that are formed to "assist, review and develop recommendations on Internet policy and structure" within specialized areas. In October 1999, the existing RIRs and ICANN jointly signed a *Memorandum of Understanding* (MoU) to establish the principles for forming and operating the *Address Supporting Organization* (ASO). It is intended that new RIRs will sign the MoU as they emerge.

Under the ASO MoU, the policy forums within each of the RIR regions continue to be responsible for development of regional IP address policy. In addition, each signatory RIR is responsible for electing three members to the ICANN *Address Council*.

The purpose of the Address Council, as described in the MoU, is to review and develop recommendations on issues related to IP address space, using the open processes that exist in the three regions; and to advise the ICANN Board on these matters. In addition, the Address Council is responsible for the appointment of three ICANN Directors to the ICANN Board.

RIR–ASO Coordination

Since the formation of the ASO, the RIRs have played an integral part in facilitating its activities. By joint agreement, the RIRs will share the ASO secretariat duties, including the hosting of the ASO Web site, on a revolving basis. APNIC provided these services in the ASO's first year of operation, and RIPE NCC is currently performing this role.

The ASO Address Council holds monthly telephone conferences, which are attended by representatives of the RIRs (and emerging RIRs on a listener basis). In accordance with the MoU, the ASO also holds regular open meetings in conjunction with the open policy meetings of the RIRs.

RIRs and Industry Development

As noted previously, the RIRs maintain high levels of participation in the conferences and activities of other organizations. Similarly, they invite the participation of interested parties in their own activities.

The RIRs are active in many areas of new technology implementation (such as *General Packet Radio Service* [GPRS] and *Universal Telecommunications System* [UMTS] mobile telephony, IPv6, and cable and *Digital Subscriber Line* [xDSL]-based Internet services).

The established regional processes have proved both flexible and open enough to incorporate such new developments into policy formation. Industry representatives frequently join policy discussions, present at plenary sessions, and participate in working groups.

The RIRs pursue relationships with industry bodies, particularly those with representative and developmental functions, to facilitate industry convergence on open standards and policy processes.

Many diverse parties have legitimate interests in the allocation and registration of IP addresses, and the RIRs remain committed to participating with these parties to achieve a consensus among the Internet community on IP address allocation issues.

The Future of RIRs

In Internet time it can be easy to forget that eight years is actually not long. Since it was first proposed in 1990, the RIR system has evolved rapidly, enjoyed strong community support, and has been relatively free of the political wrangling that has characterized the registration systems of other Internet resources. Without doubt, this position is largely due to the early determination to provide accessible, open forums for the interested stakeholders in the various regions.

New technologies, such as GPRS, broadband services, and IPv6 may raise operational and policy challenges to the RIRs, yet at the same time they bring opportunities for increased global cooperation, in a context where distinct regional concerns are represented more effectively than ever before.

It is hoped that the emergence of new RIRs will only serve to expand and enhance the inclusive nature of RIR activities.

DANIEL KARRENBERG has helped to build the European Internet since the early 1980s. As one of the founding members of the German UNIX Users Group, he has been involved in the setting up of EUnet, a pan-European coperative network providing electronic mail and news to businesses and academic institutions all over Europe. While at CWI in Amsterdam, Karrenberg helped to expand this network and convert it to a fully IP-based service. During this time he created a whois database of operational contacts, which was the nucleus of the current RIPE database. Karrenberg is one of the founders of RIPE, the IP coordination body for Europe and surrounding areas. In 1992 he was asked to set up the RIPE NCC, the first regional Internet registry providing IP numbers to thousands of Internet service providers in more than 90 countries. Karrrenberg led the RIPE NCC until 1999, when it had an international staff of 59 with more than 20 nationalities; he currently helps to develop new RIPE NCC services. Recently his contributions have been recognized by the Internet Society with its *Jon Postel Service Award*. Karrenberg's current interests include measurements of Internet performance and routing as well as security within the Internet infrastructure. In general he likes building new and interesting things. Mr. Karrenberg holds an MSc in computer science from Dortmund University. E-mail: **Daniel.Karrenberg@ripe.net**

GERARD ROSS holds a BA and LLB from University of Queensland and a Grad.Dip. (Communication) from Queensland Institute of Technology. He was employed as the technical writer at APNIC in 1998 and has been involved in the development and drafting of several major policy documents both in the APNIC region and as part of coordinated global RIR activities. He was the ASO webmaster in its inaugral year. He is currently the APNIC Documentation Manager. E-mail: **gerard@apnic.net**

PAUL WILSON has been Director-General of APNIC since August 1998. Previously, he was a founding staff member and subsequently Chief Executive Officer at Pegasus Networks, the first private ISP in Australia. Over an eight-year period he worked as a consultant to the United Nations and other international agencies on Internet projects in many countries. Since 1994, he has worked with the International Development Research Centre (IDRC) on its Pan-Asia Networking (PAN) Programme, supporting projects in Mongolia, Vietnam, Cambodia, Maldives, Nepal, Bhutan, PNG, and China. He continues to serve as a member of the PAN Research and Development Grants Committee. E-mail: **pwilson@apnic.net**

LESLIE NOBILE received her B.A. from the American University in Washington, D.C. She has over 15 years of experience in the Internet field, and has been involved with the Internet Registry system since 1991. Prior to that, she held various technical management positions while working under a U.S. Government contract that supported the engineering and implementation of the Defense Data Network, a high-speed data network that evolved from the ARPANET. Her experience with the Registry system began in 1991 working as one of the Operations managers who transitioned the Internet Network Information Center (NIC) from SRI to Network Solutions, Inc. She remained a registration services manager with the DDN/DoD NIC until August 2000, when she became Director of Registration Services at the American Registry for Internet Numbers (ARIN). She has been a contributing author to RFCs, Internet Society (ISOC) articles, and various other industry publications and has been actively involved in the global coordination of Internet addressing policy. Her e-mail address is **leslie@arin.net**

Book Reviews

Web Caching

Web Caching by Duane Wessels, ISBN 1-56592-536-X, O'Reilly, June 2001.

It's always a pleasure to read a technical book written by someone who has not just studied the topic, but has been so involved that he has spent years living and breathing the subject. Such books do more than just describe the technology, because they are invariably able to add a dimension of deeper insight and interest, and in so doing, bring the topic to life for the reader. Duane Wessel's experiences in the Harvest project, and then as self-confessed "Chief Procrastinator" in the *Squid* Web cache project, certainly place him in the category of an author who has lived the topic. The outcome is a well-researched and very readable book on the topic of Web caching.

Web Caching

Web caching has been an integral part of the architecture of the World Wide Web since its inception, and is now a broad topic encompassing a range of approaches, a range of technologies, and a range of deployment issues for the end consumer, the content publisher, and the service provider intermediaries. The book starts with a clear introduction that outlines the elements of the architecture of the Web, and describes the terminology used within the book. This section also provides a basic introduction to the operation of the *Hypertext Transfer Protocol* (HTTP). This section also describes the various forms of Web caches that are in use today.

The way in which a cache interprets the directives at the header of a delivered Web object is described in some detail. I learned something unexpected here, in that a Web object that includes a directive of the form "Cache-control: no-cache" is defined in RFC 2616 as allowing a cache to store a copy of the object and use it, subject to revalidation, for subsequent requests. It seems that if you really want the object not to be stored in a cache, then "no-store" is what you are after, because "no-cache" allows the object to be cached! As well as describing the definition of the cache control directives, this section provides a clear explanation of how document ageing is defined, and when a cache server determines that a cached object should be checked against the original to ensure that the cached copy remains a faithful reproduction.

Caching has its champions and its detractors, and the book attempts to present both perspectives in a balanced fashion. On the positive side, caching is seen as an effective way to improve the performance of the delivery of Web-based services, and to relieve network and server load. The claim is made here that a large busy cache can achieve a hit ratio of some 70 percent. Don't get too enthusiastic, however, because a more common achieved ratio is somewhere between 30 and 40 percent.

On the negative side is the ever-present issue of accuracy of the cache, the inability for a content provider to track contact access, and the issue of integrity of the cache in the face of service attacks that are directed to the cached copy of the content.

The Politics of Caching

This section of the book intrigued me, because it is certainly rare to see a technical book address the various social implications of the technology. The study includes the issues of privacy, request blocking, copyright control, content integrity, cache busting, and the modifications to the trust model in the presence of cache intermediaries. The book exposes the tension between the content provider, the user, and the service provider. The content provider would generally like to exercise some control over tracking who is accessing the content and how each client uses the content and how they navigate through the Web site. The user is interested in efficiency of content delivery, and also has to place a high level of trust in the integrity of the content-delivery system. The service provider is also interested in rapid delivery of content, as well as managing network load. Third parties, such as regulatory or law-enforcement bodies, may be interested in ensuring that the content originator is unambiguously traceable, and that various regulations with respect to content are enforced by content originators and service providers.

Practical Advice

From this overview, the book moves onto more practical topics, and first describes how to configure browsers to take advantage of caches. It also covers how various proxy auto-configurators work. The topic that has generated some attention is that of *interception caching,* where a user's Web-browser commands are intercepted by a provider cache without the direct knowledge of the user of the user's browser. The techniques of implementing such interception caches are described, including a description of the operation of the *Web Cache Coordination Protocol* (WCCP), policy routing, and firewall interception. Interception caching, or transparent caching, is a topic that has generated its fair share of controversy in the past, and the book does take the time to clearly describe the issues associated with this caching approach.

The other topic covered under the general topic of practical advice is advice to server operators and content providers on how to make servers and content work in a predictable fashion with caches, describing which HTTP reply headers affect cacheability. This section provides advice on how to build a cache-friendly Web site, and motivates this with reasons why a content provider would want to ensure that content is readily cacheable. This includes some practical advice on how a content provider can still receive hit counts and site navigation information while still allowing the content of a site to be cached.

Fun with Caches—Cache Hierarchies and Clusters

Although caches can operate in a standalone configuration, it is possible to interconnect caches so that a cache will refer to another cache in the event of a cache miss, rather than directly refer to the origin server. I gather that the author is not overly keen on such an approach, given that the arguments against such configurations consume five times as much space as the arguments in favor! The alternative to a strict hierarchy is a set of cooperating peer caches, together with an intercache protocol to allow a cache to efficiently query its peers for an object. The book describes the *Internet Cache Protocol* (ICP), the *Cache Array Routing Protocol* (CARP), which is pointed out to be an algorithm, not a protocol, despite its name, the *Hypertext Caching Protocol* (HTCP), and *Cache Digests*. The scenarios where each approach would be preferred is a helpful addition to this section. Cache clusters are also described; if I have a criticism of the book, it is that this section is too terse—I was looking for more details of cache-balancing and content-distribution techniques.

Cache Operation

The final section of the book looks at the tasks associated with designing, benchmarking, and operating cache servers. How much disk space is enough for a cache? How much memory? Where should the caches be placed in the network? What aspects of the cache operation should you monitor? And if you are considering purchasing caches, what aspects of the cache should you carefully examine?

Conclusion

This is not a book about how to build a cache, although if you are considering doing that it's a good place to start your research. Nor is it a book about every detail on how to operate a cache. But if you are operating a cache, it will be useful. Although it's not a book about how to operate a Web server, if you are operating a Web server, then caches will attempt to store your content, and this book will help you configure your server to interoperate predictably with caches.

The Web is a large part of today's Internet, and Web caches can make the Web faster, more efficient, and more resilient. If you want to understand how caches work and understand how you can use caches to improve the user's experience rather than making things worse, then this book is essential reading.

IPSec *IPSec: The New Security Standard for the Internet, Intranets, and Virtual Private Networks,* by Naganand Doraswamy and Dan Harkins, ISBN 0-13-011898-2, 1999, Prentice Hall PTR Web Infrastructure series. **http://www.phptr.com**

We all know that Internet security is a major concern. Evolving technologies such as *Virtual Private Networks* (VPNs) are making it easier to deploy secure networks at low costs. VPN technology is based upon encryption techniques that make use of different algorithms. Most of these algorithms are specified in the form of *Requests for Comments* (RFCs). Though RFCs provide the minute details, they are not exactly lively reading. This is where the *IP Security* (IPSec) book comes in handy. The authors have done their best to explain IPSec technology in layman's language, although one encounters a lot of technical jargon in this book.

Organization

The book is divided into three parts. Part I gives a history of cryptography and techniques and cryptographic tools, and overviews of TCP/IP and IPSec. Authentication methods such as *Public Key Infrastructure* (PSI), RSA, and DSA are discussed. Key exchange methods such as Diffie-Hellman and RSA Key Exchange are discussed, along with their advantages and disadvantages. IPSec architecture is explored in the IP Security Overiew section, which describes the security services provided by IPSec, how packets are constructed and processed, and the interaction of IPSec processing with policy. IPSec protocols—*Authentication Header* (AH) and *Encapsulation Security Payload* (ESP)—are the basic ingredients of the IPSec stack to provide security. Both AH and ESP can be operated in either the transport mode or tunnel mode. Part II offers a detailed analysis of IPSec, the different modes, IPSec implentation, the ESP, AH, and the *Internet Key Exchange* (IKE). The authors do a good job of describing the IPSec road map, which defines how various components within IPSec interact with each other. Detailed packet formats of different IPSec formats are discussed in Chapter 4. ESP, AH, and IKE are discussed in depth in Chapters 5 through 7. Part III deals with most of the deployment issues concerned with IPSec, as well as policy definition, policy management, implementation architecture, and end-to-end security are discussed in this section. Chapter 11 discusses the future of IPSec and what it means to the world of security. Though IPSec may be thought of as a totally secure method of communication, it has its conflicts when it comes to *Network Address Translation* (NAT), multicasting, and key management in a multicast environment.

Prerequisites

Although the authors have done a good job delivering the IPSec concept, understanding this text requires more than basic computer and communication concepts. One should understand hacking and different types of Internet attacks. OSI layer details and packet-level understanding of every layer within the OSI model is a must.

Letters to the Editor

ICANN

Mr. Jacobsen,

I very much enjoy the *Internet Protocol Journal* and put it at the top of my reading stack as soon as it is received. In particular, I enjoy the standards and high technical detail and view it as a safe place from overt commercial advertisement and politics.

That is why I was disappointed by the article from Mr. Lynn. My opinion of ICANN is that it is undemocratic in any tradition, uninterested in experimentation, and uninterested in outside views. I took offense at his continued use of the phrase "public trust" and interpreted the article as propaganda. Further, I found the technical content of the article to be zero.

On the other hand, William Stallings article on MPLS was exactly the kind of article I've come to enjoy. I wasn't familiar with MPLS and the article helped me understand the concepts, vocabulary, and high-level issues. I hope that "MPLS" serves as a model of the articles in future IPJ issues.

I keep back issues of IPJ in a binder and continue to hope you uncover more articles like "The Social Life of Routers." My copy of Mr. Krebs article has notes in all the margins—I was excited—but it was a twist on something that I thought I knew and he exposed a different design vocabulary by making an unexpected comparison.

I apologize for complaining about something that is a gift from Cisco; I do understand how crass that is. I hope that you will interpret my note in a complementary manner: I've come to respect the journal and found that it fits an unfilled niche in my reading.

—Brent D. Stewart, Global Knowledge
<brent@stewart.hickory.nc.us>

Brent,

I appreciate your feedback, as I am sure Mr. Lynn will if you send it to him. The article was, after all, published for public comment.

ICANN has unfortunately tended to polarize people and has become a forum in which a certain amount of politics is played out. I don't think this is entirely ICANN (the board)'s fault. What was set up as an organization to take over the work of one man—the late Jon Postel, is seen by some as an opportunity for "Internet Governance" and "world-wide electronic democracy."

Having watched the ICANN process since its beginnings in 1998, I would say that Mr. Lynn's version of history is pretty much on target. When the IANA was in the hands of Jon Postel, it most certainly was a "public trust" (a limited resource to say the least), and if ICANN does not take that responsibility seriously, it certainly will have failed.

However, I do not think this is the case. Yes, ICANN is now a fairly large and slow moving machinery, and I would have liked to see more new domains deployed sooner, but to some extent the slowness is caused by the structure of Supporting Organizations as much as it is by the board itself. There is a lot to sort out, a lot to comment on, and *many* divergent views are indeed being expressed in all kinds of ICANN forums, including the public meetings. So, I cannot agree that ICANN is "uninterested in outside views." A perfect democracy it is not, nor was it ever intended to be, and yes, some of the topics on the agenda such as the *Uniform Dispute Resolution Process* (UDRP) are indeed non-technical. But it is not as if ICANN had much choice in that particular matter. (Although some would argue that it could be moved outside the ICANN process.)

Being part of the ICANN process, through e-mail discussion, public meetings or through the Supporting Organizations is not difficult. Nor do I think that ICANN ignores any of the feedback it gets.

Back to the article. No, it was not particularly technical, but if you read IPJ's Call for Papers you will see that it mentions "Legal, policy and regulatory topics..." Also, in the wake of September 11, I though it was important to provide some background on the thinking of ICANN, and why they chose to refocus the most recent meeting on security etc. IPJ, by the way, also encourages the occasional "Opinion Piece," although the article by Mr. Lynn was not intended as such. The issue of alternate roots is indeed a matter of debate, and while the the IAB has already expressed its view, I appreciate that there might be other (valid) ones.

In any case, thank you for taking the time to write. I certainly don't intend to steer IPJ away from topics such as MPLS and I hope that the occasional policy or even opinion piece won't steer you away from IPJ.

—*Ole Jacobsen, Editor and Publisher* `<ole@cisco.com>`

MPLS Ole,

William Stallings otherwise-excellent article on MPLS in the *Internet Protocol Journal* Vol. 4, No. 3 had a serious error in it with respect to Virtual Private Networks (VPNs). He said that MPLS is an efficient mechanism for supporting VPNs and that MPLS provides security; neither is true.

As the rest of the article shows, MPLS provides a transport tunnel for IP packets, meaning that it helps create virtual networks. However, there is no privacy on those virtual networks, so it is inappropriate and probably dangerous to call MPLS tunnels virtual private networks.

To most Internet users, security means preventing snooping of sensitive traffic, preventing malicious changes to content, or both. MPLS does not provide either service. Instead of relying on insecure MPLS, users who want secure tunnels use systems that employ the IPsec protocol.

Many dozens of vendors supply IPsec systems appropriate for everything from tiny home offices to gigantic telco central switches, all with the same high security. Although the article showed that MPLS has many valuable features, IPJ readers should not fall into the trap of thinking that VPN support or security are MPLS features.

—Paul Hoffman, Director, VPN Consortium
<paul.hoffman@vpnc.org>

Ed: We presented this letter to a panel of experts, and here are some samples of the responses we received:

The term "VPN" has been used in many different contexts. I saw a group once call a VLAN a "VPN" as well. I honestly couldn't say that they were incorrect. It may be appropriate to say that there are IPsec VPNs and that there are MPLS VPNs, but I have a problem calling one "right" and another "wrong" simply because of some perceived, implied definition of the security level that should be provided by a "VPN." Most people support the notion that an MPLS VPN provides about as much "security" as a Frame Relay link. This amount of "security" in a VPN is acceptable to many people.

—Chris Lonvick, Cisco Systems **<clonvick@cisco.com>**

We have different views on security, I'm sure. One view is that a secure private network: a) ensures that a third party cannot impose a condition on the network such that a customer's traffic is directed to another customer b) ensures that a third party cannot inject traffic into a customer's private network, c) a third party cannot alter customer traffic and d) a third party cannot discern that communications is taking place between two parts of a private network.

MPLS uses the same mechanisms as X.25, ATM and Frame, and has similar properties—the objectives above can be met with adequate confidence as long as the network is carefully configured and managed.

Edge to edge IPSec has a different set of security principles—the basic mode of operation is that such networks may be subject to attacks that redirect customer's traffic to third party sites, and allow third parties to inject traffic into the VPN, and allow a third party to discern that communications is taking place within a private context. The essential attribute of edge to edge IPSec is that the encryption is intended to ensure that leakage can be identified: foreign injected traffic or altered traffic can be identified and rejected and leaking traffic cannot be decoded.

Both approaches have vulnerabilities and weaknesses. The first approach places trust in the integrity of the host platform. The second approach is prone to various forms of DOS attacks and traffic profiling.

But I would not concur with a view that labels the MPLS approach as inefficient or insecure, nor would I label X.25 networks, ATM or Frame as *intrinsically* inefficient and insecure. There are insecure operating practices and there are cautious operating practices.

IPSec networks have similar issues—relating particularly to the vulnerabilities of third party disruption and profiling eavesdropping.

So it's not that I believe that all MPLS networks are well designed and well operated—on the contrary! But as an architectural approach I am not able to agree with a comment that appears to condemn MPLS as intrinsically a poor choice for a VPN host technology.

So if the comment is that the article provides the impression that MPLS is such a robust technology that it creates secure private network applications such as VPNs, and appears to make this assertion so strongly that it gives the impression that this outcome occurs irrespective of MPLS network design and operating practices, and that this impression is ill-founded, then I would agree entirely with Mr. Hoffman. Secure networks, or at least robust networks, are a result of careful choice of technologies coupled with careful design and careful operation.

—*Geoff Huston, Telstra* **<gih@telstra.net>**

Ed.: We forwarded these comments to Mr. Hoffman, and he responded:

Geoff believes that it a network that does not prevent an active attacker from seeing or modifying traffic, and does not prevent a passive attacker from seeing packets, is secure and private; I do not. The fact that MPLS restricts the flow of traffic to a particular defined network is sufficient for him; it is not for me, given the fact that an attacker breaking into any node on that defined network can compromise the privacy and integrity of the traffic.

It is typical for ISPs to not want to do the work of actually securing the traffic they say they have put in a VPN by using IPsec. That work is not cheap, and takes more management than vanilla MPLS, but it is the only way to really secure the data. I am absolutely not saying that the IPsec community is without blame here: we have a tendency to ignore the valuable features of MPLS and have done almost nothing to make it easier to intelligently tunnel IPsec in MPLS (we also pretty much stonewalled the IPsec under L2TP work that is now finally standardized). But our lack of openness doesn't make MPLS a VPN technology.

—*Paul Hoffman, Director, VPN Consortium*
<paul.hoffman@vpnc.org>

Ed.: We would love to hear from you. Please send your letters to: **ipj@cisco.com**

Fragments

ACM Assembles Security and Privacy Panel

Prompted by increased public concerns about personal privacy and the security of networked information systems, the *Association for Computing Machinery* (ACM) has announced the formation of a new *Advisory Committee on Security and Privacy* (ACSP). Led by Peter Neumann and Eugene H. Spafford, the ACSP brings together a dozen leaders and innovators in the field of privacy and information assurance to serve as a powerful resource for the ACM community and the public at large.

Comprising experts from research, industry, academia, and government, the diverse group represents a wide range of viewpoints. Commenting on the formation of the ACSP, Co-Chair Peter Neumann noted, "The ACSP will provide timely and accurate assessments of situations relating to information security that are otherwise clouded by confusion, uncertainty, and often, misinformation."

Added ACSP Co-Chair Gene Spafford, "Until recently, computing professionals have been primarily concerned with making computers work consistently, cheaply, and effectively. Now it is critical that we also bring expertise to bear on how computers can be made to operate safely, keep information resources secure from attack, and protect privacy."

The ACSP consists of 12 distinguished members with expertise in information security and assurance, privacy, cybercrime, and allied fields. The group will coordinate with other ACM Committees, including the *U.S. ACM Committee on Public Policy* (USACM) and ACM Law Committee, to provide objective advice to the computing community, the public at large, and to policy-makers. ACSP is expected to provide statements and testimony on information security and privacy issues, as well as undertaking studies of related topics. For more information about the ACSP, see the web site at:
`http://www.acm.org/usacm/ACSP/homepage.htm`

Members of the ACSP (affiliations provided for identification purposes only) are:

Steve Bellovin (AT&T Labs Research)
Matthew Blaze (AT&T Labs Research)
David Clark (MIT)
Dorothy Denning (Georgetown University)
Ed Felten (Princeton University)
David Farber (University of Pennsylvania)
Susan Landau (Sun Microsystems)
Robert Morris (Dartmouth College)
Peter Neumann (SRI International)
Fred Schneider (Cornell University)
Eugene H. Spafford (Purdue University CERIAS)
Willis Ware (RAND Corporation)

For more information, see ACM's Web site at: **`http://www.acm.org`**

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

The Internet Protocol Journal

March 2002 Volume 5, Number 1

A Quarterly Technical Publication for Internet and Intranet Professionals

In This Issue

From The Editor

Major Internet events such as the IETF meetings, the Regional Internet Registry meetings, APRICOT, SIGCOMM, and NetWorld+Interop to name a few, all provide Internet access for attendees. Commonly referred to as the "Terminal Room," these facilities have evolved into complex high-speed networks with redundant paths, IPv6 routing, multicast, and more. In the last five years or so, these networks have also been providing wireless access using various flavors of the IEEE 802.11 standard. As I write this, I am sitting in the lobby of the Minneapolis Hilton Hotel, where the 53rd IETF meeting is being held. The lobby area and two floors of meeting rooms have IEEE 802.11 coverage, and a directional high-gain antenna provides access in the pub across the street. Wireless Internet computing is a reality, at least when you have a large gathering of engineers such as an IETF meeting. In our first article, Edgar Danielyan takes a closer look at this technology, its applications and evolution.

More and more software is being distributed via the Internet rather than through the use of conventional media such as CD ROMs or floppy disks. Downloading software via the Internet is very convenient, especially if you have reasonably high bandwidth. However, with this convenience comes a certain risk that you may be receiving a modified copy of the software, perhaps one that contains a virus. Code signing is a method wherein software is cryptographically signed and later verified. Eric Fleischman explains the details of code signing.

I should have known better than to announce the imminent availability of our online subscription system in the previous issue. We are working on it, but it isn't ready yet, so please continue to send your subscription requests and updates to: **ipj@cisco.com**

IEEE 802.11

by Edgar Danielyan

Introduced in 1997, the IEEE Standard 802.11 for wireless local-area networks has seen modifications and improvements in the past years and is promising a brighter wireless future, so yearned for by many of us. However, during its lifetime, the standard also has had a few setbacks, which are reminders that nothing is perfect in this world, much less in networking. This article provides a brief but comprehensive introduction to IEEE 802.11 wireless networking, its present and future, and highlights some of its security, performance, and safety aspects.

IEEE 802.11

The initial IEEE Standard 802.11 was published by the *Institute of Electrical and Electronics Engineers* (IEEE) in 1997. That standard is known as IEEE 802.11-1997 and is now updated by the current standard, IEEE 802.11-1999. The current standard has also been accepted as an American national standard by the *American National Standards Institute* (ANSI) and has been adopted by the *International Organization for Standardization* (ISO) as ISO/IEC 8802-11:1999. The completion of IEEE 802.11 in 1997 set in motion the development of standards-based wireless LAN networking. The 1997 standard specified a bandwidth of 2 Mbps, with fallback to 1 Mbps in hostile (noisy) environments with *Direct Sequence Spread Spectrum* (DSSS) modulation, and bandwidth of 1 Mbps with *Frequency Hopping Spread Spectrum* (FHSS) modulation, with possible 2-Mbps operation in friendly (noiseless) environments. Both methods operate in the unlicensed 2.4-GHz band. What is less known about IEEE 802.11 is that it also defines a baseband infrared medium, in addition to the DSSS and FHSS radio specifications, although its usefulness seems somewhat limited. There are also several task groups inside the 802.11 working group itself that work on substandards of 802.11:

- 802.11D: Additional Regulatory Domains
- 802.11E: Quality of Service (QoS)
- 802.11F: Inter-Access Point Protocol (IAPP)
- 802.11G: Higher data rates at 2.4 GHz
- 802.11H: Dynamic Channel Selection and Transmission Power Control
- 802.11i: Authentication and Security

The IEEE 802 group has an official Web site at **`www.ieee802.org`**, and IEEE 802.11 has an official Web site at **`www.ieee802.org/11/`**.

DSSS

Direct Sequence Spread Spectrum (DSSS) is one of the modulation techniques provided for by the IEEE 802.11 and the one chosen by the 802.11 Working Group for the widely used IEEE 802.11b devices. DSSS modulation is governed in the United States by FCC Regulation 15.247 and in Europe by ETSI Regulations 300-328. DSSS in IEEE 802.11 uses *Differential Binary Phase Shift Keying* (DBPSK) for 1 Mbps, and *Differential Quadrature Phase Shift Keying* (DQPSK) for 2 Mbps. The *Higher-Rate DSSS* (DSSS/HR) defined in IEEE 802.11b uses *Complementary Code Keying* (CCK) as its modulation scheme and provides 5.5- and 11-Mbps data rates. Because of their compatibility, all three modulation schemes can coexist using the rate-switching procedures defined in the IEEE 802.11. The *Orthogonal Frequency Division Multiplexing* (OFDM) used by the IEEE 802.11a is regulated in the United States by Title 47 Section 15.407 of the U.S. *Code of Federal Regulation* (CFR). IEEE 802.11a uses a system of 52 subcarriers modulated by BPSK or QPSK and 16-quadrature amplitude modulation. It also uses *forward error correction* (FEC) coding, also used by the Digital Video Broadcasting (DVB) standard with coding rates of 1/2, 2/3, and 3/4.

FHSS

Although specified by the original IEEE 802.11, *Frequency Hopping Spread Spectrum* (FHSS) modulation is not favored by vendors and, it seems, the 802.11 working group itself. DSSS has won the battle—very few vendors support 802.11/FHSS, and further developments with 802.11 use DSSS. Some have expressed ideas that frequency hopping in FHSS may contribute to the security of 802.11, but these are invalid expectations—the hopping codes used by FHSS are specified by the standard and are available to anyone, thus making the expectation of security through FHSS unreasonable.

Two supplements to the IEEE 802.11-1999, known as IEEE 802.11a and IEEE 802.11b, brought considerable changes and improvements to the IEEE 802.11-1999 standard.

IEEE 802.11a

IEEE 802.11a specifies a high-speed physical layer operating in the 5-GHz unlicensed band utilizing a complex coding technique known as OFDM. The data rates specified by IEEE 802.11a are 6, 9, 12, 18, 24, 36, 48, and 54 Mbps, with support for 6, 12, and 24 Mbps as a mandatory requirement. IEEE 802.11a is seen by some in the industry as the future of IEEE 802.11. Some products already implement the IEEE 802.11a, such as the chip from Atheros (**www.atheros.com**) and a PCMCIA/CardBus adapter from Card Access Inc (**www.cardaccess-inc.com**) based on it. However, 802.11a is not without disadvantages. The increased bandwidth of IEEE 802.11a results in a shorter operation range.

Additionally, because of the protocol overhead and interference/error correction, the real bandwidth may be considerably less than the nominal. New surveys and installation will also be required in many cases; the underlying infrastructure will also be more expensive because of the shorter operation range (about 1/3 of 802.11b) and higher density of *base stations* (also known as *access points*).

IEEE 802.11b

Probably the most widely implemented and used wireless LAN technology today, IEEE 802.11b specifies 5.5- and 11-Mbps data rates (in addition to the already specified 1 and 2 Mbps), but operates in the original 2.4-GHz band also using DSSS modulation. Most currently selling IEEE 802.11 products implement IEEE 802.1b. IEEE 802.11b-compliant devices can operate at 1, 2, 5.5, and 11 Mbps.

It is important to note that both incarnations of IEEE 802.11 use the same *Media Access Control* (MAC) protocol, *Carrier Sense Multiple Access with Collision Avoidance* (CSMA/CA); therefore, these modifications affect only the physical layer (PHY layer in IEEE parlance) of the standard. The 1/2- and 5.5/11-Mbps DSSS (IEEE 802.11b) networks can coexist, enabling a painless transition to IEEE 802.11b (High Rate) at 11 Mbps. Eleven to fourteen radio channels are available for use with IEEE 802.11b in the 2.4-GHz band, depending on the local legal and administrative restrictions.

Distance, Power, and Speed Issues

It is obvious that all three of these parameters of wireless systems are interconnected. However, as with other radio-based technologies, the external conditions (such as the line of sight in case of outdoor use) greatly affect the operation of IEEE 802.11 devices.

Antennae

Antennae used with IEEE 802.11b devices may be grouped into two categories: *omnidirectional* and *point-to-point*. Obviously, omnidirectional antennae are the easiest to use, because they do not require positioning. Omnidirectional antennae are used in most base stations, as well as in most access cards. However, because of their nature, omnidirectional antennae do not work well over longer distances, unless used with external amplifiers; and these are not always legal or appropriate to use. Directional, or point-to-point antennae, on the other hand, require careful positioning and are used outdoors. Although the typical range for an omnidirectional antenna system is 150 ft (45m), configurations with high-gain directional antennae can work on distances up to 25 miles (about 40 km). In localities where amplifiers are allowed, the maximum distance may be considerably increased and is limited only by the line of sight.

Among other factors affecting the operational range of IEEE 802.11b devices are the base-station placement (when used in the infrastructure mode) and radio interference. As mentioned earlier, IEEE 802.11b devices will auto-configure for the highest possible speed and fall back to lower speeds when circumstances so require.

Performance Issues

Aside from obvious factors that affect performance (such as antennae, distance, radio interference) there are numerous other, more subtle issues. In the infrastructure mode, when all devices have to register with the base station(s), the load on the base station(s) increases with the number of clients and may reach a point when the performance reaches unacceptable lows. For example, Apple's AirPort Base Station (Version 2) can support up to 50 simultaneous clients. However, the actual performance of the whole system also depends on the kind of traffic. In particular, isochronous traffic (time-sensitive traffic, such as some types of video, audio, and telemetry), as well as multicast traffic, are particularly taxing for IEEE 802.11 networks and are better kept off the wireless LAN. However, several groups are currently working on extensions to 802.11 to provide for such kinds of traffic in a future version of the standard.

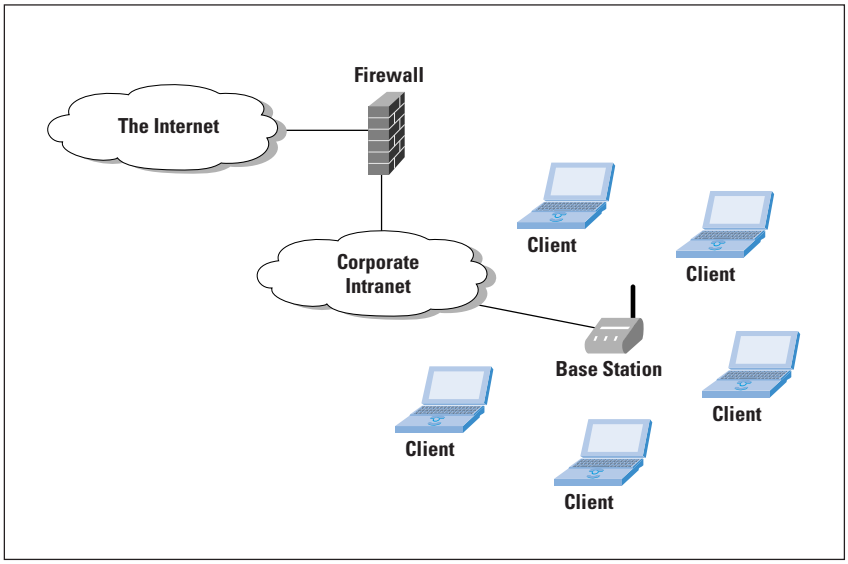

Figure 1: Typical IEEE 802.11 Configuration in Infrastructure Mode

IEEE 802.11 Base Stations and Clients

All IEEE 802.11 devices can be grouped into one of two groups: base stations or clients. Base stations can function as clients; however, not all clients can function as base stations. The reason for this is that base stations are required to provide certain network services to clients (association, distribution, integration, reassociation, and so on) that not all client hardware, firmware, or software can or intended to provide.

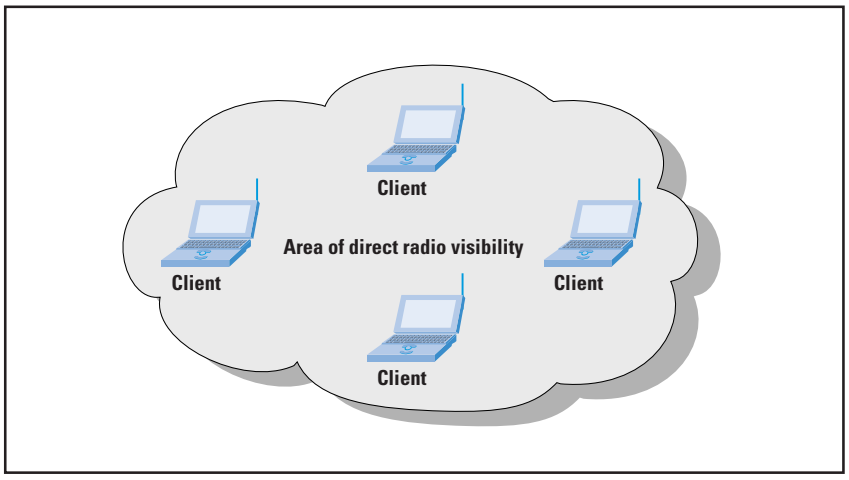
These considerations apply when the infrastructure mode of IEEE 802.11 is deployed. In *ad hoc* networks, where there are no base stations, all clients communicate directly with each other, reminiscent of a traditional shared Ethernet network, with all nodes sharing equal rights and responsibilities. As noted earlier, 11 to 14 radio channels are available, but separate networks may coexist on the same frequency (using different network IDs (*Service Set Identifiers* [SSIDs]), albeit with performance penalties.

The workings of 802.11 devices also differ in the infrastructure and ad hoc modes. In the infrastructure mode (Figure 1), clients associate (and optionally authenticate) themselves with a base station, and the presence of the base station is necessary for the operation of the network.

Complex 802.11 networks may be built using the infrastructure mode, with numerous base stations providing coverage over relatively large physical areas, and clients may roam within this roaming domain, which theoretically may extend from a single building to the entire campus or town. The *Spanning-Tree Protocol* (STP) is usually used in these cases to provide loop-free bridging in this wireless LAN.

In the ad hoc mode (Figure 2), base stations are not used and are not necessary, because all nodes of the wireless LAN have direct reachability (that is, they "see" each other). This mode is usually used in circumstances where all devices are in close proximity to each other (such as a floor or office) and when omnidirectional antennae are used.

Figure 2: IEEE 802.11 ad hoc Network



IEEE 802.11 Roaming and Mobility

IEEE 802.11 provides for roaming and mobility of 802.11 client devices and allows clients to roam among multiple 802.11 base stations that may be operating on the same or different frequencies (channels). This is achieved through the use of *beacon frames,* which are used to synchronize 802.11 devices and, in the infrastructure mode, to associate with a base station.

There are two ways to scan for existing 802.11 networks: active and passive scanning. In active scanning mode, the 802.11 device sends out "probe" frames, soliciting "I am here" responses from existing 802.11 devices. In the passive mode, the devices just listen for beacon frames, which are periodically transmitted by the active devices. In addition, the IEEE 802.11 Task Group F is working on the IAPP, which is to provide better and interoperable mobility and roaming mechanisms.

Security of IEEE 802.11

Up to this point IEEE 802.11 could be considered an absolute success; however, security of IEEE 802.11 is not quite on par with other aspects of the standard. Although an entire chapter (Chapter 8) of the standard is dedicated to authentication and privacy, it is now the common consensus that designers of IEEE 802.11 did not excel in this area. Two reports widely covered in the media, "Your 802.11 Wireless Network Has No Clothes"[7], and "Intercepting Mobile Communications: The Insecurity of 802.11"[6], shed light on the apparent shortcomings of the standard, or to be more exact, on its "vulnerability by design." They demonstrated that although the designers were well aware of the need to plan for authentication and privacy, the actual implementation was not an excellent one. The WEP algorithm, used to provide authentication and privacy in 802.11 wireless networks, is the problem.

WEP

Before discussing the security weaknesses discovered in IEEE 802.11, we quote the aim of the *Wired Equivalent Privacy* (WEP) algorithm as specified in the IEEE 802.11 standard document:

> "Eavesdropping is a familiar problem to users of other types of wireless technology. IEEE 802.11 specifies a wired LAN equivalent data confidentiality algorithm. Wired equivalent privacy is defined as protecting authorized users of a wireless LAN from casual eavesdropping. This service is intended to provide functionality for the wireless LAN equivalent to that provided by the physical security attributes inherent to a wired medium."

As you see, the aim of WEP is to provide a level of privacy equivalent to that of a wired LAN. The wording of standard is very important here: the developers of the standard did not intend to provide a level of security superior to or higher than that of a regular wired LAN, such as Ethernet. The very name of the algorithm, "Wireless Equivalent Privacy," signifies the actual intention of the developers. However, as the practice has shown, the level of security roughly equivalent to the level of security provided by wired LANs is not sufficient—and it is the assumption that "it is OK if wireless LANs are as secure as wired LANs" that is wrong. Other problems, such as the choice of *Cyclic Redundancy Check 32* (CRC-32) instead of *Message Digest Algorithm 5* (MD5) or some other secure hash algorithm, just worsen the problem.

How WEP Works

Let's now look at the workings of WEP. WEP uses a secret key shared between 802.11 nodes to encrypt 802.11 frames (Layer 2). It also uses a checksum (CRC-32) to provide data integrity. The checksum itself is also encrypted using the shared secret key. The decryption is the reverse of the encryption process: the frame is decrypted using the key and the CRC-32 checksum is computed and checked. The cipher used in WEP is RC4, a stream cipher designed by Ron Rivest, and believed to be cryptographically strong. The key is 40 or more bits long (up to 128 bits in some implementations). However, the *Initialization Vector* that is used during the encryption process is only 24 bits long. It is difficult to understand why the designers chose such a small number—more about this later. WEP does not provide any key management—the standard itself does not specify how the shared secret key should be managed and distributed. This leaves one of the most vulnerable parts of any cryptographic system—*key distribution*—open for misuse.

The Borisov Goldberg Wagner Attacks (February 2001)

In their paper entitled "Intercepting Mobile Communications: The Insecurity of 802.11," Nikita Borisov, Ian Goldberg, and David Wagner describe the vulnerabilities present in WEP and attacks against it. In the introduction to their paper, they state:

> "Unfortunately, WEP falls short of accomplishing its security goals. Despite employing the well-known and believed-secure RC4 cipher, WEP contains several major security flaws. The flaws give rise to a number of attacks, both passive and active, that allow eavesdropping on, and tampering with, wireless transmissions."

They go on to say that WEP fails to achieve all three of its security goals, namely confidentiality, access control, and data integrity.

As has been noted earlier, WEP uses the RC4 stream cipher with a 24-bit Initialization Vector for encryption. Borisov, Goldberg, and Wagner show that the poor design of WEP makes the system vulnerable in many areas, and one of the weakest parts of WEP is the 24-bit Initialization Vector, which may result in keystream reuse. Keystream reuse in turn permits successful cryptanalysis attacks against the ciphertext. However, what is surprising is that:

> "The WEP protocol contains vulnerabilities despite the designers' apparent knowledge of the dangers of keystream reuse attacks."

Another not less important but equally poorly designed aspect of WEP is the use of CRC-32. It is known that CRCs are not cryptographically strong and are not intended to be used in place of message digest or hash functions such as MD5 or the *Secure Hash Algorithm* (SHA). Because of the nature of CRC, it fails to provide the required integrity protection.

Some in the industry suggest that MD5 or SHA would introduce performance penalties if used—and indeed they would—one cannot disagree. But let's not forget that CRC-32 was intended as a security measure—which it isn't—yes, it is fast, but it is also insecure. Presumably, a slower but really secure solution is better than an inadequate though fast solution.

The Arbaugh Shankar Wau Attack (April 2001)

In the paper "Your 802.11 Wireless Network Has No Clothes,"[7] authors present their research of the authentication flaws in the IEEE 802.11 and demonstrate a simple eavesdropping attack against IEEE 802.11 authentication. This work is partially based on the knowledge obtained by Borisov, Goldberg, and Wagner in the paper described previously. The attack described in this work is possible even with WEP enabled; however, in that case it will also require application of attack(s) against WEP presented by Borisov et al. The authors also note that a good key management architecture would increase the security of the system; however, in their opinion only a comprehensive redesign of the standard would provide a good long-term solution to these issues.

The Fluhrer Mantin Shamir Attack (August 2001)

Scott Fluhrer, Itsik Mantin, and Adi Shamir describe a passive ciphertext-only attack against the key scheduling algorithm of RC4 as used in WEP[11]. They identify a large number of weak keys, in which knowledge of a small number of key bits suffices to determine many state and output bits with nonnegligible probability. They also show that the first byte generated by the RC4 leaks information about individual key bytes. This paper in particular shows how to reconstruct the secret key in WEP by analyzing enough WEP-encrypted packets. The authors have not tried to do this in practice—others did that.

The Stubblefield Ioannidis Rubin Implementation of Fluhrer Mantin Shamir Attack (August 2001)

In an AT&T Laboratories report published on August 21, 2001[14], Adam Stubblefield, John Ioannidis, and Aviel Rubin describe a real-world successful implementation of the Fluhrer Mantin Shamir attack using a $100 Linksys card on a Linux machine. They report that it took less than a week from ordering the card to recovering the WEP key on a production network. This practical work has shown that no expensive hardware or software is necessary in order to break WEP. They summarize that it is the poor implementation of reasonable secure technologies (such as RC4) that is responsible for WEP weaknesses.

WECA's Response

The *Wireless Ethernet Compatibility Alliance* (WECA) is the organization responsible for certifying compliance with the IEEE 802.11 standards. It also awards the WiFi (*Wireless Fidelity*) industry mark to the products that have passed IEEE 802.11 compliance testing.

In response to the Berkeley paper, WECA has published an official statement, clarifying its understanding of the situation. The main line of this statement is that poor security is better than no security, as well as that WEP was not intended to be a panacea for all security needs. The statement correctly notes that the biggest security threat is the failure to use available protection methods, including WEP.

IEEE 802.11 Chair's Response

In response to the research made at UC Berkeley and the University of Maryland, the Chair of the IEEE 802.11 Working Group, Stuart Kerry, has published a Chair's response intended to clarify some of the issues around the security of IEEE 802.11. He denied allegations made in the media that the security weaknesses of WEP are due to the closed standardization process. In fact, because WEP is a part of IEEE 802.11, it was developed through an open process, like other IEEE standards. The IEEE 802.11 Working Group itself is open to all interested parties to participate. He also rejects the viewpoint that frequency-hopping wireless networks would be less vulnerable to security attacks. It is evident that this is not true because both hopping codes and timing are unencrypted and are available to the attacker. Reminding us that the goal of WEP was to provide a level of security comparable to wired LANs, he states that the IEEE 802.11 Working Group is currently working on improvements to WEP to incorporate better security into the next version of the standard.

IEEE 802.1X

Security in 802.11 networks can be broken down into three components: authentication framework, authentication algorithm/protocol, and encryption. IEEE 802.1X is trying to address the authentication framework part of the puzzle. Although still in development, 802.1X provides a scalable, centralized framework for authentication. 802.1X may deploy a variety of authentication protocols (currently Cisco's *Lightweight Extensible Authentication Protocol* [LEAP] and Microsoft's *Extensible Authentication Protocol – Transport Layer Security* [EAP-TLS] are available), and it works with both wired and wireless LANs. The widely used *Remote Access Dial-In User Service* (RADIUS) protocol is also used in the 802.1X framework. 802.1X/LEAP is available with the Cisco Aironet 350 Series of wireless LAN devices; EAP-TLS is supported in Windows XP. Although it is still a draft, 802.1X may one day become the solution to the authentication issues of 802.11.

IEEE 802.11i

Task Group I of the IEEE Working Group 802.11 is currently defining MAC enhancements to provide enhanced security for 802.11. This is a work in progress, and no IEEE 802.11i draft exists at the time of writing.

Cisco's Solution

Cisco Systems has responded to both papers on the security of the WEP[10]. Cisco agrees that the WEP has serious shortcomings, and states that its Aironet series of wireless networking products offers many solutions to these problems: dynamic WEP keys, secure key derivation, and mutual authentication using LEAP[13]. However, Cisco agrees that improvements are needed in the standard itself.

RC4 Fast Packet Keying for WEP

In a Document Nr 550r2, "Temporal Key Hash," submitted by Russ Housley of RSA Security and Doug Whiting of Hifn to the IEEE 802.11 Working Group, they describe a solution to the WEP problem that uses a hashing technique that rapidly generates a unique RC4 key for each packet of data sent over the wireless network. This technique addresses the performance aspect of the security solution as well—the hash algorithm used in *Fast Packet Keying* (FPK) is much faster than traditional hash algorithms such as MD5 and SHA1 because of the special caching approach. The IEEE 802.11 Working Group has decided to include this technique in the IEEE 802.11i as an informative document. In most cases, FPK may be implemented as a firmware upgrade for the existing hardware. It is possible that when released, IEEE 802.11i may use FPK as the solution—but this decision is yet to be made. No definite plans are announced at the time of writing. For more information, see:
`http://www.rsasecurity.com/rsalabs/technotes/wep-fix.html`.

Health and IEEE 802.11

Concerns about safety and health effects of various wireless solutions such as mobile phones and wireless network devices periodically surface in the media. In particular, the question of whether mobile phones are linked to brain cancer and other diseases is still open. However, in response to these concerns regarding wireless networking equipment health effects, Cisco Systems has published a white paper entitled "Cisco Systems Spread Spectrum Radios and RF Safety," which explains why these devices do not present a threat to human health when correctly used. The bottom line is that devices certified as compliant with U.S. Federal Communications Commission or Industry Canada's regulations are safe to use because of their low emitted power.

Practical Uses

Many companies, such as MobileStar, Wayport, Surf&Sip, and Airwave, have begun providing IEEE 802.11b Internet access at numerous locations throughout the United States. Several international airports also provide 802.11b service free of charge to travelers. No doubt more such services will continue to appear all over the world, maybe making a dream—Internet anywhere—a reality.

Summary

IEEE Standard 802.11 brought the long-awaited standardization to wireless LAN networking. Unfortunately, it also brought various security problems. Despite that, IEEE 802.11 is widely used, and with the coming of IEEE 802.11a, it can only gain in popularity. What now remains to be done is more effective and truly secure privacy and authentication for 802.11 wireless networks.

The IEEE 802.11 Working Group is actively working to improve what has been done to date. The most improvements are obviously needed in the area of security, where Working Groups 802.1X and 802.11i are working to define better security mechanisms. In particular, 802.11 WG is working on a new release of 802.11, which will include improvements over 802.11-1999. In the meantime, consider your wireless LAN as an external, insecure network—just like the Internet—and employ additional security measures, such as Virtual Private Networks, Transport Layer Security, SSH, and IP Security Architecture—in addition to WEP.

Code Signing

by Eric Fleischman, The Boeing Company

Code signing is a common mechanism that authors of executable code use to assert their authorship of that code and to provide integrity assurance to the users of the code that an unauthorized third party has not subsequently modified the code in any way. Code signing is widely used to protect software that is distributed over the Internet. It is also widely used for mobile code security, being a core element of the mobile code security systems of both Microsoft's ActiveX and JavaSoft's Java applet systems. Despite this widespread use, common misunderstandings have arisen concerning the actual security benefits provided by code signing. This article addresses this issue. It explains how code signing works, including its dependence upon underlying *Public Key Infrastructure* (PKI) technologies.

Motivation for Code Signing

Code signing, which is also known as *object signing* in certain programming environments, is a subset of electronic document signing. In many ways code signing is a simplification of the more generic technology in that generally only a single signature is permitted and that signature pertains to the entire file. That is, code signing usually does not support multiple signatures, encryption of (data) content, dynamic data placement, or sectional signing, which are commonly available in many document-signing systems. As a result, code signing provides only authenticity and integrity for *electronic executable files*—it does not provide privacy, authentication, or authorization, which are supported by several electronic document-signing approaches.

A signature provides authenticity by assuring users as to where the code came from—who really signed it. If the certificate originated from a trusted third-party *Certificate Authority* (CA), then the certificate embedded in the digital signature as part of the code-signing process provides the assurance that the CA has certified that the code signer is who he or she claims to be. Integrity occurs by using a signed hash function as evidence that the resulting code has not been tampered with since it was signed.

In the pre-Internet era, software was distributed in a packaged manner via branding or trusted sales outlets. It frequently came in a shrink-wrapped form directly from the vendor or a trusted distributor. In the Internet era, software is often distributed via the Web, by e-mail, or by file transfer. Code signing provides users with a similar level of assurance as to software authenticity in this comparatively anonymous—and comparatively insecure—new distribution paradigm as was previously offered by packaged software in the pre-Internet era.

In all cases, what is assured is the authorship of the software, including the verification that third parties have not subsequently modified the code. In no case does the user receive any assurance that the code itself is safe to run or actually does what it claims. Thus, the actual value of code signing remains a function of the reliability and integrity of its author. Code signing, therefore, is solely a mechanism for software creators to assert their authorship of the product and validate that it has not been modified. In no case does it provide the end user with any claim as to the quality, intent, or safety of the code.

How Code Signing Works

Code signing appends a digital signature to the executable code itself. This digital signature provides enough information to authenticate the signer as well as to ensure that the code has not been subsequently modified.

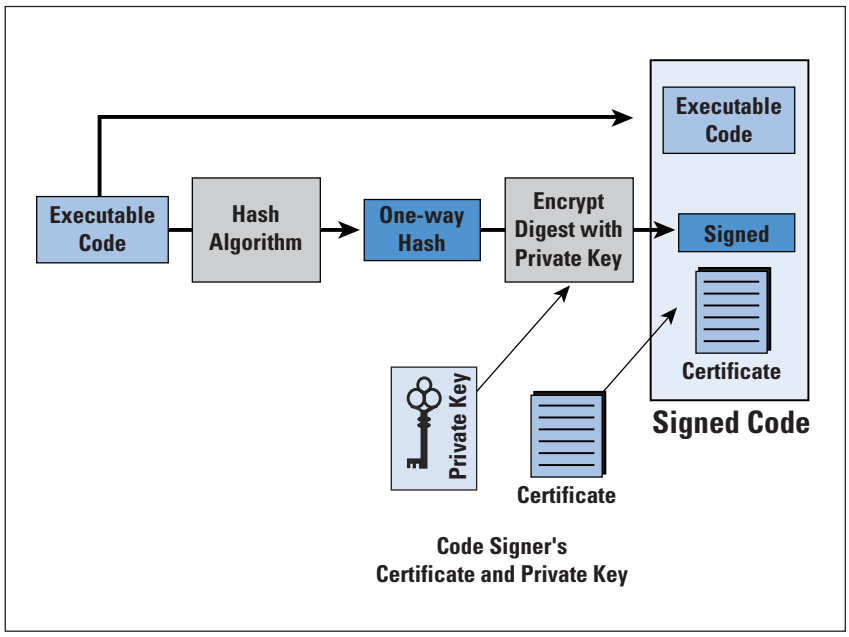
Code signing is an application within a PKI system. A PKI is a distributed infrastructure that supports the distribution and management of public keys and digital certificates. A digital certificate is a signed assertion (via a digital signature) by a trusted third party, known as the Certificate Authority (CA), which correlates a public key to some other piece of information, such as the name of the legitimate holder of the private key associated with that public key. The binding of this information then is used to establish the identity of that individual. All system participants can verify the name-key binding coupling of any presented certificate by merely applying the public key of the CA to verify the CA digital signature. This verification process occurs without involving the CA.

A *public key* refers to the fact that the cryptographic underpinnings of PKI systems rely upon asymmetric ciphers that use two related but different keys, a public key, which is generally known, and a *private key,* which should be known only by the legitimate holder of the public key. This approach is known as *public-key cryptography* and directly contrasts to symmetric ciphers, which contrastingly require the two entities to share an identical secret key in order to encrypt or decrypt information.

The certificates used to sign code can be obtained in two ways: They are either created by the code signers themselves by using one of the code-signing toolkits or obtained from a CA. The signed code itself reveals the certificate origin, clearly indicating which alternative was used. The preference of code-signing systems (and of the users of signed code) is that the certificates come from a CA, and CAs, to earn the fee they charge for issuing certificates, are expected to perform "due diligence" to establish and verify the identity of the individual or institution identified by the certificate. As such, the CA stands behind (validates) the digital certificate, certifying that it was indeed issued only to the individual (or group) identified by the certificate and that the identity of

that individual (or group) has been verified as stated. The CA then digitally signs the certificate in order to formally bind this verified identity with a given private and public key pair, which is logically contained within the certificate itself. This key pair will subsequently be used in the code-signing process. Self-created certificates, by contrast, are unconstrained as to the identities they may impersonate.

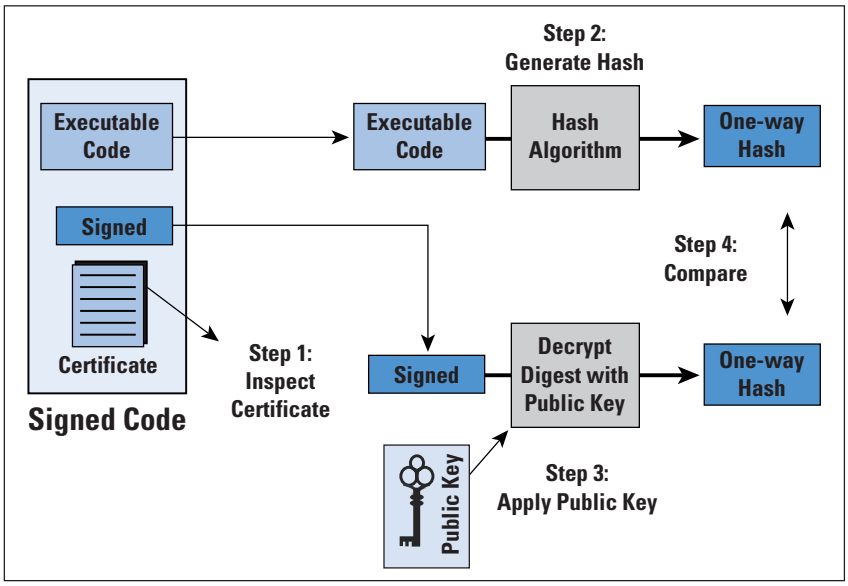
Figure 1: Code-Signing Process



Code signing itself is accomplished as follows: Developers use a *hash function* on their code to compute a *digest*, which is also known as a *one-way hash*. The hash function securely compresses code of arbitrary length into a fixed-length digest result. The most common hash function algorithms used in code signing are the *Secure Hash Algorithm* (SHA), *Message Digest Algorithm 4* (MD4), or MD5. The resulting length of the digest is a function of the hash function algorithm, but a common digest length is 128 bits. The digest is then encrypted using the developer's private key, which is part of the developer's certificate. A package containing the encrypted digest and the developer's Digital Certificate is encapsulated into a special structure called the *signature block*. The signature block is then appended to the executable code to form the signed code.

In a Java context, the signed Java byte code is called a JAR file. First introduced in the *Java Developer's Kit* (JDK) version 1.1, this capability was greatly expanded with Java 2.

Figure 2: Code Verification Process



At some subsequent time, this signed code will be presented to a recipient, usually through the agency of a code-signing verification tool on the recipient's computer. This tool will inspect the signature block to verify the authenticity and integrity of the received code. This inspection is done in the following manner, as shown in Figure 2:

1. The certificate is inspected from the signature block to verify that it is recognizable to the code-signing verification system as a correctly formatted certificate.
2. If it is, the certificate identifies the hash function algorithm that was used to create the signed digest within the received signature block. With this information, the same hash algorithm code that was used to create the original digest is then applied to the received executable code, creating a digest value, which then is temporarily stored. If it is not a correctly formatted certificate, then the code-signing verification process fails.
3. The signed digest value is then taken from the signature block and decrypted with the code signer's public key, revealing the digest value, which was originally computed by the code signer. Failure to successfully decrypt this signed digest value indicates that the code signer's private key was not used to create the received signature. If this is the case, then that signature is a fraud and the code-signing verification process fails.
4. The recomputed digest of Step 2 is then compared to the received digest that was decrypted in Step 3. If these two values are not identical, then the code has subsequently been modified in some way and the code-signing verification process fails. If any such anomaly occurs, then the verification system alerts the recipient concerning the nature of the failure, indicating that the resulting code is suspect and should not be trusted. However, if the digests are identical, then the identity of the code signer is established.

5. If establishment occurs, then the code signer's certificate is copied from the signature block and presented to the recipient. The recipient then has the option to indicate whether or not he or she trusts the code signer. If so, then the code is executed. If not, then it is not executed.

Types of Code Signing

Code signing is a mechanism to sign executable content. The term executable content refers to presenting executable programs in a manner so that they could be run locally—regardless of whether the executable file originated locally or remotely. Code signing is commonly used to identify authorship within several distinct usage scenarios:

- Applications can be code signed to identify their ownership within comparatively anonymous software distribution mechanisms using the Web, the *File Transfer Protocol* (FTP), or e-mail. This type of code signing establishes the origin for downloadable JAR, tar, zip, or CAB file software distributions, for example.
- Code signing can provide Web users more control over mobile code that is available to their Web browsers. Mobile code is code that travels a network in its lifetime in order to execute on a destination machine. The term is usually associated today with active Web content that executes on the client's machine via technologies such as Java, JavaScript, VBScript, ActiveX, and MS Word macros.
- Device drivers can be code signed to inform an operating system of the authorship of that driver. For example, the device drivers for Windows 98, Windows ME, and Windows 2000 operating systems should preferentially be certified by Microsoft's device driver certification laboratory[25]. The entity signs the device driver executable in order to certify that the device driver in question has indeed been successfully demonstrated by a Microsoft certification laboratory to correctly run on that operating system.
- A recent news report[20] has stated that Microsoft will be using code signing as a security mechanism within its forthcoming Windows XP operating system. The article stated: "Microsoft is to incorporate a 'signed application' system in Whistler [that is, Windows XP], the intention being to furnish users with a super-secure mode of operation that just plain stops [unsigned] code executing on the machine."

Code Signing Does Not Provide Total Security

A fundamental problem with code signing is that it cannot provide any guarantee about the good intentions of the signer or the quality, intent, operations, or safety of the code. The VeriSign and Thawte CAs, for example, combat this limitation somewhat for executables signed by certificates they issue by requiring the entities receiving their certificates to sign a "software publisher's pledge" not to sign a piece of malicious software. If they subsequently learn of violations of this agreement, they ask the owner to correct the problem.

If the owner refuses, then they cancel the owner's digital certificate and potentially bring a lawsuit against the offender. The code-signing literature has documented that the latter has occurred at least once[21].

Another problem is that the digital signing by even a reputable entity can be forged if the private key of the signer becomes known. This forging can occur when the criminally minded exploit any of numerous potential vulnerabilities, including hacking into the key store on the signer's machine, carelessness on the part of the signer exposing this information, or an error in a CA PKI key distribution system.

Perhaps the best summary of these issues is provided by Schneier, who wrote:

> "Code signing, as it is currently done, sucks. There are all sorts of problems. First, users have no idea how to decide if a particular signer is trusted or not. Second, just because a component is signed doesn't mean that it is safe. Third, just because two components are individually signed does not mean that using them together is safe; lots of accidental harmful interactions can be exploited. Fourth, "safe" is not an all-or-nothing thing; there are degrees of safety. And fifth, the fact that the evidence of attack (the signature on the code) is stored on the computer under attack is mostly useless: The attacker could delete or modify the signature during the attack, or simply reformat the drive where the signature is stored." (Quoted from page 163 of [17]).

Mobile Code Security

Mobile code security is a two-edged sword: it seeks to protect computer systems receiving potentially hostile mobile code and it also seeks to protect mobile code from potentially hostile users of those computer systems.

Code signing has emerged as a major adjunct to mobile code security. Because mobile code probably represents the dominant use of code signing that occurs today, this section examines how code signing assists mobile code security.

There is substantial and growing literature on mobile code security (for example, see [3] through [16]). The literature identifies four distinct approaches to mobile code security, together with a few hybrids that merge two or more methods. Each of the four approaches has an inherent trust model that identifies the assumptions upon which the approach is based. Rubin and Geer[4] list these four approaches as being:

- The *sandbox approach,* which restricts mobile code to a small set of safe operations. This is the historic approach used by Java applets. In the approach, each Java interpreter implementation attempts to adhere to a security policy, which explicitly describes the restrictions that should be placed on remote applets. "Assuming that the policy

itself is not flawed or inconsistent, then any application that truly implements the policy is said to be secure. ... The biggest problem with the Java sandbox is that any error in any security component can lead to a violation of the security policy. ... Two types of applets cause most of the problems. Attack applets try to exploit software bugs in the client's virtual machine; they have been shown to successfully break the type safety of JDK 1.0 and to cause buffer overflows in HotJava. These are the most dangerous. Malicious applets are designed to monopolize resources, and cause inconvenience rather than actual loss."[4] The trust model assumed by the sandbox approach is that the sandbox is trustworthy in its design and implementation but that mobile code is universally untrustworthy.

- In code signing, the client manages a list of entities that it trusts. When a mobile code executable is received, the client verifies that it was signed by an entity on this list. If so, then it is run; otherwise it does not run. This approach is most commonly associated with Microsoft's ActiveX technology. "Unfortunately, there is a class of attacks that render ActiveX useless. If an intruder can change the policy on a user's machine, usually stored in a user file, the intruder can then enable the acceptance of all ActiveX content. In fact, a legitimate ActiveX program can easily open the door for future illegitimate traffic, because once such a program is run, it has complete access to all of the user's files. Such attacks have been demonstrated in practice."[4] The trust model for this approach assumes that it is possible to distinguish untrustworthy authors from trustworthy ones and that the code from trustworthy authors is dependable.
- The *firewalling approach* involves selectively choosing whether or not to run a program at the very point where it enters the client domain. "Research shows that it may not always be easy to block unwanted applets while allowing other applets ... to run. The firewalling approach assumes that applets can somehow be identified. ... This approach is fundamentally limited, however, by the halting problem, which states that there is no general-purpose algorithm that can determine the behavior of an arbitrary program."[4]

  A related and more viable alternative is the playground architecture that has been used to separate Java classes that prescribe graphics actions from all other actions. The former are loaded on the client, whereas the latter are loaded on a "sacrificial" playground machine for execution and then reporting of the results to the browser. Because this approach requires byte-code modification, it cannot be used in conjunction with the usual approach to code signing.
- The *Proof-Carrying Code* (PCC) technique is a theoretical approach that statistically checks code to ensure that it does not violate safety policies. "PCC is an active area of research so its trust model may change. At present, the design and implementation of the verifier are considered trustworthy but mobile code is universally untrustworthy."[4]

The most common hybrid approach occurs for Java's JDK 1.1 and Java 2. Each combines the sandbox approach, which was the security mechanism for JDK 1.0, with code signing. This hybrid originated from the realization that the inherent restrictions of the sandbox model kept applications from doing "interesting and useful things." Therefore, a mechanism for running applications outside of the sandbox, code sharing, was devised to supplement the sandbox-based original. Specifically, in JDK 1.1 a signed applet enjoys unlimited access to system resources, just like local applications do, provided that the corresponding public key is trusted in the executing environment. This system evolved within Java 2 to optionally provide a consistent and flexible policy for applets and applications, determined by the policies established within a protection domain.

The literature is unanimous that the net result of this hybrid version "introduces the same security problems [as those] inherent in the ActiveX code-signing approach."[4] For this reason, Bernard Cole[11] has stated "neither [the sandbox nor the code signing] model is appropriate to the new environment of small information appliances, connected embedded devices, numerous web-enabled wireless phones and set-top boxes."[11] Indeed, several articles (for example, perhaps the best collection is contained in[13]) contained worrying descriptions of how to compromise specific sandbox and code-signing products.

The literature (see [3] through [16]) is also clear that despite the demonstrable weaknesses of both the sandbox and code-signing approaches as mechanisms for securing mobile code, they are the best practical alternatives available today. In the meantime, researchers are currently exploring enhanced mobile code security by making hybrids containing three—or all four—of the above mechanisms.

Researchers have also begun to investigate alternative techniques. For example, Zhao[16] reports that "Additional innovative authentication functions are needed for mobile code. One approach is to apply digital fingerprinting to authenticate mobile code. Analogous to 'biometric authentication' for access control, a digital fingerprint of mobile code is a unique authentication code that is an integral and intrinsic part of the thing being authenticated. It is placed into the mobile code during its development by using digital watermarking techniques."

Major Code-Signing Systems

Code-signing systems are often functions of specific applications. For example, Thawte[22] is a CA that provides the following certificate types:

- The *Apple Developer Certificate* is used by Apple MacOS-based application developers to sign software for electronic distribution.
- The *JavaSoft Developer Certificate* can be used with JavaSoft's JDK 1.3 and later to sign Web applets.
- A *Marimba Channel Signing Certificate* is used to sign Castanet channels on the Marimba platform.

- A *Microsoft Authenticode Certificate* is used with the Microsoft InetSDK developer tools to sign Web applets (for instance, ActiveX controls) as well as `.CAB`, `.OCX`, `.CLASS`, `.EXE`, `.STL`, and `.DLL` files, and other potentially harmful active content on Microsoft OS platforms. These Authenticode certificates work only with Microsoft IE 4.0 and later browsers.
- *VBA Developer Certificates* are identical to the Microsoft Authenticode certificates. They are used by developers to sign macros in Office 2000 and other VBA 6.0 environments.
- *Netscape Code-Signing Certificate*s are used to sign Java applets, browser plug-ins, and other active content on the Netscape Communicator platform.

Despite this diversity, the clearly dominant code-signing systems today come from Microsoft, Netscape, and JavaSoft. Although these three systems generally adhere to the same set of standards, their approaches are highly diverse from each other. Each has its own certificate type. Each system approaches code signing with different orientations, goals, and expectations.

Interoperability Problems

Although all code signing uses similar technology, interoperability problems currently impact code signing. These problems may originate from interoperability problems within the underlying PKI infrastructure, from certificate differences, or from different (vendor) approaches to code signing itself.

PKI Infrastructure Interoperability

The PKI Forum has identified ten impediments to the widespread adoption of PKI[23], the most significant being the "lack of interoperability" between PKI products. Because of this, the technical working group of the PKI Forum is currently concentrating on addressing PKI interoperability problems: "The Technical Working Group continues its focus on multi-vendor interoperability projects. Over the last six months, it has sponsored monthly interoperability "bake-offs" based on the *Certificate Management Protocol* (CMP) standard, with participation from a growing number of vendors. In addition, two workshops have been held to date on application-level interoperability through the use of digital certificates, with remote testing ongoing. Looking forward, the Technical Working group plans to initiate two new interoperability projects in the areas of Smart Card/Token Portability and CA interoperability, and it will be defining a large-scale, multi-vendor interoperability project for public demonstration in the first quarter of 2001."[24]

Certificate Interoperability

Numerous potential interoperability issues stem from the certificates themselves because certain certificates are themselves tied to specific types of applications.

However, not every certificate is a code-signing certificate. Rather, code-signing certificates are special certificates whose associated private keys are used to create digital signatures. In addition, the id-kp-codesigning value within the extended key usage field of the certificate itself (see Section 4.2.1.13 of RFC 2459) needs to be set to indicate that the certificate can be used for code signing.

In any case, code-signing certificates must be packaged in the appropriate format [*Public Key Cryptographic Standards* (PKCS)]), and the various code-signing approaches (for example, Microsoft, Netscape, JavaSoft) expect both the signing certificates and the code that is to be signed to conform to different file format requirements.

These differences between code-signing systems introduce opportunities for incompatibility, even if each approach otherwise rigorously adheres to the same basic certificate standards.

Not all certificates can be used to support all potential certificate uses, even if they originate from the same CA. For example, the Java Developer Certificates are not interoperable (exchangeable) with any other certificates at this time. Fortunately, it is possible to buy certificates that can be used for many (but not all) potential uses. For example, a single certificate can support Microsoft Authenticode, Microsoft Office 2000/VBA Macro Signing, Netscape Object Signing, Apple Code Signing, and Marimba Channel Signing.

Code Signing System Interoperability

Probably the least understood of the potential interoperability problems are due to different vendor approaches to code signing itself. Perhaps McGraw and Felten have provided the best insight to code-signing system interoperability within Appendix A of their book *Securing Java*[15]. Unfortunately, those insights were in regard to an earlier version of Java, which has evolved considerably since then.

Certificate Issues

Each of the three major code-signing systems (Microsoft, Netscape, JavaSoft) has its own certificates. Each provides its own certificate stores to house certificates within its system.

Each of the three systems supports mechanisms by which certificates may be exported from a given user's certificate store and imported into a different user's certificate store on the same or on a different machine. The Microsoft and Netscape systems also have provisions for importing certificates between code-signing systems.

Certificates are usually exported between PKI systems or certificate stores in the PKCS-12 format (**`.p12`** files if Netscape or **`.pfx`** files if Microsoft Authenticode), which contains both certificate and key pair information within the same file. Certificates can also be exported in the PKCS-7 format (for example, **`.cer`** or **`.spc`** files).

The latter approach lacks information to permit the certificate to be used for code signing by the importing system unless the missing elements can be retrieved via other mechanisms.

Code-Signing Certificates

The Netscape certificate utility (that is, *signtool –L*) indicates which of the certificates located within a certificate store can be used for code signing. By contrast, all certificates (except for those explicitly prohibited from doing code signing according to the provisions of RFC 2459 Section 4.2.1.13) within a Microsoft certificate store can be used for code signing within the Microsoft system. This means that a certificate that is unable to be used for code signing in a Netscape system can be imported into the Microsoft system and be successfully used for code signing there.

This difference stems from RFC 2459 Section 4.2.1.13, which deals with the extended key usage field. The relevant text of the standard is as follows:

> "If the extension is flagged critical, then the certificate MUST be used only for one of the purposes indicated. If the extension is flagged noncritical, then it indicates the intended purpose or purposes of the key, and may be used in the correct key/certificate of an entity that has multiple keys/certificates. It is an advisory field and does not imply that usage of the key is restricted by the certification authority to the purpose indicated. Certificate using applications may nevertheless require that a particular purpose be indicated in order for the certificate to be acceptable to that application."

What has occurred is that Netscape has implemented its system such that certificates can be used only for the purposes specified in the extended usage field. Netscape does this for both critical and noncritical markings. Microsoft, by contrast, provides that restriction solely to certificates that have been marked "critical," permitting certificates without a critical marking to be used for any activity possible. Both approaches are legal, and both fully conform to the standard.

Code Signing from an End User's Perspective

The results obtained when you try to execute signed code is a function of your underlying operating system, the browser you are using, and whether or not the executable is a Java applet. This should not be surprising, because similar differences also occur with unsigned code. For example, a Microsoft executable file will execute on a Microsoft Windows operating system but is unlikely to execute on operating systems that do not recognize that format. Similarly, a Java applet cannot be directly invoked on a Windows operating system, because that operating system does not recognize the `.jar` file extension. However, it will cleanly execute when accessed off of a Web page, regardless of the underlying operating system.

Book Review

Internet Performance Survival Guide

Internet Performance Survival Guide: QoS Strategies for Multiservice Networks, by Geoff Huston, ISBN 0-471-37808-9, John Wiley & Sons, 2000.

Many readers of IPJ are familiar with the name Geoff Huston. He contributes articles frequently. I find his style to be very lucid and his writings to be very well structured and organized.

I have need at my job to begin implementation of *Quality of Service* (QoS) strategies to deal with an ever-increasing demand for *Virtual Private Network* (VPN) tunnels over shared media. So, when I came across the title of this book and saw who wrote it, I jumped at the opportunity to review it for IPJ.

Organization

This book is organized more like a textbook than a reference manual. If you are looking for a quick and dirty guide that simply lists all the tricks of the trade and gives examples of how to implement them on specific equipment, then this book is not for you. If, however, you are looking for a well-written text that will help you to understand the issues, the practices that address them, and the theory that underlies these practices, then this is an excellent book.

The book begins with a chapter that explains in detail the problems that administrators and engineers on heterogeneous, multiprotocol networks face today. There is a quick historical survey of the evolution of networking and how that has shaped the nature of the problem. In a very topical fashion, this introduction covers the basic techniques that can be used to implement QoS, but also explains the complexity involved with these techniques, their limitations, and why they are not widely deployed yet. The book continues from there, starting with a low-level view of the building blocks of the network and gradually building to higher- and higher-level topics.

The second chapter begins with some details about the performance features built into the Internet Protocol, and in particular IPv6. This chapter continues into TCP and covers all the well-known performance features that are built into it, and then moves on to routing, switching, and *Multiprotocol Label Switching,* or MPLS. MPLS is a unified approach to switching across large networks, and it has particular applications to QoS. This topic is one of the main reasons I sought for this book, and I am glad it was covered in such detail. The second chapter ends with a survey of the various transmission systems that are available today, and discusses in detail the performance characteristics and problems that are peculiar to each.

The third chapter is a well-organized exposition of the various types of performance-tuning techniques that are available. The author keeps the discussion at a reasonably abstract level, yet is not afraid to discuss the details of the application of these techniques to the specifics of the network when such details are important. In particular, the use of QoS techniques in conjunction with the *Open Shortest Path First* (OSPF) routing protocol is discussed.

The fourth chapter combines the building blocks of Chapter 2 and the techniques of Chapter 3 into an architectural view that spans the network. The author discusses the metrics that can be used to analyze network performance, the protocols that can be used to implement service strategies, the tradeoffs that are inherent in the problem, and the policy choices that need to be made in order to come up with a clear design. In particular, the Integrated Service and Differentiated Service models are discussed separately, and then the author shows how these can be combined into an end-to-end network design. As with Chapter 3, the author explains important specific cases such as the use of the *Resource Reservation Protocol* (RSVP) with ATM.

The fifth chapter moves on to explain how the architectures that have been described can be used to attack the various kinds of problems that exist on real networks. The emphasis is clearly on the end user of the system and how to measure the levels of service being provided and to bring into play the techniques already discussed to assure a consistent level of service. The organization of this chapter seemed less clear than that of the previous chapters, but that is perhaps due more to the nature of the complexity of the problems being discussed than to the author's limitations or inattention.

The sixth chapter provides little new material, per se, and is more of a perspective on the material already provided. However, it contributes highly to the content of the book in two important ways. First, it provides more of a top-down view of QoS to complement the material in the preceding four chapters, which present a mostly bottom-up view. Secondly, it acts as a natural bookend for the first chapter. The first chapter raises the issues and poses the questions. The middle of the book examines the protocols, techniques, and architectures in detail. The last chapter then attempts to answer the questions that were initially raised.

The author does an excellent job of presenting material that is complex, vast, and is still in the process of evolving in the field. He is very diligent about managing the level of detail, and is careful to first cover the material topically before diving into the details. The examples are appropriate and have been carefully chosen.

One of the features of the material that is most appreciated is the practical perspective that the author brings to his work. The theory never gets out of hand, and is always balanced by a real-life approach to problems that, unfortunately, can never be completely solved. And, the author's observations always seem in tune with the experiences of the reader.

The material is well organized, and readers will appreciate the effort expended on the textual conventions that help to organize and structure the material. The diagrams that accompany the text are clear and well-placed, and they contribute to the reader's comprehension.

A glossary in the back helps a reader who has not thoroughly read the preceding sections of the book. The index is also well done, and the reference material is copious and pertinent.

Recommended

Overall, I would recommend this book to any professional who manages large, integrated networks, particularly those professionals who work for Internet Service Providers in an engineering capacity. I think this reflects the particular interests of the author, but that is as it should be.

—David P. Feldman, Tudor Investment Corporation

Would You Like to Review a Book for IPJ?

We receive numerous books on computer networking from all the major publishers. If you've got a specific book you are interested in reviewing, please contact us and we will make sure a copy is mailed to you. The book is yours to keep if you send us a review. We accept reviews of new titles, as well as some of the "networking classics." Contact us at **ipj@cisco.com** for more information.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at `ole@cisco.com`

Fragments

ICANN Considers Structural Reform

Stuart Lynn, President and CEO of *The Internet Corporation for Assigned Names and Numbers* (ICANN) recently proposed a sweeping series of structural reforms designed to lead ICANN towards attainment of its core mission. "The current structure of ICANN was widely recognized as an experiment when created three years ago," noted Board Chairman Vint Cerf. "The rapid expansion of and increasing global dependence on the Internet have made it clear that a new structure is essential if ICANN is to fulfill its mission."

ICANN was formed three years ago as an entirely private global organization designed to assume responsibility for the DNS root from the U.S. government and to coordinate technical policy for the Internet's naming and address allocation systems. In the new proposals, the basic mission remains intact, but the means of achieving that mission changes. "What has become clear to me and others is that a purely private organization will not work," said Lynn. "The Internet has become too important to national economic and social progress. Governments, as the representatives of their populations, must participate more directly in ICANN's debates and policymaking functions. We must find the right form of global public-private partnership—one that combines the agility and strength of a private organization with the authority of governments to represent the public interest."

Noting that current organizational inertia and obsession with process over substance has impeded agility, Lynn laid out a roadmap designed to instill confidence in key stakeholders and to ensure that ICANN can be more effective. This roadmap entails restructuring the Board of Directors into a Board of Trustees composed in part of trustees nominated by those governments who participate in the ICANN process; in part by the chairs of proposed new "policy councils" that would replace the existing supporting organizations and that would provide expert advice; and in part by trustees proposed by a broadly-based nominating committee and appointed by the Board itself. The roadmap is designed to bring all critical stakeholders to the table, something that has been difficult to achieve with the present structure and has slowed ICANN's progress and its ability to fulfill its responsibilities. It is also designed to establish a broad-based funding mechanism sufficient to support the critical mission of ICANN.

"We need to build a stronger organization, supported by our key stakeholders, led by the best team that can be assembled, and properly funded," Lynn said. "We must be structured to function effectively in this fast-paced global Internet environment." "A key requirement is to keep the best of the present ICANN," added Cerf, "in ensuring transparency, openness, and participation, while creating an ICANN that can act responsibly and quickly. That will mean rejecting practices that have emphasized process over achievement. Above all, ICANN must be—and be seen to be—effective and supportive of technical innovation and of a reliable Internet."

A paper written by Lynn that explains the reasons for change and the roadmap for reform is posted on the ICANN web site:

From The Editor

The networking industry is full of acronyms, as the table of contents for this issue clearly illustrates. According to the dictionary, an acronym is "...a word formed from the initial letter or letters of each of the successive parts or major parts of a compound term." While neither BEEP nor ENUM are strictly speaking acronyms, these "short names" are becoming ever more prevalent and difficult to keep track of. We promise to continue to provide acronym expansion whenever possible.

BEEP is an example of a technology that came to life in a very short time. While IETF standards often take years from initial idea to protocol specification, BEEP seems to have happened in just over a year. There is already a textbook on BEEP from which our first article is adapted. Marshall Rose gives an overview of the BEEP framework and explains how you can get involved in its further development.

ENUM refers to the use of the *Domain Name System* (DNS) to look up telephone numbers and subsequently route telephone calls to the right destination using the Internet as the underlying routing fabric. This integration of the traditional telephone network with the Internet is becoming a reality and several standardization bodies are working on technologies to make this as seamless as possible. Geoff Huston explains the mechanisms and politics behind ENUM.

Our series "One Byte at a Time" examines the *Dynamic Host Configuration Protocol* (DHCP). This protocol is widely used to provide IP address and other basic routing information to clients. This is particularly useful for mobile devices, but it can be used in any network environment. Since the IP addresses are assigned as leases with a configurable time limit, DHCP also provides for effective address management. Douglas Comer explains the details of DHCP and its predecessor BOOTP.

As always, we appreciate your feedback. Send your comments and questions to **ipj@cisco.com**

An Overview of BEEP

by Marshall Rose, Dover Beach Consulting

The *Blocks Extensible Exchange Protocol* (BEEP) is something like "the missing link between the application layer and the *Transmission Control Protocol* (TCP)."

This statement is a horrific analogy because TCP is a transport *protocol* that provides reliable connections, and it makes no sense to compare a protocol to a layer. TCP is a highly-evolved protocol; many talented engineers have, over the last 20 years, built an impressive theory and practice around TCP. In fact, TCP is so good at what it does that when it came to survival of the fittest, it obliterated the competition. Even today, any serious talk about the transport protocol revolves around minor tweaks to TCP. (Or, if you prefer, the intersection between people talking about doing an "entirely new" transport protocol and people who are clueful is the empty set.)

Unfortunately, most application protocol design has not enjoyed as excellent a history as TCP. Engineers design protocols the way monkeys try to get to the moon—that is, by climbing a tree, looking around, and finding another tree to climb. Perhaps this is because there are more distractions at the application layer. For example, as far as TCP is concerned, its sole reason for being is to provide a full-duplex octet-aligned pipe in a robust and network-friendly fashion. The natural result is that while TCP's philosophy is built around "reliability through retransmission," there isn't a common mantra at the application layer.

Historically, when different engineers work on application protocols, they come up with different solutions to common problems. Sometimes the solutions reflect differing perspectives on inevitable tradeoffs; sometimes the solutions reflect different skill and experience levels. Regardless, the result is that the wheel is continuously reinvented, but rarely improved.

So, what is BEEP and how does it relate to all this? BEEP integrates the best practices for common, basic mechanisms that are needed when designing an application protocol over TCP. For example, it handles things like peer-to-peer, client/server, and server/client interactions. Depending on how you count, there are about a dozen or so issues that arise time and time again, and BEEP just deals with them. This means that you get to focus on the "interesting stuff."

BEEP has three things going for it:

- It's been standardized by the *Internet Engineering Task Force* (IETF), the so-called "governing body" for Internet protocols.
- There are open source implementations available in different languages.
- There's a community of developers who are clueful.

The standardization part is important, because BEEP has undergone a lot of technical review. The implementation part is important, because BEEP is probably available on a platform you're familiar with. The community part is important, because BEEP has a lot of resources available for you.

Application Protocols

An application protocol is a set of rules that says how your application talks to the network. Over the last few years, the *Hypertext Transfer Protocol* (HTTP) has been pressed into service as a general-purpose application protocol for many different kinds of applications, ranging from the *Internet Printing Protocol* (IPP)[1] to the *Simple Object Access Protocol* (SOAP)[2]. This is great for application designers: it saves them the trouble of having to design a new protocol and allows them to reuse a lot of ideas and code.

HTTP has become the reuse platform of choice, largely because:

- It is familiar.
- It is ubiquitous.
- It has a simple request/response model.
- It usually works through firewalls.

These are all good reasons, and—if HTTP meets your communications requirements—you should use it. The problem is that the widespread availability of HTTP has become an excuse for not bothering to understand what the requirements really are. It's easier to use HTTP, even if it's not a good fit, than to understand your requirements and design a protocol that does what you really need.

That's where BEEP comes in. It's a toolkit that you can use for building application protocols. It works well in a wide range of application domains, many of which weren't of interest when HTTP was being designed.

BEEP's goal is simple: you, the protocol designer, focus on the protocol details for your problem domain, and BEEP takes care of the other details. It turns out that the vast majority of application protocols have more similarities than differences. The similarities primarily deal with "administrative overhead"—things you need for a working system, but aren't specific to the problem at hand. BEEP mechanizes the similar parts, and lets you focus on the interesting stuff.

Application Protocol Design

Let's assume, for the moment, that you don't see a good fit between the protocol functions you need and either the e-mail or the Web infrastructures. (We'll talk more about this later on in the section "The Problem Space".) It's time to make something new.

First, you decide that your protocol needs ordered, reliable delivery. This is a common requirement for most application protocols, including HTTP and the *Simple Mail Transfer Protocol* (SMTP).[3] The easiest way to get this is to layer the protocol over TCP.

So, you decide to use TCP as the underlying transport for your protocol. Of course, TCP sends data as an octet stream—there aren't any delimiters that TCP uses to indicate where one of your application's messages ends and another one begins. This means you have to design a framing mechanism that your application uses with TCP. That's pretty simple to do—HTTP uses an octet count and SMTP uses a delimiter with quoting.

Since TCP is just sending bytes for you, you need to not only frame messages, but have a way of marking what's in each message. (For example, a data structure, an image, some text, and so on.) This means you have to design an encoding mechanism that your application uses with the framing mechanism. That's also pretty simple to do—HTTP and SMTP both use *Multipurpose Internet Mail Extensions* (MIME).[4]

Back in the early 1980s, when I was a young (but exceptionally cynical) computer scientist, my advisor told me that protocols have two parts: *data* and *control*. It looks like the data part is taken care of with MIME, so it's onto the control part. If you are fortunate enough to know ahead of time every operation and option that your protocol will ever support, there's no need for any kind of capabilities negotiation. In other words, your protocol doesn't need anything that lets the participants tell each other which operations and options are supported. (Of course, if this is the case, you have total recall of future events, and really ought to be making the big money in another, more speculative, field.)

The purpose of negotiation is to find common ground between two different implementations of a protocol (or two different versions of the same implementation). There are lots of different ways of doing this and, unfortunately, most of them don't work very well. SMTP is a really long-lived, well-deployed protocol, and it seems to do a pretty good job of negotiations. The basic idea is for the server to tell the client what capabilities it supports when a connection is established, and then for the client to use a subset of that.

Well, that's just the first control issue. The next deals with when it's time for the connection to be released. Sometimes this is initiated by the protocol, and sometimes it's required by TCP because the network is unresponsive. To further complicate things, if the release is initiated by the protocol, maybe one of the computers hasn't finished working on something, so it doesn't want to release the connection just yet.

Some application protocols don't do any negotiation on connection release, and just rely on TCP to indicate that it's time to go away—even though this is inherently ambiguous. Is ambiguity a good thing in a protocol? Computers lack subtlety and nuance, so in protocols between computers, ambiguity is a bad thing. For example, in HTTP 1.0 (and earlier), you often didn't know whether a response was truncated or not. For a more concrete example, interested readers will be amused by page 2 of RFC 962.[5]

The final control issue deals with what happens between connection establishment and release. Most application protocols tend to be client/server in nature: one computer establishes a connection, sends some requests, gets back responses, and then releases the connection. But, are the requests and responses handled one at a time (in lock-step), or can multiple requests be outstanding, either in transit or being processed, at the same time (asynchronously)?

In the original SMTP, the lock-step model was implicitly assumed by most implementors; later on, SMTP introduced a capability to allow limited pipelining. Regardless, as soon as we move away from lock-stepping, it looks as though we'll need some way of correlating requests and responses.

Although this is a step in the right direction, some application protocols need even more support for asynchrony. The reasoning is a little convoluted, but it all comes down to performance. There's a lot of overhead involved in terms of establishing a connection and getting the right user state, so it makes sense to maximize the number of transactions that get done in a single connection. While this helps in terms of overall efficiency, if the transactions are handled serially, then transactional latency—the time it takes to transit the network, process the transaction, and then transit back—isn't reduced (and may even be increased); a transaction might be blocked while waiting for another to complete. The solution is to be able to handle transactions in parallel.

Earlier I mentioned how, back in the 1980s, protocols had two parts, *data* and *control*. Today, things have changed. First of all, I'm still cynical, but more comfortable with it, and—perhaps as important—many might argue that protocols now have a third part, namely *security*.

The really unfortunate part is that security is a moving target on two fronts:

- When you deploy your protocol in different environments, you may have different security requirements.
- Even in the same environment, security requirements change over time.

This introduces something of a paradox: modern thinking is that security must be tightly integrated with your protocol, but at the same time, you have to take a modular approach to the actual technology to allow for easy upgrades. Worse, it's very easy to get security very wrong. (Just ask any major computer vendor!) Few applications folks are also expert in protocol security, and obtaining that expertise is a time-consuming, thankless task, so there's a lot of benefit in having a security mechanism menu, developed by security experts, that applications folk can pick from.

Now the good news: there's already something around designed to meet just those requirements. It's called the *Simple Authentication and Security Layer* (SASL), and a lot of existing application protocols have been retrofitted over the last four years to make use of it.

Well, let's see what all this means. Without ever having talked about what your application protocol is going to do to earn a living, we have to develop solutions for:

- Framing messages
- Encoding data
- Negotiating capabilities (versions and options)
- Negotiating connection release
- Correlating requests and responses
- Handling multiple outstanding requests (pipelining)
- Handling multiple asynchronous requests (multiplexing)
- Providing integrated and modular security
- Integrating all these things together into a single, coherent framework

So, going back to the question "Why use BEEP?", the answer is pretty simple: if you use BEEP, you simply don't have to think about any of these things. They automatically get taken care of.

Now maybe you're the kind of hardcore engineer that really wants to solve these problems yourself. Okay, go right ahead! But first, I'll let you in on a little secret: engineers have been solving these problems since 1972. In fact, they keep solving them over and over again. For each problem, there are usually two or three good solutions, and while individual tastes may vary, the sad fact is that you can make any of them work great if you're willing to put in the hours. But why put in the hours if they have nothing to do with the primary reason for writing the application protocol to begin with? Isn't there something more productive that you'd care to do with your life than design yet another framing protocol?

So, what's really *new* about BEEP? The short answer is: not much. The innovative part is that some folks sat down, did an analysis of the problems and solutions, and came up with an integrated framework that put it all together. That's not really innovation, but it's really good news if you're already familiar with the building blocks that BEEP uses.

Doesn't all this stuff add a lot of overhead? The short answer is: nope. The reason is a little more complex. BEEP is fairly minimalistic—it provides a simple mechanism for negotiating things on an à la carte basis. If you don't want privacy, no problem; don't turn it on. If you don't want parallelism, that's easy; just say "no" if the other computer asks for it. The trick here is two-fold:

- BEEP's inner mechanisms (for example, framing) are pretty lightweight, so you don't incur a lot of overhead using them (even if you don't use all the functionality they provide).
- BEEP's outer mechanisms (for example, encryption) are all controlled via bilateral negotiation, so you can decide exactly what you want to get and pay for.

There's no free lunch, but if you want to start with something "lean and mean," BEEP doesn't slow you down, and when you want to bulk up (say, by adding privacy), BEEP lets you negotiate it. You incur only the overhead you need. (This overhead *will* show up, regardless of whether you use BEEP or grow your own mechanisms.)

It turns out that this philosophy can yield some interesting results. For example, take a look at this high-level scripting fragment:

```
::init -server example.com -port 10288 -privacy strong
```

This fragment is invoking a procedure to establish a BEEP session. With the exception of the last two terms, it looks pretty conventional.

The last two terms tell the procedure to "tune" the session by looking at the security protocols supported in common, selecting one that supports "strong privacy," and then negotiating its use. What's interesting here is that neither the person who designed the application protocol nor the person who wrote the application making the procedure call has to be a security expert. The choice to use strong privacy, and how it gets transparently used, is all an issue of provisioning. Of course, the application protocol designer may still provide security guidelines to the implementor; naturally, the implementor may bundle a wide range of security protocols with the code. However—and this is key—everyone got to focus on what they do best (even the security guys), and it still comes together into a working system.

The cool part here is how easily this all integrates into an evolving protocol. Back in the good ol' days (say the mid-1980s) when the *Post Office Protocol* (POP)[6] was defined, this kind of flexibility wasn't available. Whenever someone wanted to add a new security mecha-

nism for authentication or privacy, you had to muck with the entire protocol. With BEEP's framework, you just add a module that works seamlessly with the rest of the protocol. This means less work for everyone, and presumably fewer mistakes getting the work done.

Now we've come full circle: the reason for using BEEP is because it makes it a lot easier to specify, develop, maintain, and evolve new application protocols.

The Problem Space

BEEP works for a large class of application protocols. However, you should always use the right tool for the right job. Before you start using BEEP for a project, you should ask yourself whether your application protocol is a good fit for either the e-mail or Web models.

Dave Crocker, one of the Internet's progenitors, suggests that network applications can be broadly distinguished by five operational characteristics:

- Server push or client pull
- Synchronous (interactive) or asynchronous (batch)
- Time-assured or time-insensitive
- Best-effort or reliable
- Stateful or stateless

For example:

- The World Wide Web is a pull, synchronous, time-insensitive, reliable, stateless service.
- Internet mail is a push, asynchronous, time-insensitive, best-effort, stateless service.

This is a pretty useful taxonomy.

So, your first step is to see whether either of these existing infrastructures meet your requirements. It's easiest to start by asking if your application can reside on top of e-mail. Typically, the unpredictable latency of the Internet mail infrastructure raises the largest issues; however, in some cases it's a non-issue. For example, in the early 1990s, some of the earliest business-to-business exchanges were operated over e-mail (for example, USC/ISI's FAST project). If you can find a good fit between your application and Internet e-mail, use it!

More likely, though, you'll be tempted to use the Web infrastructure, and there are a lot of awfully good reasons to do so. After all, when you use HTTP:

- There's lots of tools (libraries, servers, etc.) to choose from.
- It's easy to prototype stuff.
- There's already a security model.
- You can traverse firewalls pretty easily.

All of this boils down to one simple fact: it is pretty easy to deploy things in the Web infrastructure. The real issue is whether you can make good use of this infrastructure.

HTTP was originally developed for retrieving documents in a LAN environment, so HTTP's interaction model is optimized for that application. Accordingly, in HTTP:

- Each session consists of a single request/response exchange.
- The computer that initiates the session is also the one that initiates the request.

What needs to be emphasized here is that this is a perfectly fine interaction model for HTTP's target application, as well as many other application domains.

The problem arises when the behavior of your application protocol doesn't match this interaction model. In this case, there are two choices: make use of HTTP's extensibility features, or simply make do. Obviously, each choice has some drawbacks. The problem with using HTTP's extensibility features is that it pretty much negates the ability to use the existing HTTP infrastructure; the problem with "just making do" is that you end up crippling your protocol. For example, if your application protocol needs asynchronous notifications, you're out of luck.

A second problem arises due to "the law of codepaths." The HTTP 1.1 specification, RFC 2616[10] is fairly rigorous. Even so, few implementors take the time to think out many of the nuances of the protocol. For example, the typical HTTP transaction consists of a small request, which results in a (much) larger response. Talk to any engineer who's worked on a browser and they'll tell you this is "obvious." So, what happens when the "obvious" doesn't happen?

Some time ago, folks wanted a standardized protocol for talking to networked printers. The result was something called the *Internet Printing Protocol* (IPP)[1]. IPP sits on top of HTTP. At this point, the old "obvious" thing (small request, big response) gets replaced with the new "obvious" thing—the request contains an arbitrarily large file to be printed, and the response contains this tiny little status indication. A surprising amount of HTTP software doesn't handle this situation particularly gracefully (that is, long requests get silently truncated). The moral is that even though HTTP's interaction model doesn't play favorites with respect to lengthy requests or responses, many HTTP implementors inadvertently make unfortunate assumptions.

A third problem deals with the unitary relationship between sessions and exchanges. If a single transaction needs to consist of more than one exchange, it has to be spread out over multiple sessions. This introduces two issues:

- In terms of stateful behavior, the server computer has to be able to keep track of session state across multiple connections, imposing a significant burden both on the correctness and implementation of the protocol (for example, to properly handle time-outs).
- In terms of performance, TCP isn't designed for dealing with back-to-back connections—there's a fair amount of overhead and latency involved in establishing a connection. This is also true for the security protocols that layer on top of TCP.

HTTP 1.1 begins to address these issues by introducing persistent connections that allow multiple exchanges to occur serially over a single connection, but still the protocol lacks a session concept. In practice, implementors try to bridge this gap by using "cookies" to manage session state, which introduces ad-hoc (in)security models that often result in security breakdowns (as a certain Web-based e-mail service provider found out).

This brings us to a more general fourth problem: although HTTP has a security model, it predates SASL. From a practical perspective, what this means is that it's very difficult to add new security protocols to HTTP. Of course, that may not be an issue for you.

If you can find a good fit between your application and the Web infrastructure, use it! (For those interested in a more architectural perspective on the reuse of the Web infrastructure for new application protocols, consider RFC 3205[7].)

Okay, so we've talked about both the e-mail and Web infrastructures, and we've talked about what properties your application protocol needs to have in order to work well with them. So, if there isn't a good fit between either of them and your application protocol, what about BEEP?

BEEP's interaction model is pretty simple, with the following three properties:

- Each session consists of one or more request/response exchanges.
- Either computer can initiate requests or notifications.
- It's connection-oriented.

By using BEEP, you get an amortization effect with respect to the cost of connection establishment and state management. This is largely derived from the first property. Similarly, the second property gives BEEP its ability to support either peer-to-peer or client-server interactions. What we really need to explain is the connection-oriented part.

To begin, all three of the interaction models we've looked at (BEEP, e-mail, and the Web) are connection-oriented. (Although e-mail may get delivered out of order, the commands sent over each e-mail "hop" are processed in an ordered, reliable fashion.) The connection-oriented model is the most commonly used for application protocols, but it does introduce some restrictions.

A connection-oriented interaction model means that data is delivered reliably and in the same order as it was sent. If you don't require ordered, reliable delivery, you don't need a connection-oriented interaction model. For example, Internet telephony applications don't fit this model, nor do traditional multicast applications.

So, BEEP is suitable for unicast application protocols (two computers are talking to each other). However, not all unicast applications need a connection-oriented model—for example, the *Domain Name System* (DNS) manages name-to-address resolutions just fine without it. In fact, if your protocol is able to limit each session to exactly one request/response exchange with minimalist reliability requirements, and also limit the size of each message to around 65K octets, then it's probably a good candidate for using the *User Datagram Protocol* (UDP) instead.

The IETF and BEEP

BEEP is an emerging standard from the *Internet Engineering Task Force* (IETF). The IETF is a voluntary professional organization that develops many of the protocols running in the Internet. (Of course, anyone is free to develop their own protocols to run in their own little part of the Internet, but if you want multi-vendor support, you need an organization like the IETF.) So why does the IETF care about BEEP?

The answer is that the largest area in the IETF deals with application protocols. There are usually over two dozen working groups developing different application protocols. And, the IETF has been doing this for a long, long time. It turns out that even though there are well-engineered solutions to the different overhead issues, BEEP is the first time that the IETF decided to develop a standard approach that integrates the best practices for each issue. Before BEEP, each working group would spend endless hours arguing about different solutions, and then, if any time was remaining, they might sit down and look at the actual problem domain. (Okay, this is an exaggeration... but not by much!)

So, here's the process by which BEEP got designed:

- Identify the common domain-independent problems.
- Determine the best solution for each problem.
- Integrate the solutions into a consistent framework.
- Declare victory.

Now, the obvious question is: how do you determine what's "best?"

The truth is that in some cases, the answer is obvious, and in other cases, the answer is arbitrary. (Protocol experts hate to admit this, but in some cases, there is no clear winner, and it's simply better to pick *one* and order another drink.) Since most of what BEEP does is hidden from the application designer and implementor, there's really not a lot of mileage in going through it here.

beepcore.org

Where can you find out more about BEEP? To start, you can always consult the two RFCs: the BEEP core framework[8] and the BEEP's mapping onto TCP[9]. However, it's probably better to start with the BEEP community Web site **`http://beepcore.org`** where you'll find:

- News about BEEP meetings and events
- Information about BEEP projects, programmers, and consultants
- Information about beepcore (open source) and commercial software
- BEEP-related RFCs, Internet-Drafts, and whitepapers

ENUM—Mapping the E.164 Number Space into the DNS

by Geoff Huston, Telstra

Many communications networks are constructed for a single form of communication, and are ill suited to being used for any other form. Although the Internet is also a specialized network in terms of supporting digital communications, its relatively unique flexibility lies in its ability to digitally encode a very diverse set of communications formats, and then support their interaction over the Internet. In this way many communications networks can be mapped into an Internet application and in so doing become just another distributed application overlayed on the Internet. From this admittedly Internet-centric perspective, voice is just another Internet application. And for the growing population of *Voice over IP* (VoIP) users, this is indeed the case. Being able to transmit voice over the Internet is not enough. Allowing one Internet handset to connect to any other Internet handset is still not enough. In the same way that walkie-talkies became ubiquitous mobile phones only when there was a seamless integration with the telephone network, a truly useful VoIP approach will be one that supports seamless integration with the telephone network.

The basics of the telephony world are very simple indeed. Telephone handsets are little more than a speaker and a microphone. When a call is made, the network connects the microphone of one party to the speaker of the other, and vice versa. Of course you don't need a specialized telephone network to support the carriage of voice. As any user of a desktop computer would confirm, there are now a plethora of applications that can deliver a voice signal across the network. For an application to support a voice conversation, a conventional approach is to use a network base of the *User Datagram Protocol* (UDP) transport protocol, with a *Real-Time Protocol* (RTP) overlay, and the RTP payload is an encoded version of the original analogue voice signal. Carrying voice signals in real time across an Internet is a well-understood network service, with an accompanying set of existing protocols and associated applications.

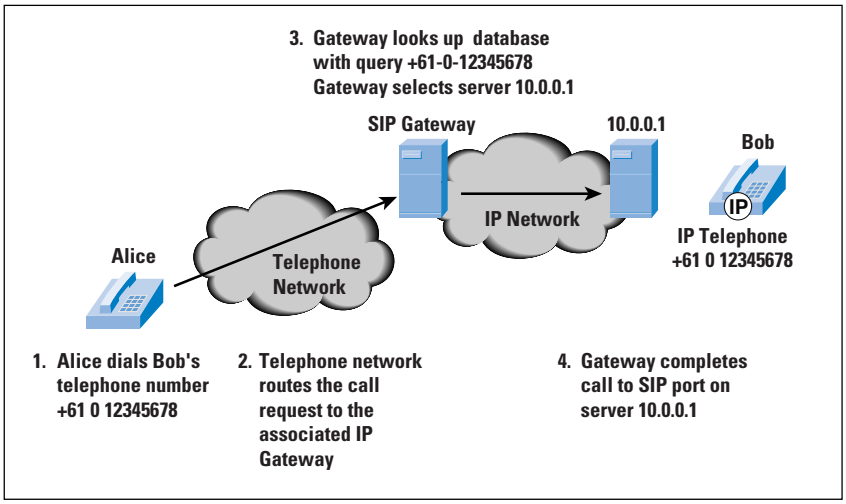
E.164 Addresses and IP Services

However, being able to transmit voice signals across a network is not enough. It was Strowger's step-by-step switching system of the late 19th century that transformed the telephone into a truly useful communications network, allowing any telephone subscriber to initiate a conversation with any other subscriber. This has evolved today into a global numbering plan where every device connected to the telephone network is assigned a unique numerical address. This numbering plan is administered by the *International Telecommunication Union* (ITU), and the plan, Recommendation E.164, involves the assignment of number prefixes to each country code administrator[1].

If the Internet voice domain interoperates seamlessly with the telephone network, supporting this E.164 numbering plain into the realm of the Internet is a critical step. To make Internet telephony truly useful, the Internet telephony world has to be able to interface to the telephone network by allowing Internet-connected telephone devices to make and receive calls to any other telephone device, whether the other device is connected to the Internet, connected to the telephone network, or connected to any other network that seamlessly interoperates with the telephone network. For this to work, one of the preconditions is that every Internet device that supports telephone operation needs to also have an alias in the form of a unique telephone address. But there's a bit more to it than simple numbering.

Each Internet telephone is also an IP device, and, for the Internet component of the end-to-end path, the voice traffic will be carried by IP packets. These packets obviously require the IP address of the Internet telephone device. So each Internet telephone requires both an Internet address and a telephone address. It is the mapping from a telephone number to an IP address that is the crucial part of this function.

Figure 1: Calling an IP Telephone



Consider an example. When Alice, on a normal telephone, wants to call Bob, on an Internet phone, all Alice needs to do is simply dial Bob's telephone number, or his E.164 address (Figure 1). Of course, because Bob's phone is connected to the Internet and can't directly receive Alice's call request, a gateway is necessary. The telephone system should be able to map Alice's call request to the Internet telephony gateway that is configured to act as Bob's gateway agent. The gateway then needs to translate Bob's E.164 phone number into an IP address. Then the gateway has to map the telephone network signals associated with Alice's call request to corresponding signals within an Internet session initiation protocol, and then send these IP packets to Bob's Internet phone. If Bob answers the call, the phone uses the same protocol to inform the gateway, which then sends a corresponding telephone call code across the telephone network to Alice.

When Bob accepts the call, the gateway can then pass all data originating from Alice to Bob's IP address, and all data received from Bob's IP address across to the telephone connection to Alice for the duration of the call. Alice never needs to know that Bob is using an Internet device. Alice dialed a phone number, heard it ring, and then heard Bob answer the call. For Alice, nothing has changed. Bob heard the phone ring, picked it up, and talked to Alice. For Bob, nothing has changed.

The simplest way to configure each gateway is to load each gateway with a configured list of E.164 phone numbers and corresponding IP addresses. This approach is currently very common, but, like all statically configured approaches, has its weaknesses. But what happens when the IP device is numbered dynamically using the *Dynamic Host Configuration Protocol* (DHCP), or if it's mobile, and moves from one service provider's IP network to another, or when the end subscriber changes providers and that subscriber's network is renumbered, or when the primary gateway fails and the providers want to switch to a secondary device? In other words, how can this mapping be dynamic rather than static?

The way a dynamic domain name-to-IP address mapping can be maintained on the Internet is through the Internet *Domain Name System* (DNS). The telephony gateway can use the the E.164 address as the DNS query, and request the DNS to return the corresponding IP address. In our example, when Alice rings Bob, the gateway can use the DNS to obtain Bob's current IP address. The gateway can then use the *Session Initiation Protocol* (SIP) to send to Bob's Internet phone a call request, which then starts Bob's phone ringing. If Bob changes IP address, then the corresponding change is a change in the DNS, not in the gateway itself. If the primary gateway fails and a secondary gateway is used, the secondary system can already access all necessary mappings through the DNS.

So the general approach of using the DNS to contain this mapping is one with some merit, but, as always, the devil is in the details. There are two parts to mapping a E.164 number into the DNS. The first is the nature of the transforms to be applied to the E.164 address to obtain a DNS query string, and the second is the form of the DNS response to this query.

Mapping E.164 Addresses into DNS Query Strings

One possible approach to mapping an E.164 number into the DNS is to simply place numbers as text blocks into the DNS. In this way, the number *+61-0-12345678* could be mapped to the DNS string **`61012345678.example.com.`** If this method were to be used for a sizable number of E.164 numbers, there are obvious DNS performance implications associated with the size of this DNS zone file, together with the issue of frequency of update of the zone and its cache characteristics.

There are also a large number of E.164 country code delegated authorities and, consequently, a large number of entities who would like to be the authority for parts of such a monolithic unstructured DNS zone file.

In order to avoid these issues, some structure in the E.164 address space has to be used to map into the hierarchical name structure used in the DNS. One helpful observation is that E.164 numbers and Internet domain names use opposite ordering. Whereas a fully qualified domain name, such as **`test.example.com,`** has the more specific parts to the left and the most general part, the root, on the right of the name, a telephone number code has the most general part, the reference to the country code prefix "**`+`**" to the left and the more specific parts to the right. If one were to reverse the order of E.164 symbols, then the two address domains would have a similar structure.

One of the first efforts to provide a mapping between E.164 number and the DNS was part of the TPC fax gateway service, started in 1993[2]. This approach uses a reversed E.164 number, and treats every digit as a node on the DNS name hierarchy. In our example, the E.164 address *+61 0 12345678* would map to the DNS query string **`8.7.6.5.4.3.2.1.0.1.6.tpc.int.`** (in the TPC service, the parent DNS zone of this mapping is **`tpc.int.`**)

This mapping has some very convenient properties. Each country code corresponds to a delegatable DNS domain, so that the international country code for Australia, *+61,* can have a corresponding DNS delegation for the zone **`1.6.tpc.int.`** Within the country code the DNS can be further delegated to operators in a manner that parallels the further delegation of E.164 common prefix number blocks.

This same mapping is used by ENUM, using a DNS name parent of **`e164.arpa.`** The mapping entails taking a complete E.164 address (including the country code), and then removing all nondigit symbols from the address. The digit string is reversed and a "**`.`**" is placed between each pair of digits. The string **`.e164.arpa.`** is then appended to make a complete DNS query string. Using this process, our example number *+61-0-12345678* is transformed into the DNS query:
`8.7.6.5.4.3.2.1.0.1.6.e164.arpa.`

Although this form of mapping is technically well suited to the DNS, it does mean that the DNS equivalent of the E.164 address is not very easily adapted to our conventional use of telephone numbers. The implication is that it is likely that Internet-based telephony applications will continue to present E.164 numbers in their user interfaces as conventional telephone numbers, and manipulate the DNS equivalent strings as internal objects.

The DNS Response

The telephone network supports more than simple voice conversations, and any serious attempt to bridge the telephone network and the Internet also should be able to also handle various forms of text messaging and paging services as well as document transmission undertaken as faxes. The desired outcome is that the interface between the telephone network and the Internet should be able to seamlessly redirect the telephone service to the appropriate Internet service. In other words, we are seeing a requirement that a set of services associated with the same E.164 address should be able to be mapped to a set of IP servers, rather than a single server with a single IP address.

The implication is that the DNS response to an ENUM query should have a richer functionality than simply returning a single IP address. In DNS terms, associating a conventional "A" DNS resource record with each ENUM domain name is not sufficiently flexible for our purposes.

The approach adopted by the TPC fax gateway service was to map a fax in the telephone environment to an e-mailed multimedia message in the Internet environment. To support this mapping, telephone numbers were mapped to DNS *Mail Exchange* (MX) resource records, and these records were mapped to a mail server's IP address in a second DNS lookup.

ENUM attempts to solve a more general model of providing mappings for any relevant service. One possible approach is to use a collection of DNS name roots, one for each mappable service. Thus, for example, **`fax.e164.arpa.`** could hold mappings for the fax service, while **`voice.e164.arpa.`** could hold mappings for voice services, and so on. However, this approach is not consistent with the generic architecture of the DNS, and the distribution of service information has the potential to lead to synchronization errors. Usefully, the DNS allows a collection of resource records to be associated with a DNS name, and this set of records is returned as the answer to a query. It is then left to the application to determine which particular record to use, with perhaps some preference hints provided in the DNS response. The approach used by ENUM takes advantage of this DNS capability, and ENUM uses the DNS to map an **`e164.arpa`** number onto a collection of service-specific *Uniform Resource Identifiers* (URIs)[3].

A gateway that uses ENUM to query the DNS will receive the complete collection of service-specific URIs in response to a request to translate an E.164 address to a URI. Depending on the type of service being requested, the gateway can then select the most appropriate URI and use the DNS a second time to translate the domain name part of the URI to an IP address using the URI-specific DNS resource record as a query term. The gateway can then use the full URI specification to open an IP session with the selected service port and complete the service transaction.

The URI resource records used by ENUM are *Naming Authority Pointers* (NAPTR) records[4]. This form of use of the DNS allows for entries where the entry itself can be decomposed into further delegations, using name formats that use URI syntax[5].

NAPTR fields contain numerous components:

- An *Order* field to specify the order in which multiple NAPTR records must be processed
- A *Preference* field to determine the processing order when multiple NAPTR records have the same order value
- A *Service* field to specify the resolution protocol and service
- *Flags* to modify the actions of further DNS lookups
- A *regular expression* to allow the query client to rephrase the original request in a DNS format
- A *Replacement* field to define the next DNS query object

The intended operation of ENUM is to first take the E.164 number and convert it to a query in the **`e164.arpa`** domain. The resultant set of services is specified by the returned collection of NAPTR records. The agent selects a service that matches the service characteristics of the original request, and takes the corresponding URI for further resolution by the DNS. The elements of this URI are further decomposed as per any rewrite rules in the NAPTR record. DNS queries are generated as per the sequence of preferred NAPTR rewrite operations. The ultimate result of this sequence of DNS queries is the specification of a protocol, an associated port address, and the IP address for a preferred server for the service.

An Example of the Use of ENUM

Let's say Bob's Internet telephone services are mapped to the E.164 address *+61-0-12345678*. When Alice tries to call Bob, the telephone network routes the call request toward the Internet gateway that is the nominated service agent for this E.164 number. The Internet gateway takes the call setup request with Bob's number and first reverses the digits, then inserts a "**`.`**" between each digit, and finally appends **`e164.arpa.`** The resultant DNS string is the fully qualified domain name **`8.7.6.5.4.3.2.1.0.1.6.e164.arpa.`** This name is then passed as a query to the DNS, to retrieve all associated NAPTR DNS resource records.

Bob has specified that he prefers to receive calls using SIP addressed to user **`bob`** at the server **`telebob.au`** by placing the following in the DNS:

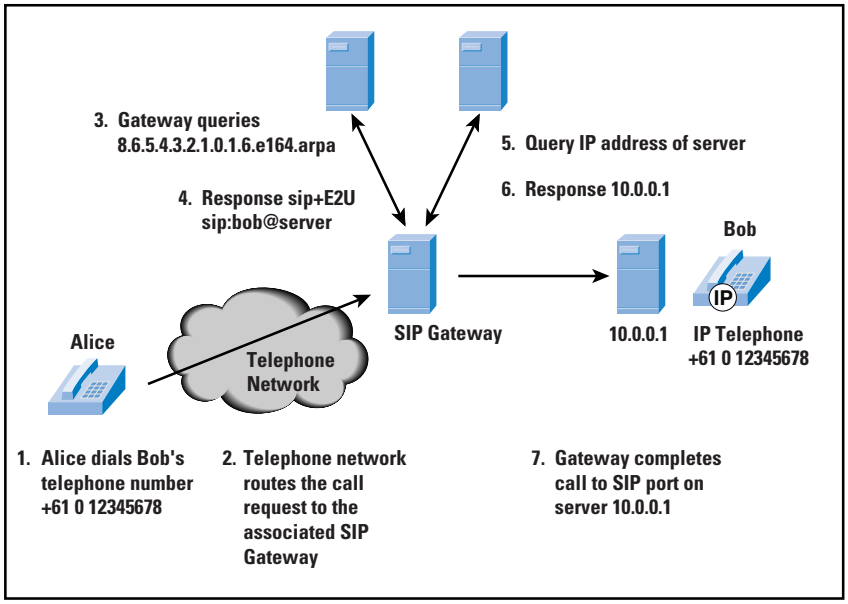
```
$ORIGIN 8.7.6.5.4.3.2.1.0.1.6.e164.arpa.
   IN NAPTR 100 10 "u" "sip+E2U"  "!^.*$!sip:bob@sip.telebob.au!" .
```

In this case the DNS entry uses an order value of 100 and a preference of 10. The "**u**" flag indicates that the rule is terminal and that the specified URI is to be used. The service field specifies that the SIP protocol is to be used, in conjunction with the E.164 to URI (E2U) resolution service[6]. The operation of the regular expression produces the URI of the form **sip:bob@telebob.au.**

For this call request, the gateway picks the **sip+E2U** service and performs the associated regular expression transform using the original E.164 number and the regular expression. This produces the **sip:** URI. The gateway then uses the DNS a second time to translate the domain part of the URI, **sip.telebob.au**, into an IP address using a DNS A record.

The gateway then opens up a session with UDP port 5060 on this SIP server to complete the call setup, requesting a voice session with the user Bob on this server. (Figure 2).

Figure 2: Using ENUM to Call an IP Phone



If, on the other hand, Alice is sending Bob a short text message, then Bob may want this to be delivered to him as mail. Bob would add the following entry into the DNS:

```
$ORIGIN 8.7.6.5.4.3.2.1.0.1.6.e164.arpa.
   IN NAPTR 100 10 "u" "sip+E2U"     "!^.*$!sip:bob@sip.telebob.au!"   .
   IN NAPTR 102 10 "u" "mailto+E2U"  "!^.*$!mailto:bob@mail.pobob.au!" .
```

In this case the gateway would use this **mailto:** URI and use the domain part of the URI as a MX DNS query. The DNS responses are a list of mail server names and associated preferences. The gateway then selects this more preferred server and resolves this name to an IP address by a further query to the DNS for an A address record.

The gateway can complete the original text message delivery request by opening a TCP session on port 25 of the mail server and sending the message as mail addressed to user **bob@mail.pobob.au.**

Services in ENUM

Other URIs can also be associated with an E.164 number, even services not normally associated with a mapping of a telephone function. These may include **http:** URIs, even other E.164 telephone numbers, specified by **tel:** URIs.

Let's complete the example of Bob, who wants his SIP phone, mail address, Web page, and mobile telephone to be referenced from a single telephone number.

```
$ORIGIN 8.7.6.5.4.3.2.1.0.1.6.e164.arpa.
    IN NAPTR 100 10 "u" "sip+E2U"     "!^.*$!sip:bob@sip.telebob.au!"   .
    IN NAPTR 100 10 "u" "mailto+E2U"  "!^.*$!mailto:bob@mail.pobob.au!" .
    IN NAPTR 100 10 "u" "http+E2U"    "!^.*$!http://www.webhostbob.au"  .
    IN NAPTR 103 10 "u" "tel+E2U"     "!^.*$!tel:+61-4-12341234"        .
```

Alice can enter the phone number *61012345678* into her browser and retrieve Bob's Web page in response. She can address e-mail to this number and thereby send mail to Bob. Or she can make a telephone call to Bob's SIP phone, and if it does not answer she can try Bob on his mobile phone. And she can do all this from a single number.

Numerous interesting technical issues still need to be resolved, such as the necessity and level of cacheing within the global ENUM system and the creation of a standard registry scheme for ENUM service definition.

The Politics of ENUM

There is quite some depth in the capabilities of the regular expression rewrite rules in ENUM, but the basic functionality is one of mapping a telephone number to a collection of service points that are associated with the telephone customer who was assigned that telephone number.

Despite this apparent functional simplicity, ENUM appears to have a powerful set of attractors for regulatory and social controversy.

A key benefit of moving into ENUM and the associated realm of IP-based voice communications is that service creation becomes a function of the edge and not the network. What were seen as telephone network functions such as no answer and busy redirect, call forwarding, number translation, and conference calls can all be implemented as edge applications driven by user scripts, rather than what we now see in the telephone network as value-added network-based services. One way of viewing this ENUM approach is that the DNS is functionally capable of assuming the role of service control point for telephone services, taking over the role undertaken by *Signaling System 7/Channel 7* (SS7/C7).

Service creation and signaling are slipping away from the hands of network operators into the hands of enterprises and eventually consumers, in much that same way that the Internet has redefined other services in terms of edge-based function instead of network mediation.

There is also the issue of ownership of these ENUM DNS zones, or to put it another way: who gets to populate the **e164.arpa** domain with all these URIs? It could be that this is a responsibility of existing telephone service providers, because after all these entities operate the E.164 address space in each country. It could also be that this is a responsibility of Internet Service Providers (ISPs), because the data in the resource records is describing Internet-based services. Or maybe the end subscribers get to populate the DNS with their own entries, based on a collection of services that may be sourced from a set of providers.

It is quite conceivable that we could see ISPs that have no direct role in carrying voice traffic wanting access to a country's E.164 number plant in order to provide various forms of ENUM services. Given that each element of an ENUM service collection can use URIs that refer to different ISP services, it is possible that the one ENUM record can be populated by URIs referring to numerous different service providers. This model of multi-agent access to such infrastructure resource records is a novel concept to many regulatory and operating regimes, where a single operator manages the entire associated infrastructure elements that are needed to deliver a service.

Some of the discussion about ENUM has been on more subtle aspects of this mapping. There's the choice of **e164.arpa** as the common DNS root for ENUM DNS entries. At an international level there's a lingering perception that "**arpa**" is too American and that a name root of "**int**" appears to be more neutral.

But there's something else lurking here, which has surfaced within the regulatory debate in the United States. North America has the .164 country code of "1," implying that under ENUM there is a single DNS domain for ENUM, namely **1.e164.arpa.** Single domains imply single operators, and single operators have an implication of a noncompetitive monopoly service regime. There has been a call for multiple E.164 DNS root locations for North America, allowing for two or more competing service operators using different DNS hierarchies to locate their ENUM services.

On the one side there is the view that such attempts to create multiple partially populated ENUM name hierarchies to support competitive service provision in ENUM-based services are no more than an incitement to address and service chaos. This chaos would, in turn, seriously hamper the uptake of ENUM services.

On the other hand, the competitive provision proponents of multiple DNS root domains argue that a regulatory-sanctioned monopoly is still a monopoly, and this monopoly situation will likely lead to high service prices for ENUM services. This escalated pricing structure would, in turn, seriously hamper the uptake of ENUM services.

As we have seen with the use of multiple services for an **`e164.arpa`** entry, the proponents of ENUM envisage a single telephone number as being an alias not only for your Internet phone service, but also for instant messaging, e-mail, your Web page, and any other service that is associated with you. One identifier is all that would be required to reach you, using a service protocol and service provider of your choice. The implication of such a use of a telephone number is, on a personal level, no more business cards cluttered with phone numbers, fax numbers, mobile numbers, e-mail addresses, Web addresses, and instant-messaging handles. Phone numbers are still the most widely used naming scheme in communications, and the use of these numbers as a universal locator has the advantage of being linguistically neutral as well as enjoying almost ubiquitous use. There are no international character set issues within this particular number space. All we need is just one ENUM address, or just one number, for all these services.

> "One number to rule them all, one number to find them, one number to bring them all and in the darkness bind them," is the ENUM version of Tolkien's saga[7].

But one person's ease of use is often another's opportunity to exploit. To be *Lord of the Numbers* would indeed be a powerful role if such uses of ENUM were to become widespread. In addition to the commercial opportunity in operating ENUM registries, ENUM can be seen as yet another erosion of personal privacy on the Internet. It can be viewed as one more step toward the use of single individual digital identity that could be used to track individuals within the Internet. On a more immediate and mundane level of concern it opens up the opportunity for spammers to use a wealth of new ways to drive you to complete distraction.

It appears that the technical components of ENUM are generally the most straightforward part. The regulatory and social implications of ENUM are more of a concern, and it is here that with ENUM we are entering into "the Land of Mordor where the shadows lie."

One Byte at a Time

Bootstrapping with BOOTP and DHCP

by Douglas Comer, Purdue University

The process of starting a computer system is known as *bootstrapping*. In most systems, the initial bootstrap sequence begins with code in ROM, which the CPU executes. The ROM code only contains a first step—it merely loads an image into the computer's RAM and branches to the image. There are two approaches used to obtain an image:

- *Embedded system:* On a diskless computer, the ROM code contains sufficient support software to permit network communication. The ROM code uses the network support to locate and download an image.
- *Conventional computer:* On a computer that has secondary storage (for instance, a PC), the ROM code loads the image from a well-known place on disk. Typically, the loaded image consists of an operating system that then controls the computer.

In either case, the image loaded by ROM is not tailored to the specific physical hardware. Instead, an image is *generic*, which means that before it can be used, it must be configured for the local hardware. In particular, the image does not contain such networking details as the computer's IP address, address mask, or domain name. Each of these items must be supplied before applications can use TCP/IP.

Early in the history of TCP/IP, designers chose to provide a separate mechanism for each item of configuration information. Thus, the *Reverse Address Resolution Protocol* (RARP) only allowed a computer to obtain its IP address. When subnet masks were introduced, ICMP Address Mask messages were added to allow a computer to obtain a subnet mask. The chief advantage of such an approach lies in flexibility—a computer can decide which items to obtain from a local file on disk and which to obtain over the network. The chief disadvantage becomes apparent when one considers the network traffic and delay. A given computer must issue a series of small request messages. More important, each response returns a small value (for instance, a 4-octet IP address). Because networks enforce a minimum packet size, most of the space in each packet is wasted.

BOOTP

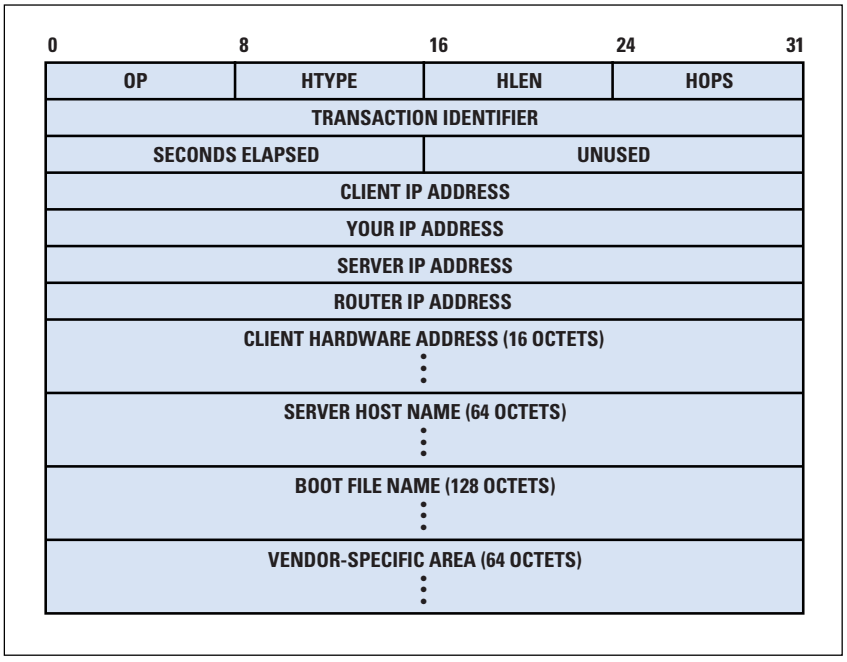
As the complexity of configuration grew, TCP/IP protocol designers observed that many of the configuration steps could be combined into a single step if a server was able to supply more than one item of configuration information. To provide such a service, the designers invented the *BOOTstrap Protocol* (BOOTP). To obtain configuration information, protocol software broadcasts a *BOOTP Request* message.

A BOOTP server that receives the request looks up several pieces of configuration information for the computer that issued the request, places the information in a single *BOOTP Response* message, and returns the reply to the requesting computer. Thus, in a single step, a computer can obtain information such as the computer's IP address, the server's name and IP address, and the IP address of a default router.

Like other protocols used to obtain configuration information, BOOTP broadcasts each request. Unlike other protocols used for configuration, BOOTP appears to use a protocol that has not been configured: BOOTP uses IP to send a request and receive a response. How can BOOTP send an IP datagram before a computer's IP address has been configured? The answer lies in a careful design that allows IP to broadcast a request and receive a response before all values have been configured. To send a BOOTP datagram, IP uses the all-1's limited broadcast address as a *DESTINATION ADDRESS*, and uses the all-0's address as a *SOURCE ADDRESS*. If a computer uses the all-0's address to send a request, a BOOTP server either uses broadcast to return the response or uses the hardware address on the incoming frame to send a response via unicast. (The server must be careful to avoid using ARP because a client that does not know its IP address cannot answer ARP requests.)

Thus, a computer that does not know its IP address can communicate with a BOOTP server. Figure 1 illustrates the BOOTP packet format. The message is sent using UDP, which is encapsulated in IP.

Figure 1: BOOTP Packet Format



Each field in a BOOTP message has a fixed size. The first seven fields contain information used to process the message. The *OP* field specifies whether the message is a *Request* or a *Response*, and the *HTYPE* and *HLEN* fields specify the network hardware type and the length of a hardware address. The *HOPS* field specifies how many servers forwarded the request, and the *TRANSACTION IDENTIFIER* field provides a value that a client can use to determine if an incoming response matches its request. The *SECONDS ELAPSED* field specifies how many seconds have elapsed since the computer began to boot. Finally, if a computer knows its IP address (for instance, the address was obtained using RARP), the computer fills in the *CLIENT IP ADDRESS* field in a request.

Later fields are used in a response message to carry information back to the computer that is booting. If a computer does not know its address, the server uses field *YOUR IP ADDRESS* to supply the value. In addition, the server uses fields *SERVER IP ADDRESS* and *SERVER HOST NAME* to give the computer information about the location of a computer that runs servers. Field *ROUTER IP ADDRESS* contains the IP address of a default router.

In addition to protocol configuration, BOOTP allows a computer to negotiate to find a boot image. To do so, the computer fills in field *BOOT FILE NAME* with a generic request (for instance, the computer can request the UNIX operating system). The BOOTP server does not send an image. Instead, the server determines which file contains the requested image, and uses field *BOOT FILE NAME* to send back the name of the file. Once a BOOTP response arrives, a computer must use a protocol like the *Trivial File Transfer Protocol* (TFTP) to obtain a copy of the image.

Automatic Address Assignment

Although it simplifies loading parameters into protocol software, BOOTP does not solve the configuration problem completely. When a BOOTP server receives a request, the server looks up the computer in its database of information. Thus, even a computer that uses BOOTP cannot boot on a new network until the administrator manually changes information in the database.

Can protocol software be devised that allows a computer to join a new network without manual intervention? Yes—several such protocols exist. For example, IPX and IPv6 can generate a protocol address from the computer's hardware address. To make automatic generation work correctly, the hardware address must be unique. Furthermore, if the hardware address and protocol address are not the same size, it must be possible to translate the hardware address into a protocol address that is also unique.

The AppleTalk protocols use a *bidding* scheme to allow a computer to join a new network. When a computer first boots, the computer chooses a random address. For example, suppose computer *C* chooses address *17*. To ensure that no other computer on the network is using the address, *C* broadcasts a request message and starts a timer. If no other computer is using address *17*, no reply will arrive before the timer expires; *C* can begin using address *17*. If another computer is using *17,* the computer replies, causing *C* to choose a different address and begin again.

Choosing an address at random works well for small networks and for computers that run client software. However, the scheme does not work well for servers. To understand why, recall that each server must be located at a well-known address. If a computer chooses an address at random when it boots, clients will not know which address to use when contacting a server on that computer. More important, because the address can change each time a computer boots, the address used to reach a server may not remain the same after a crash and reboot.

A bidding scheme also has the disadvantage that two computers can choose the same network address. In particular, assume that computer *B* sends a request for an address that another computer (for example, *A*) is already using. If *A* fails to respond to the request for any reason, both computers will attempt to use the same address, with disastrous results. In practice, such failures can occur for a variety of reasons. For example, a piece of network equipment such as a bridge can fail, a computer can be unplugged from the network when the request is sent, or a computer can be temporarily unavailable (for instance, in a hibernation mode designed to conserve power). Finally, a computer can fail to answer if the protocol software or operating system is not functioning correctly.

DHCP

To automate configuration, the *Internet Engineering Task Force* (IETF) devised the *Dynamic Host Configuration Protocol* (DHCP). Unlike BOOTP, DHCP does not require an administrator to add an entry for each computer to the database that a server uses. Instead, DHCP provides a mechanism that allows a computer to join a new network and obtain an IP address without manual intervention. The concept has been termed *plug-and-play networking*. More important, DHCP accommodates computers that run server software as well as computers that run client software:

- When a computer that runs client software is moved to a new network, the computer can use DHCP to obtain configuration information without manual intervention.
- DHCP allows nonmobile computers that run server software to be assigned a permanent address; the address will not change when the computer reboots.

To accommodate both types of computers, DHCP cannot use a bidding scheme. Instead, it uses a client-server approach. When a computer boots, the computer broadcasts a *DHCP Request* to which a server sends a *DHCP Reply*. (The reply is classified as a DHCP *offer* message that contains an address the server is offering to the client.)

An administrator can configure a DHCP server to have two types of addresses: permanent addresses that are assigned to server computers, and a pool of addresses to be allocated on demand. When a computer boots and sends a request to DHCP, the DHCP server consults its database to find configuration information.

If the database contains a specific entry for the computer, the server returns the information from the entry. If no entry exists for the computer, the server chooses the next IP address from the pool, and assigns the address to the computer.

In fact, addresses assigned on demand are not permanent. Instead, DHCP issues a *lease* on the address for a finite period of time. (When the administrator establishes a pool of addresses for DHCP to assign, the administrator must also specify the length of the lease for each address.)

When the lease expires, the computer must renegotiate with DHCP to extend the lease. Normally, DHCP will approve a lease extension. However, a site may choose an administrative policy that denies the extension. (For example, a university that has a network in a classroom might choose to deny extensions on leases at the end of a class period to allow the next class to reuse the same addresses.) If DHCP denies an extension request, the computer must stop using the address.

Optimizations in DHCP

If the computers on a network use DHCP to obtain configuration information when they boot, an event that causes all computers to restart at the same time can cause the network or server to be flooded with requests. To avoid the problem, DHCP uses the same technique as BOOTP: each computer waits a random time before transmitting or retransmitting a request.

The DHCP protocol has two steps: one in which a computer broadcasts a *DHCP Discover* message to find a DHCP server, and another in which the computer selects one of the servers that responded to its message and sends a request to that server. To avoid having a computer repeat both steps each time it boots or each time it needs to extend the lease, DHCP uses *caching*. When a computer discovers a DHCP server, the computer saves the server's address in a cache on permanent storage (for example, a disk file). Similarly, once it obtains an IP address, the computer saves the IP address in a cache. When a computer reboots, it uses the cached information to revalidate its former address. Doing so saves time and reduces network traffic.

DHCP Message Format

Interestingly, DHCP is designed as an extension of BOOTP. As Figure 2 illustrates, DHCP uses a slightly modified version of the BOOTP message format.

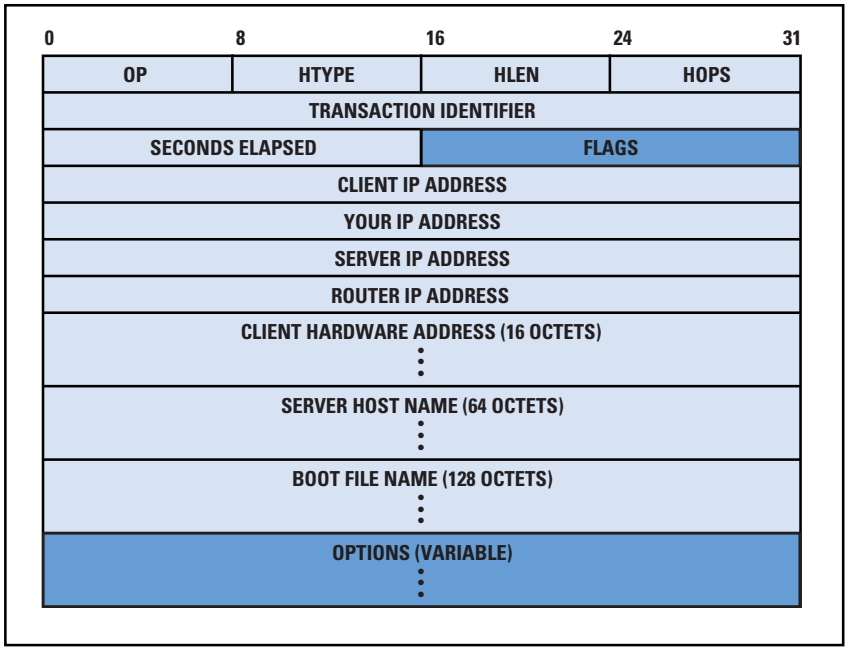


Figure 2: DHCP Message Format

Most of the fields in a DHCP message have the same meaning as in BOOTP; DHCP replaces the 16-bit *UNUSED* field with a *FLAGS* field, and uses the *OPTIONS* field to encode additional information. For example, as in BOOTP, the *OP* field specifies either a *Request* or a *Response*. To distinguish among various messages that a client uses to discover servers or request an address, or that a server uses to acknowledge or deny a request, DHCP uses a *message type option*. That is, each message contains a code that identifies the message type.

DHCP and Domain Names

Although DHCP makes it possible for a computer to obtain an IP address without manual intervention, DHCP does not interact with the Domain Name System. As a result, a computer cannot keep its name when it changes addresses. Interestingly, the computer does not need to move to a new network to have its name change. For example, suppose a computer obtains IP address **`192.5.48.195`** from DHCP, and suppose the domain name system contains a record that binds the name **`x.y.z.com`** to the address. Now consider what happens if the owner turns off the computer and takes a two-month vacation during which the address lease expires. DHCP may assign the address to another computer. When the owner returns and turns on the computer, DHCP will deny the request to use the same address. Thus, the computer will obtain a new address. Unfortunately, the *Domain Name System* (DNS) continues to map the name **`x.y.z.com`** to the old address.

For several years, researchers have been considering how DHCP should interact with the DNS. Although a dynamic DNS update protocol has been defined, it has not been widely deployed. Thus, many sites that use DHCP do not have a mechanism to update a DNS database. From a user's perspective, the lack of communication between DHCP and DNS means that when a computer is assigned a new address, the computer's name changes.

Summary

The bootstrapping sequence loads a generic image into a computer, either from secondary storage or over the network. Before application software can use TCP/IP protocols, the image must be configured by supplying values for internal parameters such as the IP address and subnet mask, and for external parameters such as the address of a default router; the process is known as *configuration*. Initially, separate protocols were used to obtain each piece of configuration information. Later, the *BOOTstrap Protocol,* BOOTP, was invented to consolidate separate requests into a single protocol. A BOOTP response provides information such as the computer's IP address, the address of a default router, and the name of a file that contains a boot image.

The *Dynamic Host Configuration Protocol* (DHCP) extends BOOTP. In addition to permanent addresses assigned to computers that run a server, DHCP permits completely automated address assignment. That is, DHCP allows a computer to join a new network, obtain a valid IP address, and begin using the address without requiring an administrator to enter information about the computer in a server's database. When DHCP allocates an address automatically, the DHCP server does not assign the address forever. Instead, the server specifies a lease during which the address may be used. A computer must extend the lease, or stop using the address when the lease expires.

For Further Study

Details about BOOTP can be found in reference [1], which compares BOOTP to RARP and serves as the official protocol standard. Reference [2] tells how to interpret the vendor-specific area, and reference [3] recommends using the vendor-specific area to pass the subnet mask. Most uses of BOOTP have been replaced by DHCP. Reference [4] contains the specification for DHCP, including a detailed description of state transitions. A related document, [5], specifies the encoding of DHCP options and BOOTP vendor extensions. Finally, reference [6] discusses the interoperability of BOOTP and DHCP. The chair of the DHCP working group, Ralph Droms, and Ted Lemon have written a book about DHCP [7].

Book Review

The Elements of Networking Style

The Elements of Networking Style, by M. A. Padlipsky, originally published by Prentice-Hall, 1985, ISBN 0132681110; now available from iUniverse, 2000, ISBN 0595088791.

Sometime in the autumn of 1986, I read Padlipsky on a flight from Boston to San Francisco, and about 15 minutes into it I began to get enraged. A few minutes later, I was snickering. By the time the attendants came around with profferings of alleged comestibles, I was laughing aloud, and a gentleman sitting near the window was grateful that there was a vacant seat between us.

Padlipsky brought together several strands that managed to result in the perfect chord for me over 15 years ago. I reread this slim volume (made up of a Foreword, 11 chapters (each a separate arrow from Padlipsky's quiver) and three appendixes (made up of half a dozen darts of various lengths and a sheaf of cartoons and slogans) several months ago, and have concluded that it is as acerbic and as important now as it was 15 years ago.

The instruments Padlipsky employs are a sharp wit (and a deep admiration for François Marie Arouet), a sincere detestation for the ISO Reference Model, a deep knowledge of the *Advanced Research Projects Agency Network* (ARPANET)/Internet, and wide reading in classic science fiction.

Arouet is better known by his pen name, Voltaire. He was a social rebel, a political agitator, and an acerbic satirist comparable to Swift. Isaiah Berlin, in a lecture published in Salmagundi 27 [1974], remarks:

> "Voltaire is the central figure of the Enlightenment, because he accepted its basic principles and used all his incomparable wit and energy and literary skill and brilliant malice to propagate the principles and spread havoc in the enemy's camp. Ridicule kills more surely than savage indignation..."

Padlipsky is pungent and sharp and witty ... and knowledgeable. His critiques of X.25, of the *International Organization for Standardization* (ISO) seven-layer cake, and of the standards process in general, are still relevant.

History

In the early 1970s, the CCITT (now the ITU), made up of PTTs and monolithic telcos, fixed upon a putative standard for a network interface protocol, X.25. First approved in 1976, and revised in 1977, 1980, 1984, 1988, and 1992, X.25 was unsatisfactory in its original form and remains less than effective.

One of the greatest drawbacks is that it is basically a store-and-forward mechanism, meaning that it has an intrinsic delay and (as noted by Sangoma Technologies) this delay is typically 0.6 seconds. It also requires a great deal of buffering space.

Padlipsky's "Critique of X.25" (Mitre Corporation Report, M82-50, September 1982; RFC 874 12 August 1983) is revised as Chapter 9 in *The Elements of Networking Style*. Padlipsky has restored, however, his original title: "Low Standards."

Flush with the failure of X.25, the *Consultative Committee for International Telegraph and Telephone* (CCITT) moved ahead.

In 1977, the British Standards Institute proposed to ISO that an architecture was needed to define the communications infrastructure. To me, this, as with *International Federation for Information Processing* (IFIP), CCITT, and similar efforts, shows how "the road to hell is paved with good intentions." Because X.25 was unsatisfactory, the IFIP Working Group was set up in the hope that that the technological community could forestall the highly political arena of ISO. (It didn't.)

ISO set up a technical committee [ISO/TC 97/SC 16]. The next year (1978), ISO published its "Provisional Model of Open Systems Architecture" [ISO/TC 97/SC 16 N 34]. This was labeled a "Reference Model," and referred to as the *Open Systems Interconnection Reference Model* (OSIRM or ISORM—pronounced "eye-sorm"—by Padlipsky).

In general, it was based on work done by Mike Canepa's group at Honeywell Information Systems, which came up with a seven-layered architecture, which itself owed a great deal to IBM's proprietary *Systems Network Architecture* (SNA). SNA had been announced in 1974, and its seven layers do not correspond exactly to OSI/ISORM's. TC 97/SC 16 turned over proposal development to the *American National Standards Institute* (ANSI), to which Canepa and his technical lead, Charlie Bachman, presented their layered model.

This, in turn, was the only proposal presented to the ISO subcommittee at a meeting in Washington in March 1978. It was accepted and published immediately. A "refined" version of the ANSI submission to ISO appeared in June 1979. This published version is nearly identical to Honeywell's of 1977.

Rage and Ridicule

While he eschews the history I've outlined here, Padlipsky is enraged by the standards process and its results. As Dave Walden and Alex McKenzie (both then at BBN, both now retired) pointed out in 1979, both virtual circuit and datagram services are valuable. "An international standard would do well to support both." [*IEEE Computer,* September 1979].

The 1977–1979 models were such that extant host-host protocols did not fit ISORM. ISO was trying to construct a set of geometric figures that would be a "tidy model." The ARPANET workers, of whom Padlipsky was one, were interested in getting things to actually work. They were into pushing bits around the system.

The irascible Padlipsky has described the OSI system as two high rises with parking garages. The two high-rises are seven-story buildings; the parking garages are the three-story X.25 structures.

John Quarterman once pointed out:

> "OSI specified before implementation. So specification took forever and implementation never happened, except for bits and pieces. In addition, heavy government backing (by the EC, now the EU, and various national governments) led some OSI participants to attempt to substitute official authority for technical capability. OSI and TCP/IP started at about the same time (1977). OSI wandered off into the weeds and TCP/IP won the race. Those governments that backed OSI bet on the wrong horse."

TCP/IP had clearly "won the race" by the early 1980s; it took till 1994 for the U.S. government to recognize the de facto standard by rescinding its *Federal Information Processing Standards* (FIPS). At that time, too, the *Defense Data Network* (DDN) was made up of IP router nets, not X.25-based nets.

In a totally different vein, there's Chapter 11: "An Architecture for Secure Packet-Switched Networks" (based on a presentation to the Third Berkeley Workshop on Distributed Data Management and Networking, August 1978). Here, Padlipsky suggests per-host processes. It was a really good notion.

Padlipsky's rants—and many of the chapters are just that—precede Quarterman's remarks by nearly a decade. But they are worth reading (and rereading).

I'm glad *The Elements of Networking Style* is available again.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable, fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

Fragments

Stephen D. Crocker Receives 2002 IEEE Internet Award

The *Institute of Electrical and Electronics Engineers* (IEEE) has named Stephen D. Crocker, chief executive officer of Shinkuro, Inc. in Bethesda, Md., as recipient of the 2002 *IEEE Internet Award*. The award recognizes Crocker for his leadership in the creation of key Internet protocols. It will be presented on 19 June, at INET 2002, in Arlington, Va.

In the formative days of the Internet and its predecessor, the ARPANET, Crocker led the development of crucial technologies, processes and organizations that continue to support the Internet today. At the University of California at Los Angeles, Crocker and his team developed protocols for the ARPANET such as the *Network Control Protocol*. NCP laid the groundwork for today's *Transmission Control Protocol* (TCP). Crocker also founded and led the *Network Working Group* (NWG), which has evolved to become the *Internet Engineering Task Force* (IETF).

In organizing the notes from the first few meetings of NWG, Crocker was anxious to expand the community and invite further discussion and responses, and thus named the series *Requests for Comments*. RFCs remain a mainstay of Internet protocol publishing today, and have played a big part in creating the environment of open and evolving standards of the Internet.

"The Internet Society is honored that INET 2002 was chosen as the venue to present this year's prestigious IEEE Internet Award," said Lynn St. Amour, president and CEO of the Internet Society (ISOC). "Dr. Stephen Crocker is highly regarded throughout the international Internet community and we're pleased that his contributions will be recognized at INET 2002 in front of his peers."

Crocker's many contributions to the Internet also include extensive work organizing the standards process of the IETF, where he has served as area director of security and on the Internet Architecture Board. Crocker previously worked for the University of Southern California Information Sciences Institute in Marina del Rey, the Aerospace Corporation in El Segundo, Calif., and at Trusted Information Systems, Inc., in Glenwood, Md. In 1994, he co-founded CyberCash of Reston, Va., and served as its senior vice president for development and chief technology officer. He also has started other ventures including Steve Crocker Associates in Bethesda, Md.; Executive DSL in Bethesda, Md.; and Longitude Systems in Chantilly, Va.

He has served on the Council of Visitors at the Marine Biological Laboratory, as part of the National Research Council Study of Information Systems Trustworthiness and currently chairs the ICANN Security and Stability Advisory Committee and the ISOC 2002 Jonathan B. Postel Service Award Committee. The author of numerous papers, Crocker also holds patents in relation to his security and electronic commerce work.

He received his bachelor's degree in mathematics and doctoral degree in computer science, both from UCLA, he and studied artificial intelligence at the Massachusetts Institute of Technology.

The IEEE is the world's largest technical professional society with more than 377,000 members in approximately 150 countries. Through its members, the IEEE is a leading authority on areas ranging from aerospace, computers and telecommunications to biomedicine, electric power and consumer electronics. Additional information is available at **http://www.ieee.org**

The Internet Society **http://www.isoc.org/** is a non-profit, non-governmental, open membership organization whose worldwide individual and organization members make up a veritable "who's who" of the Internet industry. It provides leadership in technical and operational standards, policy issues, and education. ISOC is the organizational home of the International Engineering Task Force, the Internet Architecture Board, the Internet Engineering Steering Group, and the IETF—the standards setting and research arms of the Internet community. For information about INET 2002 please visit **http://www.inet2002.org**

Interim Approval for ENUM Provisioning

The *International Telecommunication Union* (ITU) and the *Internet Architecture Board* (IAB) recently announced interim approval for a single domain for ENUM, a technology that builds a bridge between the public switched telephone network and the Internet.

Voice on IP networks today operate by translating telephone numbers to IP addresses and placing an H.323 or SIP call to the device. The interchange format and translation record has not heretofore been standardized, limiting the possibility of deployment of multi-corporate and international Voice on IP services. Under the ENUM proposal, E.164 numbers can be represented as Internet Domain Names,providing a scalable and standard way to translate the numbers, and opening the way to such services. ITU has begun approving delegations for the purposes of trials. "The lack of an interoperable standard way to turn a telephone number into an IP Address has been one factor limiting the deployment of Voice on IP services internationally," said Leslie Daigle, Chair of the IAB.

If desk-mounted computers or servers are given telephone numbers as well as mnemonic names, this system further enables common telephone handsets to place Voice or Video on IP calls to such computers. This is a significant step towards integrating Internet-based services with the global telephone network, and the current agreements between IAB and ITU will allow trials to take place.

Patrik Fältström, member of the *Internet Engineering Steering Group* (IESG), said that "the integration of the desktop telephone and computer allows corporations to simplify their internal networks."

Roy Blane, Chair of ITU-T's Study Group 2, concurred, saying that "In the long term this protocol may facilitate many new internet services. In the short term, countries wishing to trial the system can begin work on developing it."

This interim approval is made possible due to cooperation between ITU, IAB and the IETF. As outlined in the ENUM specification document, RFC 2916, sub-domains from a single domain will be delegated after acceptance by the registries according to the existing assignment of country codes in the telephone address space. Information on how the ENUM registration requests will be processed can be found at:
http://www.ripe.net/enum/

The IETF is an international community of network designers, operators, vendors, and researchers concerned with the evolution of the Internet architecture and the smooth operation of the Internet. The definition of the ENUM protocol, as proposed by the IETF can be found at **http://www.ietf.org/rfc/rfc2916.txt** The IETF is an organized activity of the Internet Society.

The ITU is a global organization where the public and private sectors cooperate for the development of telecommunications and the harmonization of national telecommunications policies. Study Group 2 of the *ITU Telecommunication Standardization Sector* (ITU-T), where work on ENUM is being carried out, is the Lead Study Group on Service definition, Numbering, Routing and Global Mobility and is responsible for the operational aspects of service provision, networks and performance. More information on the ENUM protocol, and the issues related to it, can be found at **http://www.itu.int/ITU-T/worksem/enum/index.html**

Committee on ICANN Evolution and Reform posts Recommendations

Following the publication in February of "President's Report: ICANN—The Case for Reform," by Stuart Lynn, President and CEO of *The Internet Corporation for Assigned Names and Numbers* (ICANN), a committee of the board has been examining the details of the restructuring proposal, receiving input from the community at large, and publishing several documents with recommendations. You can find pointers to all of these documents in the "Announcements" section at **http://www.icann.org**

Upcoming Events

INET 2002, the annual conference of the Internet Society, will be held June 18–21, 2002 at the Crystal Gateway Marriott, in Arlington, Virginia (5 minutes from downtown Washington, DC).
http://www.inet2002.org/

The *IETF* will be meeting in Yokohama, Japan, July 15–19, 2002 and in Atlanta, Georgia, USA, November 17–22, 2002.
http://www.ietf.org/meetings/meetings.html

ACM SIGCOMM 2002 is the annual conference of the *Special Interest Group on Data Communication* (SIGCOMM), a vital special interest group of the *Association for Computing Machinery* (ACM). This year, SIGCOMM will be held in Pittsburg, Pennsylvania, August 19–23.
http://www.acm.org/sigcomm/sigcomm2002/

ICANN will meet in Bucharest, Rumania, June 24–28, 2002 and in Shanghai, China, October 27–31, 2002.
http://www.icann.org/meetings/

The *Asia Pacific Network Information Centre* (APNIC) will hold its next Open Policy Meeting, September 3–6, 2002 in Kitakyushu, Japan. **http://www.apnic.net/meetings/index.html**

The next *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT) will take place February 19–28 in Taipei, Taiwan. **http://www.apricot2003.net/**

Errata List

This is the 17th issue of *The Internet Protocol Journal.* Inevitably, some minor, and a few major errors have made their way into print since our June 1998 issue. We are planning to publish a list of correctionson our Web site in the near future. Since the online material is a reflection of the printed version, we feel it would be inappropriate to simply "silently" correct the online editions, thereby rewriting history. Instead, a list of the errors along with the corrections will be presented.

From The Editor

The *Internet Protocol Journal* (IPJ) does not have a marketing department. New subscribers learn about IPJ through our Web page, or perhaps by picking up a copy at an Internet conference or meeting such as the IETF. Word of mouth is perhaps the most effective "marketing tool." I was reminded of this in July when an article in IPJ was mentioned on the *SlashDot* Web site. Within a few days we received more than 900 new subscriptions, on the order of ten times the normal sign-up rate. I think this illustrates the power of the Web as a tool for information dissemination.

I am a big fan of visitor networks. Such networks, typically found in larger hotels, allow high-speed access to the Internet for a daily or weekly fee. Although most of the conferences and meetings I attend have purpose-built "terminal rooms," it is still nice to be able to work in your hotel room at speeds orders of magnitude better than what can be obtained with a dialup modem. Dory Leifer explains how visitor networks are designed and operated in our first article.

In a previous article we explored the basics of IEEE 802.11 wireless networking. Such networks are growing at an amazing rate. Reports about wireless network "wiretapping" are frequently found in the trade press. Gregory R. Scholz describes an architecture for securing wireless networks, using a variety of technologies and protocols.

Geoff Huston is back with another opinion piece, this time discussing the role of the *Internet Service Provider* (ISP) as a "common carrier." Many ISPs are finding themselves in the middle of disputes between customers, copyright owners, regulators and others. What role should an ISP play in this regard? Geoff provides some answers.

Please continue to provide your feedback to anything you read in this journal. Our "Letters to the Editor" section provides a sample of some of the correspondence we receive. As always, use **ipj@cisco.com** to contact us.

Visitor Networks

by Dory Leifer, DEL Communications Consulting

Visitor networks are LANs that are most often deployed in hotels, airports, cafés, college campuses, apartments, and other locations. They enable the public network access on an ad-hoc basis. Recently, 802.11 "hot spots" have gained increased attention; they represent one example of a visitor network.

Visitors attach devices such as a laptop or *personal digital assistant* (PDA) that they use only while traveling or, more often, they attach machines normally used in the office or home. These machines can be thought of as "visiting hosts."

This article explores some of the technical issues with IP visitor networks and considers practical options for service provider deployment on wired Ethernet and wireless networks. In exploring deployment options, the article focuses mainly on solutions that do not require client software on the visiting host. These clientless techniques are based on heuristics and, although they do not work effectively under all circumstances, they have proven to be quite useful in practice.

For this discussion, it is assumed that the service provided by the visitor network is for access in one location at a time. Therefore, the article does not address network hand-off for mobile clients that are moving from one network attachment point to another while attempting to maintain connectivity.

Traditional LANs vs. Visitor Networks

Traditional LANs have been well optimized for enterprise networks. They provide high bandwidth and an economical and universal method of delivering network connectivity. In comparison, visitor networks are a rather curious hybrid of a LAN and a public network, such as one used for dial-in network access. Their objective is to physically use LANs to deliver what has normally been considered a public network service: *universal access*.

In enterprise networks, traditional LANs are usually carefully administrated. Normally the connected hosts are owned and administrated by the same enterprise that operates the network. Hosts that are connected to the network are configured according to the designated protocol and address schemes. They are often configured for at least *Simple Mail Transfer Protocol* (SMTP), *Post Office Protocol* (POP), file, and print sharing. On visitor networks, the hosts are typically owned and configured by the visitors, while the service provider administrates the network.

This difference in administration creates a serious challenge for the visitor network. The network must support a wide range of configurations because they will differ from one visiting host to another. For example, if a host had previously been configured for a static IP address, that address is likely to be from a different subnet, perhaps from a private network that the visitor normally uses at the office. Even if a host gets some of its configuration from *Dynamic Host Configuration Protocol* (DHCP), *Domain Name System* (DNS) and SMTP servers may refer to addresses or names on a private network that are not reachable on the visitor network.

Traditional wired LANs normally span physically secure areas, so any person who has access to the Ethernet wall jack for the building can connect anything to the network. With a visitor network it may be undesirable to allow everyone access. For example, a visitor network deployed in a university library may be available only to students. Similar to public dial-in access, visitor networks often rely on authentication and authorization before granting service.

Whereas LANs are excellent at facilitating peer-to-peer services such as file and print sharing between connected hosts, visitor networks often attempt to minimize these direct interactions between visitors, instead establishing a set of services that the service provider itself offers or simply routing the IP packets off the LAN to an Internet Service Provider. Minimizing interactions between visitors is desirable because service providers will want to reduce the risk of a visitor's machine being attacked by another visitor. On some occasions, however, visitors who do trust each other may want to use the visitor network for file sharing, printing, or even network gaming.

Going Clientless

One of the most difficult choices for service providers deploying visitor networks is to decide whether or not to rely on the installation of specialized client software on the visiting host.

Client software allows specific network protocols to be passed between the client and the visitor network. Protocols such as *Point-to-Point Protocol over Ethernet* (PPPoE)[1], *Layer 2 Tunneling Protocol* (L2TP)[2], and Mobile-IP[3] support both authentication as well as IP tunneling to assist in routing and address assignment. On some wireless LANs and networks with high-end Ethernet switches, 802.1x (which will be discussed in more detail later) supports flexible authentication schemes and aids in data encryption[4]. Although these protocols implemented on the client can present a significant technical advantage for implementing visitor networks, they require at least some modification to the configuration on the visiting host.

The lowest common denominator for traveling laptops is a simple TCP/IP stack and a browser. If the service can accommodate the visitor with only these items, the visitor network becomes much more suitable to the broadest audience. Of course without authentication, tunneling, and client configuration available from client software, the visitor network must rely on a set of heuristics or, said by some, hacks, to perform its tricks. Subsequent sections of this article illustrate technically how a visitor network can operate without relying on the installation of client software.

The service provider may choose to distribute client software in a situation where the visitor may use the service repeatedly. In many other situations, however, it is not feasible. For example, the last thing that travelers want to find in a hotel room upon arriving at midnight and needing a network connection is a CD-ROM full of new software drivers to drop on their laptop before using the hotel's in-room Ethernet. Even if the provided software does nothing but change the configurations, such as select a Web proxy server, it may have negative consequences when the laptop is returned to the office. Such added steps could also discourage visitors from using the visitor network again.

Visitor Network Basics

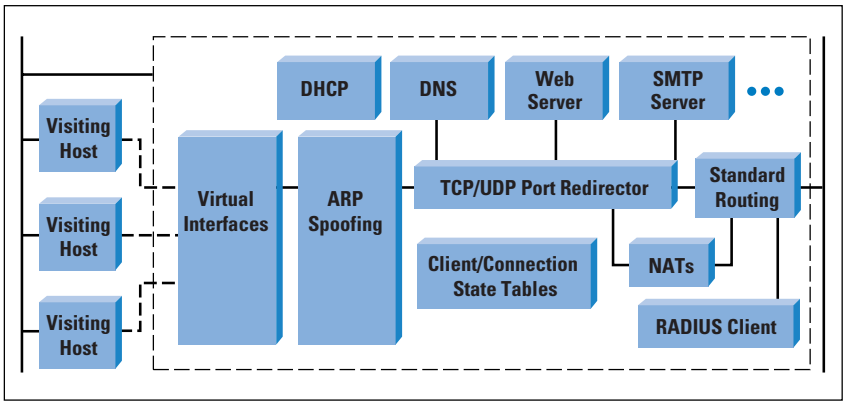
There are no hard guidelines or standards on what constitutes a visitor network. However, numerous vendors are selling devices that operate with wired and wireless networks, and act as gateways between the visitor network and the traditionally routed infrastructure. The typical visitor experience proceeds as follows (this is essentially a clientless example): the visiting host would not require the installation of special software, and in many cases would not require configuration changes:

- The visiting host is physically attached to the network by connecting to a twisted-pair Ethernet port.
- Visitors open their browser and attempt to load any page with the *Hypertext Transfer Protocol* (HTTP).
- Regardless of the specified URL, the browser loads a default page that requests authentication or billing information.
- When authenticated, the visitors now have general Internet access.
- An accounting record describing a visitor's session is generated and processed by the service provider's billing system, resulting in a charge on either the visitor's account or a corporate account.

Visitor Gateways

Visitor networks can be implemented with a special-purpose device called a "visitor gateway." Figure 1 illustrates the basic functional schematic of an example device. (Unfortunately, just about every vendor selling these devices uses a different name. This article uses the term in a generic sense and not to refer to any company's particular product.)

Figure 1: Visitor Gateway



The visitor gateway sits between the LANs used to provide service to the visitors and a standard routed interface. Physically, a visitor gateway is a device that appears much like a router or firewall, with minimally two Ethernet interfaces.

Hybrid of NAS and LAN

The following sections focus on the visitor gateway, specifically its operational model, its handling of various Internet packet types, *virtual LANs* (VLANs), authentication, and accounting.

Visitor gateways behave as a hybrid of a standard LAN and a *Network Access Server* (NAS). For illustration, one can compare the operation of the visitor gateway with the operation of a NAS. Like a NAS with individual modem ports, the visitor network gateway typically builds virtual port structures as new hosts are discovered on the connected LAN. These virtual interfaces are configured by the gateway to accommodate the IP addresses used and referred to by the visiting host. The visitor gateway may create a virtual port structure for every host based on its *Media Access Control* (MAC) address or VLAN identifier and treat every virtual interface as an independent subnet upon which the visiting host and the virtual interface of the visitor network are the only attachments. Think of the relationship as a logical point-to-point link.

Conversely, the NAS, using the *Point-to-Point Protocol* (PPP)[5] on a dial-in connection, has a significant advantage over the visitor gateway in this scenario. PPP allows the NAS to negotiate an acceptable IP address for the dial-in client, set the client's default gateway, and even in some cases configure the client's DNS. The NAS normally has at least *Password Authentication Protocol* (PAP) and *Challenge Handshake Authentication Protocol* (CHAP) for authentication. If the visiting host requests configuration through DHCP[6], the visitor network has an opportunity to assign private or public addresses that are mutually convenient for both parties. On the other hand, if the visiting host already has a static address configured for its native network, for example, then the visitor gateway must spoof or imitate the behavior of the configured subnet.

The appeal of PPP in the dial-in world led to the recent development of PPPoE for LANs. Although PPPoE has been used with service selection gateways to offer public *Digital Subscriber Line* (DSL), there has been little use of it on visitor gateways. This is likely to be true because of the lack of a ubiquitous client and the complexities of solving multilevel authentication and encryption involving the local link, local network, and private network. PPPoE certainly is worth future study for visitor networks.

ARP

Hosts learn Layer 2 MAC addresses using the *Address Resolution Protocol* (ARP). Although hosts and routers respond only when asked about the IP address of their interfaces or those on a proxy-ARP table, visitor gateways usually respond with their own MAC address to any ARP requests from the attached visiting hosts, effectively proxying for the host's default gateway (if one is configured). The visitor gateway can also configure the interface address of its virtual port based on the host's IP address. In this manner, the gateway auto-configures itself to accommodate the visitor, who can continue to use his/her configured address.

Used on a standard shared LAN, this technique only goes so far. If, for example, one host on the visitor network shared its default router configuration with the IP addresses of another host (not that uncommon for private network numbers), then when the first host attempted to get the MAC address of its default router, it would end up with two responses, one from the visitor gateway and one from the other host on the LAN.

TCP/UDP Port Redirector

The visitor gateway for each *Transmission Control Protocol* (TCP) and *User Datagram Protocol* (UDP) packet received from the visiting host decides whether to pass the packet through or direct it to a local service such as DNS, SMTP, or Web server. It makes this decision based on some configured policy from the service provider (such as to redirect all SMTP) and from authorization states of the visitors. For example, if the service provider wishes to charge visitors $10 for daily access at a hotel, the port redirector could reflect HTTP requests to the local Web server that would, in turn, present the option to the visitor. Subsequent HTTP requests presumably would always be passed transparently through the gateway to the intended address.

The operation of the redirector is fairly simple. It works as a backwards network address-port translator. Instead of modifying the source, it modifies the destination and then applies standard IP forwarding on the resulting packets.

DNS

Visitor gateways typically implement proxies for domain name service requests and channel all DNS requests from the visiting host through the proxy. This serves at a minimum to reflect DNS requests to a closer DNS server, a useful performance advantage if the visitor's configured DNS server is a considerable distance away. Of greater significance is that it allows general Internet access by the visitor even if the configured DNS server is on a private network, which is now unreachable because the visitor's laptop has been moved from the office.

Redirecting to a DNS server not of the visitor's choosing may work smoothly until the visitor attempts to resolve domain names known only to the real DNS server on the private network. There is, of course, a limit to how well you can hide reality.

One common problem encountered by visitor networks is with a Web proxy on a private network. If the visitor refers to a Web proxy by name, the visitor gateway may choose to respond, inventing an IP address for the proxy and then assuming, by itself, operation of the proxy function. This technique has to be used with some care because hosts often cache DNS responses; these are effectively convenient lies that could end up being carried as "dirty entries" on the visitor's machine for longer than intended.

Rewriting DNS queries and responses does open the opportunity for the service provider to "assume" (some may say "hijack") sites. This opens the door to the possibility that, for example, `yahoo.com` is resolved to an address that is not Yahoo but rather a Web site with an affiliation to the service provider. Although this is a policy and business issue for the service provider, it is likely to irritate quite a number of visitors and reduce the perceived value of the service.

NATs

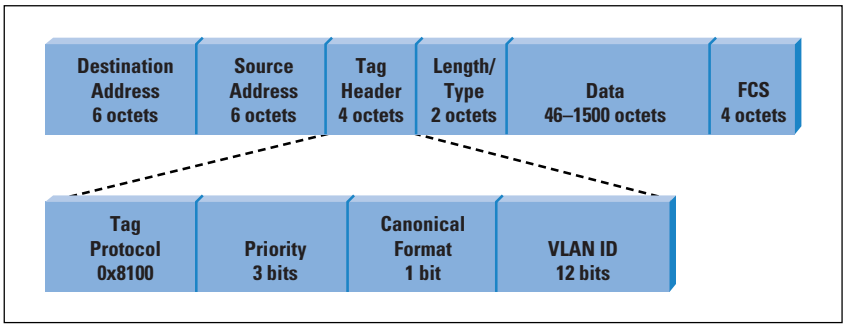
Visitor network gateways frequently use *Network Address Translation* (NAT), and often with port translation, in order to conserve IP addresses by sharing a small address pool with a large number of visitor hosts. In addition, NAT is required by the gateway if the source address used by the visiting host is not routable by the rest of the network back to the visitor gateway. This is almost always the case when the visiting host is using a static preconfigured IP address from another network. The gateway may choose its application of NAT based on policy. For example, two visitors may be configured for DHCP but one is assigned a private "Net 10" (RFC 1918) address that is passed through a NAT while another is assigned a routable address. In practice this flexibility is useful for service in apartments where the visitors are expected to "visit" for months. The service provider may choose to offer tiered services, one with a routable address suitable for the customers to run servers, and another with a private address suitable only for outgoing connections (e-mail, HTTP, and so on).

VLANs

The visitor gateway—modeling its relationship with visiting hosts as a virtual point-to-point link—may attempt to ignore the fact that hosts are on a shared network. However, certain interactions between hosts are inevitable on a shared LAN. For example, if a visitor's Windows laptop is configured for file sharing with no security enabled, other visitors may see, or worse, have permission to write to, critical files.

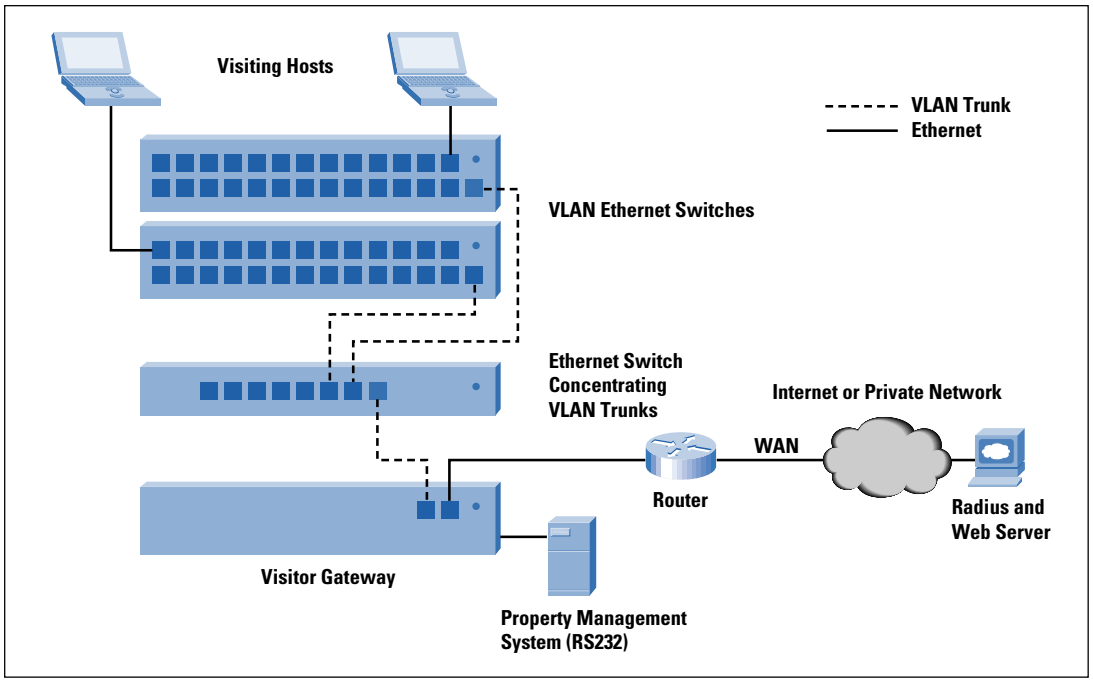
Virtual LANs provide a solution for isolating individual clients. On a wired Ethernet, many modern Ethernet switches can be configured to implicitly treat each port as a member of a different VLAN. For example, port 1 could be on VLAN 11; port 2 on VLAN 12; and so on. The visitor gateway is connected to one or more "trunk" ports that are configured as a member of all VLANs. This effectively allows another level of addressing so the visitor gateway can individually address a single Ethernet network connected to a port. The VLAN switches then act as simple concentrators. If a visiting host attempts to broadcast or multicast, these frames end up only traveling to the gateway and are not seen by other visiting hosts.

Figure 2: VLAN Frame Format



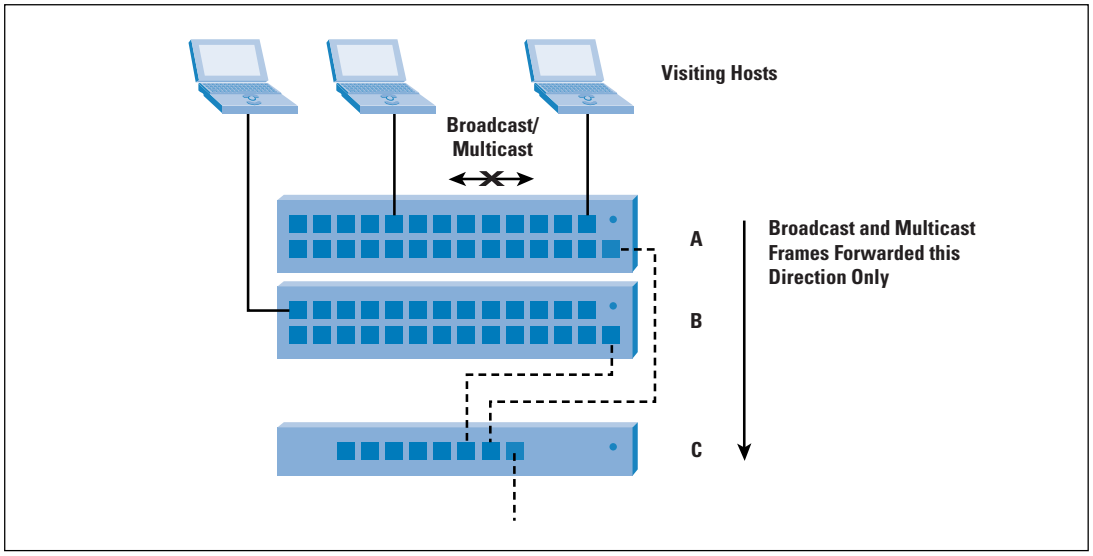
The VLAN frame format is shown in Figure 2. IEEE 802.1q defines the "tagging"[8]. The VLAN-enabled Ethernet switch can add the appropriate headers to standard Ethernet frames, and it forwards these through the trunk port. Optionally, another Ethernet switch concentrates the trunk traffic and attaches to the visitor gateway, as seen in Figure 3. One potential catch is that some Ethernet switches will not pass the oversized (maximum 1504 octet) VLAN frames; others attempt to be "overly aware" of the VLAN membership rules and insist on configuration of each of the VLANs, a challenging prospect if you are concentrating thousands of ports, each with a unique VLAN identifier.

Figure 3: VLAN Configuration



Some Ethernet switch vendors have implemented a nonstandard technique whereby broadcasts and multicasts are forwarded exclusively to a designated port, the theory being that if a host's broadcast and multicast frames do not get forwarded to other hosts, the hosts effectively will not "see" each other because they do not see ARP requests or higher-layer service advertisements. In some ways, this is simpler than using VLANs and provides some isolation over standard Ethernet networks.

Figure 4: Switch Multicast Blocking



Combinations of these switches with normal ones can lead to some interesting frame forwarding scenarios. For example, as seen in Figure 4, Ethernet switches A and B are each connected to Ethernet switch C. Visiting hosts are attached to the ports on A and B. A and B are designed to have the forwarding restriction described, but C is a normal switch. This means that a broadcast from a visitor connected to A will not be seen by other visitors on A (by nature of the restriction) but it will be forwarded "upstream" to C, which will then forward it to B. Because B received it coming from the upstream, it will forward it to all the visiting hosts on B, causing the isolation technique to fail. A, B, and C all need to have the forwarding restriction.

Web-Based Authentication and Policy

Visitor networks often avail themselves of the one reliable way to converse with a human without additional client software: the Web browser. By selectively reflecting HTTP requests to the local gateway, the gateway can perform or facilitate several operations:

- Authenticate users with traditional username/password—The visitor gateway may, in turn, use a *Remote Access Dial-In User Service* (RADIUS)[7] authentication request to validate the user.
- Provide links within a "walled garden"—sites that can be visited without authentication—These sites are implemented with either a Web proxy inside the gateway or access control lists effective on the individual visiting host's virtual interface.
- Gather and validate credit card information through third-party credit card processing Web sites
- Offer visitors Web pages they can use to subscribe to services or to change service parameters

Using the browser can have a significant advantage, even over installed client software. The browser allows a conversation with a human user instead of a software client. This affords the network provider a wide variety of options, such as dealing politely with an authentication rejection, providing additional troubleshooting help, or confirming "conditions of use" before the user accepts charges. It is also a place for offering the user other products and services through Web links.

A central repository for visitor policy and configuration is especially important when a large number of gateways are deployed in disparate physical locations. An interesting option for visitor gateways is for them to learn policy by participating in the exchange of HTTP between the visiting host and an external Web server. The visitor gateway can piggyback the origin and state of a visiting host in a URL and refer the visitor's browser to a Web site. This origin information when presented to a service selection application running in a provider's data or operation center allows the application to determine which gateway the visitor is attached to as well as the visitor's virtual port identification and MAC address.

With the origin information, the service selection gateway can present the visitor with any number of billing, quality of service, or IP addressing options that apply to his/her connection. When the service selection application needs to affect the policy information stored in the visitor gateway, it can use a similar piggyback technique in the return direction.

Accounting

Finding an easy-to-deploy accounting method is crucial for service providers to generate accurate billing. The visitor gateway may send RADIUS accounting records in response to connections and disconnections made by visiting hosts. Disconnections can be determined by *Simple Network Management Protocol* (SNMP) traps from the physical layer devices or by repeated interval polling of the visiting host using ARPs or pings. Because RADIUS has been widely deployed by service providers for dial-in or other networks, it is very possible that the existing accounting system would be able to support the visitor gateway if it, too, offers RADIUS.

In hotels, accounting information can be sent directly to the hotel's *Property Management System* (PMS), causing users to see an access charge on their folio. This is normally accomplished by connecting a standard low-speed serial interface between the visitor gateway and the PMS. The visitor gateway posts the charges by exchanging records with the PMS. A simple record format is used to identify a room and associated charge. Although the format and exchange protocols are usually simple, they are rarely standard. Interfacing to a PMS may require the vendor of the visitor gateway to pay a license fee to the company selling the PMS before it can implement a PMS protocol. Additionally, after implementation, the visitor gateway vendor may need to go through certification for each PMS to which the gateway will be connected. Even if the equipment vendor pays the license, service providers are rarely free to go to a hotel and attach to the hotel PMS—often the service provider is shocked that the hotel insists that they be reimbursed for "interface license fees" charged by the PMS vendor to "enable the protocol."

The 802.1x Standard and Wireless LANs

Techniques of implementing visitor networks using wireless LANs (WLANs) have been both widely publicized and debated. Wireless 802.11 "hot spots" and the like have been the subject of great publicity because these WLANs are so convenient and cost-effective to deploy that they allow service providers to economically deploy them in areas that would be impractical to serve with wired networks. However, WLANs continue to be the topic of great debate because they have been plagued by the lack of compatibility and weaknesses in security architectures.

The 802.1x standard, recently ratified by the IEEE, holds the best promise in offering a standard authentication scheme for LANs. The 802.1x standard operates with client software. In one sample scenario, the visiting host, also known as the "supplicant," receives an *Extensible Authentication Protocol* (EAP) request/identity message from the visitor network via an Ethernet switch, a WLAN access point, or a visitor gateway, any of which function as the "authenticator." The authenticator then relays the client's identification to an authentication server. The server then decides if the supplicant is to be allowed access and responds appropriately to the authenticator.

With WLANs, the *Wired Equivalent Privacy* (WEP) keys can be loaded as part of the exchange so the client and access points can operate without manual key selection. WEP has been used for several years as a method of encrypting user data over the air interface. Without WEP (or even with it, as we have seen), anyone with a laptop and a receiver can spy on the exchanged traffic[10, 11].

Microsoft ships an 802.1x client in the standard distribution of Windows XP, an important move forward in making the protocol universal. Other software vendors are shipping or have announced product for older versions of Windows, Macintoshes, Linux, and some PDAs. The 802.1x standard client implementations, however, may need firmware support on the host adapters, and support may never be available on a large number of 802.11 cards already deployed. Furthermore, all 802.1x standards are not alike because they may implement different authentication schemes. Microsoft's current implementation uses the *Extensible Authentication-Transport Level Security* (EA-TLS) protocol, which requires a *Public Key Infrastructure* (PKI)[9]. Some critics contend that this creates additional deployment burdens on organizations with small networks. If a common provider, such as Boingo or T-Mobile, provides the visitor network in "hot spots" (that is, cafés and airports), the PKI requirement should not be an issue.

On Ethernet switches, 802.1x implemented directly on the switches may be adequate if the policy for visitor access is relatively simple. For example, if users on a particular network are all trusted employees working for the same business, the work of the authentication/authorization scheme is then to determine whether or not to allow someone to access the network, simply "port on" or "port off." A more sophisticated approach would allow users to be classified as belonging to a set of classes. On some switches, 802.1x would allow each port to assume a set of VLAN memberships. For example, VLAN 120 would allow unrestricted Internet access, VLAN 119 would restrict access to a set of Web servers, and VLAN 118 would restrict access further to only an authentication server. The authentication system using 802.1x would direct the switch port configuration.

In practice, the control required by visitor networks needs to be far more flexible, and perhaps should be left to the visitor gateway. The gateway, as diagrammed in Figure 1, can control the routing system as well as higher-level protocol proxies based on policy. Besides, leaving the authentication behind the switches allows network implementors the flexibility of using virtually any Ethernet switch, or even other media such as Ethernet framing over xDSL.

The switch-based 802.1x approach, however, may have a significant advantage over the visitor gateway in that after the authentication is out of the way, the Ethernet switch can switch traffic simply at full speed without additional per-packet overhead.

Security Concerns—Better Just to Bootstrap?

Visitor networks are particularly vulnerable to hacking and snooping by virtue of their physical locations, especially if serviced by WLANs. Unfortunately, security is one of the few things that a service provider cannot deliver to visitors without their explicit cooperation and participation. The service providers face a difficult choice to either stay out of the solution or attempt to deliver adequate security through client configuration or special software distribution. The answer is difficult to determine; however, at least two factors to consider are whether the network is wired or wireless, and what the expectations of the visitors will be.

Weaknesses in WEP commonly offered on wireless LAN products have been very well publicized[10,11]. These weaknesses involve the encryption protocols and the fact that most implementations use manually configured keys. The latter is of little use on a visitor network because the network provider would need to disclose the same keys to everyone. Better proprietary systems have been deployed using PKI, and 802.1x is also a possibility. WEP may be replaced by much stronger *Advanced Encryption Standard* (AES) in *Offset Codebook* (OCB) mode as part of the IEEE 802.1i working group[12]. No solution has been both standardized and universally deployed. The lack of a standard and universal solution to replace WEP requires that the service provider who chooses another form of security customize a wireless solution. They may need to distribute specialized client software and/or restrict their service to supporting a set of wireless cards and drivers.

Simple Ethernet switches can provide some isolation between ports, but the learning bridge algorithms they use are designed to efficiently deliver Ethernet frames, not provide a secure service. With many switches, it takes one frame with a sham source MAC address to convince the switch to spill someone else's traffic onto the wrong port. "Man in the middle" attacks are often trivial after a visiting host is tricked into sending its traffic somewhere else; the opportunities of doing this to another machine on the same LAN are abundant.

As an end user of a visitor network, trusting an unfamiliar service provider in an unknown environment is a fundamentally insecure process. So, why not let the visitor network provide the basic IP connectivity in order to bootstrap the connection, and then let the visitors themselves implement the security on top? One reason is that unsuspecting users getting hacked at their favorite hotel chain does not bode well for the hotel if the incidents end up in the press. Guests probably feel pretty secure using the hotel phone for a dial-in network connection without any encryption; many also feel secure locking the door with the sliding chain.

One reasonable compromise is matching the security of a dial-in connection. A wired Ethernet, assuming that it cannot be easily coaxed to spill traffic between ports, could present an acceptable risk level. On the other hand, a poorly protected wireless network is like a hotel door without a lock.

If the visitor network offers no protection, then the burden is placed completely on the visitors to implement their own end-to-end security. Using *Virtual Private Network* (VPN) software that implements *IP Security* (IPSec) is one possibility. Unfortunately, even that is not always straightforward, given the complexities with using protocols such as IPSec over NATs[13]. Other protocols such as *Transport Layer Security* (TLS) and *Secure Shell* (SSH), which operate above the network layer, may be a better option. In addition, several proprietary VPN protocols are designed to tunnel through NATs. Those without any security solution could compromise not only their personal data but also the security of their employer's networks.

Any long-term security solution is going to demand proper client configuration and compatible software. Ultimately, development of standards and client sophistication will make this possible, but in the meantime, we will need to choose between ease of connecting to an insecure network and dealing with the potential multiple layers of authentication and encryption before gaining access. Sadly, faced with this choice and looking forward to a 7 a.m. meeting, the trusty hotel phone and modem jack on the laptop might look pretty inviting.

Summary

Visitor networks allow service providers to provide access in public places. These networks can be implemented in a way that either may or may not require specialized client software on the visiting host. Client software allows service providers to more carefully control the behavior of the visiting host but, at the same time, may limit the user base to those who have the software installed.

Visitor networks often rely on a visitor gateway to perform functions generally not required on a traditional LAN. The gateway, which shares certain characteristics with a NAS, is responsible for routing, address assignment, translation, TCP/UDP redirection, authentication, accounting, and affecting policy.

The visitor gateway exchanges packets with the visiting hosts via LANs. On Ethernet, VLANs are often best suited to visitor networks because they allow the gateway to address each client separately providing the greatest level of isolation compared to other Ethernet options.

WLANs represent an important advance toward the universal deployment of visitor networks in "hot spots." However, the lack of a common and effective solution may force service providers to choose between ease of access and security. Visitors may choose to implement a VPN or security scheme on top of the raw IP access offered by the visitor network.

An Architecture for Securing Wireless Networks

by Gregory R.Scholz, Northrop Grumman Information Technology

Wireless networks are described as both a boon to computer users as well as a security nightmare; both statements are correct. The primary purpose of this article is to describe a strong security architecture for wireless networks. Additionally, the reader should take from it a better understanding of the variety of options available for building and securing wireless networks, regardless of whether all options are implemented. The security inherent with IEEE 802.11 wireless networks is weak at best. The 802.11 standard provides only for *Wired Equivalent Privacy,* or WEP, which was never intended to provide a high level of security[1]. For an overview of 802.11 and WEP, see reference[2]. Wireless networks can, however, be highly secure using a combination of traditional security measures, open standard wireless security features, and proprietary features. In some regard, this is no different than traditional wired networks such as Ethernet, IP, and so on, which have no security built in but can be highly secure. The design described here uses predominantly Cisco devices and software. However, unless explicitly stated to be proprietary, it should be assumed that a described feature is either open standard or, at least, available from multiple vendors.

Customer needs

Customer needs range from highly secure applications containing financial or confidential medical information to convenience for the public "hot spot" needing access to the Internet. The former requires multiple layers of authentication and encryption that ensures a hacker will not be able to successfully intercept any usable information or use the wireless network undetected. The latter requires little or no security other than policy directing all traffic between the wireless network and the Internet. Security is grouped into two areas: maintaining confidentiality of traffic on the wireless network and restricting use of the wireless network. Some options discussed here provide both, whereas others provide for a specific area of security.

The level of security required on the wireless network is proportional to the skill set required to design it. However, the difficulty of routine maintenance of a secure wireless network is highly dependant on the quality of the design. In most cases, routine maintenance of a well-designed wireless network is accomplished in a similar manner to the existing administrative tasks of adding and removing users and devices on the network. It is also assumed that security-related services such as authentication servers and firewall devices are available on the wired network to control the wireless network traffic.

It is not necessarily the case that one can see the user or device attempting to use the wireless network. This is the most alarming part of wireless network security. In a wired network, an unauthorized connected host can often be detected by link status on an access device or by actually seeing an unknown user or device connected to the network. The term "inside threat" is often used to refer to authorized users attempting unauthorized access. This is the inside threat because they exist within the boundaries that traditional network security is designed to protect. Wireless hackers must be considered more dangerous than traditional hackers and the inside threat combined because if they gain access, they are already past any traditional security mechanisms. A wireless network hacker does not need to be present in the facility. This new inside threat may be outside in the parking lot. *War Driving*[3] is the new equivalent to the traditional war dialing. All that is required to intercept wireless network communications is to be within range of a wireless access point inside or outside the facility.

Physical Wireless Network

In a highly secure environment, a best practice is to have the wireless access points connect to a wired network physically or logically separate from the existing user network. This is accomplished using a separate switched network as the wireless backbone or with a *Virtual LAN* (VLAN) that does not have a routing interface to pass its traffic to the existing wired network. This network terminates at a *Virtual Private Network* (VPN) device, which resides behind a firewall. In this manner, traffic to and from the wireless network is controlled by the firewall policy and, if available, filters on the VPN device. The VPN device will not allow any traffic that is not sent through an encrypted tunnel to pass through, with the exception of directed authentication traffic described later. With this model, the wireless clients can communicate among themselves on the wireless network, but there is no access to internal network resources unless fully encrypted from the wireless client to the VPN. This design may be further secured by configuring legitimate wireless-enabled devices to automatically initiate a VPN tunnel at bootup and by enabling a software firewall on the devices that does not allow communication directly with other clients on the local wireless subnet. In this manner, all legitimate communication is encrypted while traversing the wireless network and must be between authenticated wireless clients and internal network resources.

Authentication

Many security measures available relate to access controlled through individual user authentication. Authentication can be accomplished at many levels using a combination of methods. For example, Cisco provides *Lightweight Extensible Authentication Protocol* (LEAP)[4] authentication based on the IEEE 802.1x[5] security standard. LEAP uses *Remote Authentication Dial-In User Service* (RADIUS)[6] to provide a means for controlling both devices and users allowed access to the wireless network.

Although LEAP is Cisco proprietary, similar functionality is available from other vendors. Enterasys Networks, for example, also uses RADIUS to provide a means for controlling *Media Access Control* (MAC) addresses allowed to use the wireless network. With these features, the access points behave as a kind of proxy, passing credentials to the RADIUS server on behalf of the client. When these features are properly deployed, access to the wireless network is denied if the MAC address of the devices or the username does not match an entry in the authentication server. The access points in this case will not pass traffic to the wired network behind them. For security, the authentication server should be placed outside the local subnet of the wireless network. The firewall and VPN devices must allow directed traffic between the access points and the authentication server further inside the network and only to ports required for authentication. This design protects the authentication server from being attacked directly.

In addition to authenticating users to the wireless network, the VPN authentication and standard network logon can be used to control access further into the wired network. In this solution, the VPN client has the ability to build its tunnel prior to the workstation attempting its network logon, but after the device has been allowed on the wireless network. After the tunnel is built, specific rules on the VPN and the firewall allow the traditional network logon to occur. A robust VPN solution also treats the users differently based on the group to which they are assigned. Different IP address ranges are assigned to each group, allowing highly detailed rules to be created at the firewall controlling access to internal network resources based on user or group needs. The policy on the firewall must be as specific as possible to restrict access to internal resources to only those clients for whom it is necessary. Building very specific policy for users' access will also allow an *Intrusion Detection System* (IDS) to better detect unauthorized access attempts.

Encryption

LEAP also provides for dynamic per-user, per-session WEP keys. Although the WEP key is still the 128-bit RC4 algorithm proven to be ineffective in itself[7], LEAP adds features that maintain a secure environment. Using LEAP, a new WEP key is generated for each user, every time the user authenticates to use the wireless network. Additionally, using the RADIUS timeout attribute on the authentication server, a new key is sent to the wireless client at predetermined intervals. The primary weakness of WEP is due to an algorithm that was easy to break after a significant number of encrypted packets were intercepted. With LEAP, the number of packets encrypted with a given key can be tiny compared to the number needed to break the algorithm.

When using LEAP for user and device authentication, WEP encryption is automatically enabled and cannot be disabled. However, if added security is needed, a VPN, as described earlier, can provide any level of encryption desired. Using a VPN as the bridge between the wired and wireless network is recommended regardless of the underlying vendor or technology used on the wireless network. *IP Security* (IPSec) is a proven, highly secure encryption algorithm available in VPNs. By requiring all wireless network traffic to be IPSec encrypted to the VPN over the WEP-encrypted 802.11 Layer 2 protocol, any data passed to and from wireless clients can be considered secure. All traffic is still susceptible to eavesdropping, but will be completely undecipherable.

Aside from WEP and LEAP, some vendors provide other forms of built-in security. Symbol Technologies' Spectrum24 product provides Kerberos encryption when combined with a Key Distribution Center. Kerberos is more lightweight than IPSec and, therefore, may be better suited to certain applications such as IP phones or low-end *personal digital assistants* (PDAs). Other methods of automating the assignment and changing of WEP keys are also available, such as Enterasys' Rapid-Rekey[8]. Wireless vendors have realized that security has become of critical importance and most, if not all, are working on methods for conveniently securing wireless networks. When available, most vendors seemingly prefer to use open-standard, interoperable security mechanisms with proprietary security being additionally available.

Bringing it all together

Numerous options are available to secure a wireless network. A highly secure design will include, at a minimum, an authentication server such as RADIUS, a high-level encryption algorithm such as IPSec over a VPN, and access points that are capable of restricting access to the wireless network based on some form of authentication. When all the security options are tied together, the wireless network requires explicit authentication to allow a device and the user on the wireless network, the traffic on the wireless network is highly encrypted, and traffic directed to internal network resources is controlled per user or group by an access policy at the firewall or in the VPN.

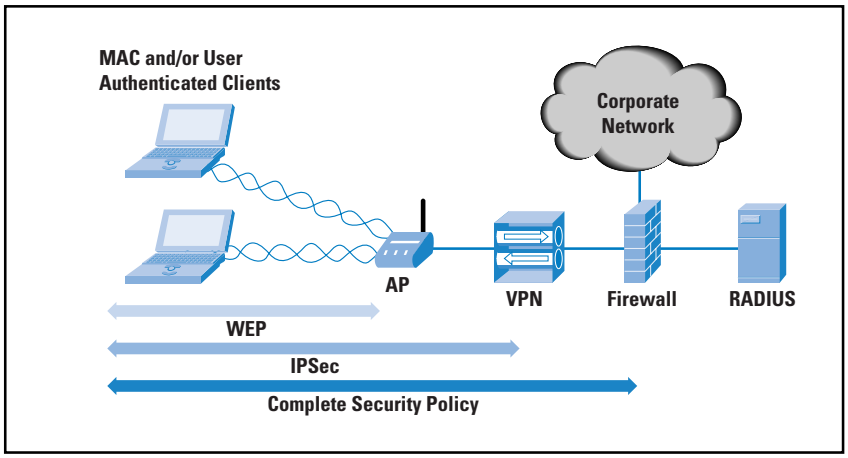

Figure 1: A Highly Secure Wireless Network

There is no substitute for experience and research when designing a network security solution. Using network security and design experience to exploit available technologies can further increase security of a wireless network. For example, grouping users into IP address ranges based on access requirements allows firewall access policy to help restrict unnecessary access. This can be accomplished using *Dynamic Host Configuration Protocol* (DHCP) reservations, assigning per-user or -group IP address ranges to the VPN tunnels or statically assigning addresses. Using a centralized accounts database for all authentication helps avoid inadvertently allowing an account that has been disabled in one part of the network to access resources through the wireless network. To use an existing user database for authentication while providing for dynamic WEP keys, use a LEAP-enabled RADIUS server that has the ability to query another server for account credentials. As with most network designs, a solid understanding of the available technologies is paramount to achieving a secure environment.

Utilizing all the security described in this article would yield the following design. When a device first boots up, it receives an IP address within a specified range on a segregated portion of the network. This IP range is based on the typical usage of the device and is most useful for machines dedicated to specific applications. As a user attempts to log onto a wireless device, a RADIUS server authenticates both the MAC address and the username of the device. If the user authentication is successful, access is granted within the wireless network. In order for traffic to leave the wireless network to access other network resources, a VPN tunnel must be established. Again, the IP address assigned to the tunnel can be controlled based on individual user authentication to help enforce access policy through the firewall. When the tunnel is established, firewall access policy will restrict access to resources on the network. Most, if not all, of the authentications required may be automated to use a user's existing network logon and transparently complete each authentication. This is not the most secure model, but it would be as secure as any single signon environment.

Summary

A secure wireless network is possible using available techniques and technologies[8] [9] [10]. After researching needs and security requirements, any combination of the options discussed here, as well as others not discussed, may be implemented to secure a wireless network. With the right selection of security measures, one can ensure a high level of confidentiality of data flowing on the wireless network and protect the internal network from attacks initiated through access gained from an unsecured wireless network. At a minimum, consider the current level of network security and ensure that the convenience of the wireless network does not undermine any security precautions already in place in the existing infrastructure.

Opinion: The ISP—The Uncommon Carrier

by Geoff Huston, Telstra

There is a long-standing role in the communications industry where a provider of public carriage services undertakes the role of a *common carrier*. What's so special about the role of a common carrier, and why is this role one that is quite uncommon in the *Internet Service Provider* (ISP) world?

Side comment: There once was a time when you could not trust the messenger. There once was a time when not only did you pay to have your message sent, but you paid to *receive* messages. And there was no guarantee that the message would not be read by the messenger. The contents of your note could have been used to determine how much the receiver should pay for the message. Your message could have been copied and sold to other parties. If you can't trust the messenger, then communications becomes a risky business.

The Messenger

Throughout history the position of a messenger has been a mixed blessing. To be the bearer of bad news was not an enviable role, and rather than being rewarded for the effort of delivering the message, the messenger might have been in dire straits, given the level of wrath of the recipient. The option of reading the message before delivering it could be seen as a personal survival strategy, as well as being a prudent business move—bad news could be discarded immediately, whereas good news could have the potential of extracting a higher delivery fee from the recipient. Although this scenario would have been good for the messenger, such a mode of operation was not beneficial to all. For the parties attempting to use the messenger service, message delivery could be a very haphazard affair. The message might or might not get delivered, the delivery time was variable, as was the cost of delivery, and if the message itself was intended to be a secret, then one could confidently anticipate that the messenger would compromise this secrecy.

The Common Carrier

For a communications network to be truly useful, numerous basic attributes must be maintained. These include predictability, so that a message passed to a communications carrier is delivered reliably to the intended recipient. Integrity is also necessary, because a message must not be altered by the carrier in any way. Privacy is also an essential attribute, because the message must not be divulged to any party other than the intended recipient, nor should even the existence of the message be made known to any other party. And above all there must be a solid foundation for trust between the carrier and the clients of the service. So in this form of social contract, what does the carrier get in return?

Apart from payment for the service, the carrier is absolved from liability regarding the content of the messages, and from the actions of the customers of the service. This form of social contract is the basis for the status of a common carrier.

It may have taken some time, but this role is well understood by the public postal network. And as many national postal operators encompassed the role of national telephone carrier, the common carrier role has been an integral part of the public telephone network.

The ISP's Role

But in the world of the ISP the position of common carrier is very uncommon indeed.

There once was a time when folk did not need to encrypt their letters nor speak in scrambled code to undertake a private conversation. The assumption, made law in many countries, was that the entity entrusted with public communications, the common carrier, was barred from deliberately inspecting the contents of the plain transmission, and various dire penalties were in place if a public carrier's employees or agents divulged anything they may have learned by virtue of being public carriers. Various measures were put in place to execute interception and monitoring, but these measures required due process and reference to some law enforcement agency and also the judiciary to ensure that the rights of the public user were adequately safeguarded.

The issues of the role of a common carrier and the current role of an ISP are clearly seen when looking at the reactions to unsolicited commercial e-mail, or spam. Every day ISPs receive strident demands of the form: "One of your users is sending unsolicited messages—disconnect him now!" Internet users are, in effect, holding the ISP responsible for the actions of its customers. A similar expectation of the ISP's responsibility for the actions of its customers is seen in response to various forms of hacking, such as port scanning. Similar messages are sent to ISPs, demanding the immediate disconnection of those customers who are believed to be originating such malicious attacks. From a small set of complaining messages some years back, the volume of such demands for ISP action is now a clamor that is impossible for any ISP to ignore.

What should the ISP do? Many responsible ISPs see it as appropriate to conduct an investigation in response to such complaints. ISPs often include provisions in their service contracts with their customers to allow them to terminate the service if they believe that their investigation substantiates the complaints on the basis of a breach of contract. When disconnected, such customers are often blacklisted by the ISP to ensure that they cannot return later and continue with their actions. Surely this is an appropriate response to such antisocial actions?

This may be the case, but it is not necessarily consistent with the role of the ISP as a common carrier. A common carrier is not a law enforcement agency, nor is it an agent of the judiciary. It may be entirely appropriate for a common carrier to investigate, under terms of strict privacy, a customer's activities and inspect the contents of traffic passed across the network if it has reasonable grounds to suspect that the integrity of the network itself is under threat. Equally, it is probably inappropriate for a common carrier to extend the scope of such investigations on the basis of external allegations of activities that are not related to the integrity of the service itself.

The assumption that an ISP is, in some way, responsible for the actions of its customers has been extended further in some countries, such that the ISP is, in part, responsible for the content carried over its network, including content that originates with a customer of its service. This expectation that ISPs should actively control and censor content passed across their network is not just an expectation of some Internet users. This expectation appears in numerous legislative measures enacted in many countries. The *Communications Decency Act* in the United States legislature is an example of such an expectation of the active role of the ISP in controlling content passed across its network.

Who Will You Call?

Perhaps the issue here is one of expediency. Where can a user direct a complaint after receiving yet another piece of unsolicited, and possibly highly offensive, e-mail, apart from the ISP of the sender of the message? Where else can users direct a complaint after being the subject of yet another port scan of their system, but to the ISP? And what else can an ISP do in response? The ISP often has little choice but to investigate such complaints in good faith, and take corrective action if the complaint is substantiated. In the absence of any effective regulatory framework that would allow such investigations to be undertaken by an appropriate external agency, the ISP is in a difficult position.

Whereas it may be the correct common carrier position to disclaim all responsibility for the actions of its customers together with the content passed across its network, to ignore such complaints marks the ISP as a haven for such antisocial activities. Adopting such a position often has a negative impact on the ISP's ability to interconnect with other ISPs, because ISPs also tend to hold each other responsible for the actions of their customers and the content passed across their network. ISPs tend to avoid extending interconnection services to those ISPs that disclaim any such responsibility. So the expedient response is for the ISP to assume some level of responsibility for its customers and the content of its network and act accordingly.

But short-term expedient measures should not be confused with long-term effective solutions. The problem with these short-term responses lies in the uniquely privileged position of the carrier. Even rudimentary forms of data mining of each customer's communications patterns and the content of their communications can yield vast quantities of valuable information. Such information can allow a carrier to discriminate between customers, compromise the integrity of the customer's use of the network, and actively censor the content passed across the network. Positions of privilege without accompanying checks and balances are readily abused. There is already the widespread expectation and acceptance that an ISP has the ability and duty to inspect network content and monitor customers' activities with respect to various forms of antisocial and often malicious activities. But how can checks and controls be enforced such that the information gained through such monitoring activities is not used for other purposes? Such monitoring is not without cost, and the option of recouping some revenue to balance this expenditure by regarding this information as a business asset is always present. The regulatory impost of a common carrier role is intended to be an economically efficient response to this issue. The common carrier role is intended to reduce the social power of public carriers and protect the public's open, uncensored, and equal access to the carrier's services.

It is often said that the road to hell is paved with the best of intentions—that the ultimate outcome of the solution is potentially far worse than the immediate problem being addressed. The ultimate outcome of erosion of the common carrier role is that public users of a public communications service can confidently expect their communications to be monitored, potentially stored and cross referenced, and possibly later acted on.

Public Policy

Today the short-term expedient measures abound. There is enormous pressure on ISPs from both the Internet's user base and numerous legislatures to take an active position of being responsible—and liable, for the content on the networks and the actions of their clients. If left unchecked, this will have severe longer-term consequences for free speech, basic personal privacy, and uncensored, nondiscriminatory, universal access to the Internet. And when the user base comes to recognize the debased value of such a compromised communications system, they will inevitably look to other means of communication that have retained their essential integrity as a common carriage service.

Perhaps it is time for the debate regarding the role and responsibilities of an ISP to be placed on the agenda of public policy makers. Perhaps it is time to recognize that ISPs are indeed common carriers, and that they have a clearly bounded set of responsibilities with respect to both content and the actions of clients of the service.

Perhaps it is time to consider how best to enforce social norms on the Internet without compromising the basic integrity of the carrier as a neutral party to the content being carried across the network. Perhaps it is time to recognize that in this domain the Internet is not entirely novel, and what we have learned from a rich history of carriage provision in society has direct relevance to the Internet today.

The Internet is simply too valuable a communications service to have its long-term potential as a universal communications service mindlessly destroyed on the altar of short-term expediency.

Disclaimer: I am by profession neither a lawyer nor a public policy maker. However, by virtue of working in the ISP industry, I have an increasing level of interest in the activities of these folk, for the reasons outlined above. I should also note that personal opinion comes in many forms. The above is one such form.

GEOFF HUSTON holds a B.Sc. and a M.Sc. from the Australian National University. He has been closely involved with the development of the Internet for the past decade, particularly within Australia, where he was responsible for the initial build of the Internet within the Australian academic and research sector. Huston is currently the Chief Scientist in the Internet area for Telstra. He is also a member of the Internet Architecture Board, and is the Secretary of the APNIC Executive Committee. He is author of *The ISP Survival Guide*, ISBN 0-471-31499-4, *Internet Performance Survival Guide: QoS Strategies for Multiservice Networks*, ISBN 0471-378089, and coauthor of *Quality of Service: Delivering QoS on the Internet and in Corporate Networks*, ISBN 0-471-24358-2, a collaboration with Paul Ferguson. All three books are published by John Wiley & Sons.

Letters to the Editor

ENUM

Ole,

I was looking at the June 2002 issue of *The Internet Protocol Journal,* and noticed what might be a misprint. In the story on ENUM, the next-to-last paragraph on page 21 has a sentence reading:

> North America has the .164 country code of "1," implying that under ENUM there is a single DNS domain for ENUM, namely **`1.e164.arpa.`**

I suspect it should read "... there is a single DNS domain for North America..." or something like that. (The ".164" should probably also be "E.164"—you don't refer to it as just ".164" elsewhere in the article.)

A more substantive comment on Marshall Rose's BEEP article in the same issue: It was a good overview, but I would have liked to see a mention of which application protocols are likely to use BEEP (assuming that none has already) in the near future. The middle of page 11 explains why the IETF thinks this is a good idea and why new application protocols need BEEP, but it was hard to tell whether it actually is being actively considered for use by any IETF working group.

Overall, I liked the issue, and particularly Peter Salus's review of Padlipsky's book—I came across it in the late 1980s, and actually met Michael sitting in a hallway at one of the Interop conferences before they got too big for Silicon Valley and I stopped attending. I still remember some of his cartoons and slogans (e.g., something to the effect "... the ITU is planning to have an 11-layer model because it's a sacred number in Bali..."). I've also found the articles in some of the other recent issues of the IPJ—e.g., the articles on wireless LANs (particularly the discussion of security issues) and code signing/mobile code in the March 2002 issue—very helpful, and have pointed colleagues to them.

Best wishes.

Managing Director,
Technology Forecast Publications
PricewaterhouseCoopers Technology Centre
`Eric.Berg@us.pwcglobal.com`

Geoff Huston responds:

While we all try hard to eliminate various errors in manuscripts prior to publication, there are always a few author-mishaps that manage to sneak past the eagle eyes of the editor, and this is one of them.

The offending sentence should read:

> North America has the .E164 country code of "1," implying that under ENUM there is a single DNS domain for ENUM in North America, namely **`1.e164.arpa.`**

Thanks for pointing this out.

—Geoff

More about ENUM

Ole,

In the June 2002 issue of IPJ (Volume 5, Number 2), Geoff Huston wrote an interesting article about ENUM. The technical side of ENUM (using DNS to map E164 numbers to services) seems rather straightforward. But its implications on both technical and social issues are much more complex and (in my opinion) interesting. I am not an expert on the subject, but I'd like to share a few thoughts about this. First, two technical issues come to mind.

The first one is about the use of the *Domain Name System* (DNS). The DNS has been very successful as a distributed replicated database of hostname-to-IP address (and reverse) mappings. Will it be able to handle gracefully all the stuff people intend to put in it? This is not certain, as shown by ICANN's cautious attitude concerning the creation of new Top Level Domains. Content Distribution Networks, for example, often use lots of domain names with short TTLs, reducing the effectiveness of DNS caching (Geoff mentions this caching issue for ENUM). After all, DNS stands for "Domain Name System," not "General Purpose Infinitely Scalable Distributed Dynamic Database."

The second issue is about the status of addresses and names in the Internet. Simplifying things, we can say the following happens when somebody wants to access an Internet service with an E.164 number: The E.164 number is translated into a DNS name, and a DNS lookup gives back an URI. If the URI is a simple URL, the domain name in the URL is DNS-looked-up for an IP address, and then packets are sent to that IP address. If the URI is not a simple URL (such as a URN), some other resolving process implying the DNS occurs anyway.

That makes two levels of indirection, but, moreover, creates an "interesting" situation: IP addresses are "addresses," i.e., network-friendly identifiers, whose structure is tied to the network topology.

Such identifiers are not user friendly, so user-friendly identifiers called "names" have been created, and a "domain name system" set up to translate names into addresses. E.164 numbers are really telephone addresses. They are tied to the telephone network topology and are surely not user friendly. There are no user-friendly names in the telephone system.

The strange thing is that with ENUM, E.164 numbers are not linked anymore to the network topology, but rather become names intended for user usage. In a sense, they even are "meta names," since they translate to DNS names (that translate to addresses). But they obviously have not become user-friendly in the process.

I must admit I oversimplify a bit since I don't distinguish between names and addresses identifying level 3 (network) resources (i.e., hosts) and those identifying level 7 (application) resources (e-mails, Web pages, etc.), but this doesn't invalidate the idea.

Addresses are what the network needs, and names are what the users need. This brings me to the politics aspects of ENUM: who administers/controls/owns the namespace? A namespace is only partly technical; defining a namespace includes defining how and by whom the namespace is operated. The DNS is technically a big success, but the politics side is controversial, as shown by domain-name disputes or the setting up of alternative domain-name systems. It seems that social aspects are often more difficult to deal with than technical issues are to solve.

When I was studying networking we were taught how the technical differences between the Internet and the telephone network took their roots into a fundamental difference of culture. Now that the Internet culture seems to have won on the technical aspect (IP over broadband ISDN), wouldn't it be a strange outcome for the Internet namespace to be owned by telephone companies?

To conclude, I think this ENUM stuff shows that the Internet community really needs to work on the namespace issue, to ensure a technically and socially sound namespace for the Internet.

Book Review

Carrier-Scale IP Networks

Carrier-Scale IP Networks: Designing and Operating Internet Networks, edited by Peter Willis, ISBN 0-85296-982-1, The Institute of Electrical Engineers, London, United Kingdom, 2001

My heart jumped when I saw the nondescript brown box, about the thickness of a book, sitting by the receptionist. It was finally here! I had waited almost two months in great anticipation for this book to show up. Was it going to be the all-encompassing handbook for the network designers, operators, and managers in large-scale IP environments? The first few lines in the text indicated that it just might be: "The aim of this book is to give the reader an understanding of all the aspects of designing, building and operating a large global IP network."

The definition of "large-scale" as given by the author and for the purposes of this review follows: Provides services for millions of end users, high-speed (greater than 100 Mbps) transit services, and is reliable, scalable, and manageable.

One thing to keep in mind is the way this book was constructed. The 16 chapters had 29 authors. Almost all authors came from some area of British Telecom (BT) and all were subject matter experts in the chapter they wrote. The 16 chapters are grouped roughly into four sections: Designing and building IP networks, transmission and access networks, operations, and development of future networks. Sadly, all of this is squeezed into 293 pages.

Designing and building IP networks

For the reader new to designing and building large-scale IP networks, the first few chapters are gold. For the reader already experienced in this area, it may bring back nostalgic feelings for the good old days of exponential growth. A lot of ground is covered, including the obligatory overview of IP, sufficient enough to give a nontechnical person the key concepts of IP routing, but can by skipped by those with even basic knowledge in this area. The examples given throughout this chapter (and the rest of the book) come directly from the design of BT's and Concert's backbone. A whole chapter, "The Art of Peering," not to be mistaken for an excellent paper of the same name[1], gives excellent key concepts in peering. Some coverage is even given to the logistics and difficulties in building points of presence globally, going so far as to mention earthquake bracing for equipment bays.

The next set of chapters give the reader detail about the transmission network (for some, be prepared to think *Synchronous Optical Network* [SONET] when you read *Synchronous Digital Hierarchy* [SDH]), and access networks, including various forms of broadband, wireless, dial, and satellite.

The technical information was squeezed into these chapters, not enough for a good technical treatise, but enough to give readers good grounding in a technology that is unfamiliar to them. The coverage was closer to being marketing material. These chapters alone are not enough to bring those new to the field up to speed if they are to design or operate such a network.

BT opened itself up and gave us a view into the operations of its network. Individuals who have worked in an environment like this will find something familiar. We get to see how BT structures the people, processes, and technologies. This is something that is not usually open to inspection by people outside of an organization. Planning and developing the operations side of the house is a difficult job. These chapters may give a kick-start to those coming into such a role.

I was disappointed with the two final chapters. Of course anything listed as being "the future" will one day become the present, but I digress. These two chapters seem like the odd couple that just did not fit with the rest of the chapters. The first chapter is on Traffic Engineering. It is really a primer on *Multiprotocol Label Switching Traffic Engineering* (MPLS TE). The second chapter covers *Virtual Private Networks* (VPNs), both the MPLS and *IP Security* (IPSec) types.

Recommendation

The authors set out with a lofty goal, and did not quite hit the mark. This book would be appropriate for someone trying to get a feel for what goes on inside of a carrier-scale network. People already in the business would be better served by just paying attention to what goes on around them.

Perhaps a small focused group could set out to create a book (or should I say tome) covering the elements of design, the foundation of support, and the basics of management. Something timeless is required here, independent of the protocol du jour, to develop the next generation of competent netheads.

Stephen Wolff receives Postel Service Award

In June 2002, Internet pioneer Stephen Wolff was honored by the *Internet Society* (ISOC) for his significant contributions on behalf of the Internet. A founding member of the ISOC, Wolff is considered one of the "fathers of the Internet" and was directly involved with its development and evolution.

Wolff received the *Postel Service Award,* named for Dr. Jonathan B. Postel, an Internet pioneer and head of the organization that administered and assigned Internet names, protocol parameters, and *Internet Protocol* (IP) addresses. He was the primary architect behind what has become the *Internet Corporation for Assigned Names and Numbers* (ICANN), the successor organization to his work. The recipient of the award receives a $20,000 cash honoraria.

"We are pleased to recognize Steve with the Postel Award," said ISOC President/CEO Lynn St.Amour, "especially as his contributions are well know to ISOC, having previously been commended by ISOC's board for helping transform the Internet from an activity serving the particular goals of the research community to a worldwide enterprise which has energized scholarship and commerce in dozens of nations."

The 1994 commendation from the ISOC board also states that "The personal leadership of Dr. Wolff, often under conditions of public controversy, has been an indispensable ingredient in surmounting a daunting array of technical, operational and economic challenges. His extraordinary commitment to the growth and success of the Internet reflect the highest standard of service to the networking community and command our respect and admiration."

As Director of the Division of Networking and Communications Research and Infrastructure at the US National Science Foundation, he was responsible for NSNET, the *National Research and Education Network* (NREN), and for NSF's support of basic research in networking and communications. While at the NSF he was among the founders of the interagency and international research networking management and advisory structure whose descendants today include the Large-scale Networking (LSN) working group and the PITAC.

Wolff left the federal government and joined Cisco Systems, Inc. in 1995, where he works in the University Research Program—Cisco's program supporting academic investigators with unrestricted grants for research on computer networks.

Wolff was educated at Swarthmore College, Princeton University, and Imperial College. He taught electrical engineering at the Johns Hopkins University for ten years and subsequently spent fifteen years leading a computing- and network-related research group at the U.S. Army Research Laboratory. In 1983 he took a sabbatical half-year as a Program Director in the Mathematics Division of the U.S. Army Research Office.

ISOC is a not-for-profit membership organization founded in 1991 to be the international focal point for global cooperation and coordination in the development of the Internet. Through its current initiatives in support of education and training, Internet standards and protocol, and public policy, ISOC has played a critical role in ensuring that the Internet has developed in a stable and open manner. For 10 years ISOC has run international network training programs for developing countries which have played a vital role in setting up the Internet connections and networks in virtually every country that has connected to the Internet. For more information, please visit: **`http://www.isoc.org/`**

ISOC to Run `.org`?

Recently ICANN posted a preliminary Staff Report on the selection of a new registry operator to assume responsibility on January 1, 2003 for the **`.org`** registry. The report, which is subject to public comment and comment by all the bidders before being submitted for approval to the ICANN Board of Directors, recommends that the Board select the *Internet Society* (ISOC) as the successor registry operator for the **`.org`** registry, currently operated by VeriSign.

This preliminary report follows an extensive bid solicitation and evaluation process that was launched last April. Eleven bids were received in response to a Request for Proposals. These bids were analyzed and evaluated by three evaluation teams that operated independently of each other.

"We received eleven very strong and thoughtful proposals," noted Stuart Lynn, President of ICANN. "We appreciate the response of the institutions behind these proposals. The ISOC proposal was the only one that received top ranking from all three evaluation teams. On balance, their proposal stood out from the rest." Lynn also emphasized the openness and transparency of the solicitation and evaluation process.

Two evaluation teams focused on technical issues: one from Gartner, Inc., an international consulting and research organization that specializes in information technologies, and the other a team mainly composed of CIOs of major universities. Another team was provided by ICANN's *Non Commercial Domain Name Holders* constituency; the NCDNHC team focused on the effectiveness of the proposals to address the particular needs of the **`.org`** registry. The staff report integrates these evaluations and other factors into the preliminary recommendation.

ISOC is an international not-for-profit organization of over 6,000 individual and 150 organizational members with chapters in over 100 countries. It provides leadership in addressing issues that confront the future of the Internet, as well as being a home for the *Internet Engineering Task Force* (IETF) and the *Internet Architecture Board* (IAB).

In operating the **.org** registry, ISOC will team with Afilias, an operating registry that recently launched the **.info** *top level domain* (TLD) that was authorized by ICANN as one of seven new TLDs over this past year.

"Afilias will provide ISOC with the necessary experience at operating a large registry," said Lynn. "The **.info** registry already houses about 1 million domain names, which is on a scale that approaches the much older **.org** registry."

ICANN is re-assigning the **.org** registry under a revised agreement among ICANN, VeriSign, and the U.S. Department of Commerce that was signed in May 2001. Under that agreement, VeriSign was permitted to keep its registrar business, NSI (that it was obligated to sell under the prior agreements) provided that it agreed to relinquish **.org** at the end of December 2002, and subject to other provisions of the revised agreements. As part of those revised agreements, VeriSign agreed to endow the new operator with US$ 5 million to help fund operating costs, provided that the new operator was a not-for-profit organization.

Following an open and transparent process, ICANN has posted all eleven applications online together with all supplemental material and community comments received. The preliminary staff report and the evaluations are posted at:
http://www.icann.org/tlds/org/preliminary-evaluation-report-19aug02.htm.

Applicants and any member of the community are invited to send comments on the preliminary report and evaluations by e-mail to:
org-eval@icann.org

Upcoming Events

The *IETF* will meet in Atlanta, Georgia, USA, November 17–21, 2002.
http://www.ietf.org/meetings/meetings.html

ICANN will meet in Shanghai, China, October 27–31, 2002.
http://www.icann.org/meetings/

The next *Asia Pacific Regional Internet Conference on Operational Technologies* (APRICOT) will take place February 19–28, 2003 in Taipei, Taiwan. **http://apricot2003.net/**

From The Editor

In December 1999 we published Part One of a two-part article on Internet Multicast. Some readers have asked "what happened to Part Two?" Finally, in this issue we are able to bring you the second article, "Internet Multicast Tomorrow." Multicast remains a technology with limited Internet-wide deployment, but numerous research activities are underway that may change this situation. Ian Brown, Jon Crowcroft, Mark Handley and Brad Cain provide an overview of current developments in multicast.

If all computer networking was a simple matter of "plug-and-play," I suppose this journal would not exist. Nevertheless, it is encouraging to see developments that aim to simplify configuration of network devices, particularly those that move around a lot. The Zeroconf working group of the *Internet Engineering Task Force* (IETF) has been developing standards for "configuration-free" networks. Edgar Danielyan explains the details in our second article.

We continue to receive numerous letters in response to our articles. Your feedback is very much appreciated, because it helps us develop material for future issues. Please keep your letters coming to **ipj@cisco.com**

The long-awaited online subscription system is now ready for deployment and you will be able to try it out in the very near future at **www.cisco.com/ipj**. With this system, you can update your mailing address as well as select delivery options, online notification of new issues and so on. As with any computer based system, I anticipate that we, with your help, will uncover a few bugs. Please report any problems you may encounter to **ipj@cisco.com**.

A new important resource is available from the *Internet Society* (ISOC). *The Internet Report* is a catalogue of IETF documents, including RFCs and Internet Drafts, that document the technology, protocols and operating procedures that form the Internet. The report includes RFCs, IETF Working Group drafts as well as individual drafts. The Internet Report is maintained by Geoff Huston. You can access the report online at **http://ietfreport.isoc.org/**

Internet Multicast Tomorrow

by Ian Brown, University College London,
Jon Crowcroft, University of Cambridge,
Mark Handley, ICIR,
Brad Cain, Storigen Systems

This article is part of a pair, the first of which looked at the state of play in IP multicast routing[0]. In this article, we look at the broader problems and future activities with multicast. We divide the areas into routing, addressing, transport, security, operations, and research.

There has been quite a bit of debate about the nature of compelling applications for multicast recently.[44] It is certainly the case that we do not completely understand the "market" for multicast—this is at least in part because multicast does not yet provide a complete set of functions for all the applications and services we might imagine. This is a typical "chicken and egg" situation, though: To put an extreme version of the argument, the application writers do not see any multicast deployed; the *Internet Service Providers* (ISPs) do not see any multicast applications; and the router vendors do not see any multicast service demand from ISPs. (The same problem afflicts IPv6, Integrated and possibly Differentiated Services, and mobile IP, of course.)

As we discussed in the part I of this article[0], this situation has been somewhat alleviated by streaming applications for audio and video from the classical content providers in the entertainment and news industries. And although we are still seeing some problems, we are also seeing broader interest and development.

The next section presents recent work on routing and addressing. After that we look at transport. Subsequently, we discuss security. Then we look at operations and management. Finally, we examine some of the research ideas that are available.

Routing and Addressing

The single biggest step recently in multicast routing and addressing has been the recognition that the demand for large-scale multicast is largely for one-to-many or single source. Combined with the ability to select sources at the receiver (as a means to prevent denial-of-service attacks) in the *Internet Group Management Protocol* (IGMP)v3, this has made a significant improvement to ISPs' willingness to deploy the service[42].

Source-Specific and Single-Source Multicast

The origins of the idea were thesis work at Stanford by Hugh Holbrook on Express multicast[43]. This is a specialized multicast architecture for one-to-many multicast groups. In this way, Express is a subset of the current multicast model in that it allows only a single sender to a multicast group. The advantages of Express are that certain aspects of multicast routing and addressing are easier solved by ignoring the many-to-many case. Many feel that the most likely large-scale applications of multicast are one-to-many, a fact that explains why Express is becoming popular as a short-term solution.

Express addresses are *channels* that are 64-bit addresses (that is, source address plus group address). Express sources transmit to a channel and advertise that channel. Receivers learn about these channels through advertisements or through other means (that is, URL) and initiate an Express join. Routers propagate these joins directly toward the source, building a source rooted multicast forwarding tree.

The Express model offers two primary benefits. First, Express simplifies the complexity of multicast routing. Secondly, Express simplifies the assignment of multicast addresses for IPv4. Because Express channels are 64 bits, a source can select any lower 32 bits (any group address) for its channel and not collide with another.

In order to implement Express with IPv4 multicast protocols, a special range of multicast addresses was defined. The 232/8 address has been allocated by the *Internet Assigned Numbers Authority* (IANA) for single-source multicast experimentation. In this range, an address has meaning only when "coupled" with a source address. Another way to explain it is that this address range is reserved for the lower 32-bit Express addresses. With this scheme, Express requires no modification to multicast data packets.

Express can be implemented with two protocols that have already been developed: IGMPv3[42] and *Protocol Independent Multicast Sparse Mode* (PIM-SM).

IGMPv3 extends IGMP to allow source-specific joins to a multicast address. This capability can be used to carry 64-bit (S,G) joins to a router. When a router receives the IGMPv3 join, it must be able to build the source-specific tree with a multicast routing protocol. PIM-SM, widely deployed in service provider networks, already possesses this capability. The combination of IGMPv3 and PIM-SM allows Express to be implemented without creating more protocols; this is one of the most powerful benefits of the Express model.

Interdomain Multicast

Currently there are four fairly widely deployed multicast routing protocols: *PIM Dense Mode* (PIM-DM), PIM-SM or *Source-Specific Multicast* (SSM), *Multicast OSPF* (MOSPF), and the *Distance Vector Multicast Routing Protocol* (DVMRP). Because of the different properties of these protocols, there are many difficulties in connecting heterogeneous routing domains together[38]. In general, most problems arise when connecting explicit join type protocols with flood-and-prune protocols. With service providers rolling out multicast using PIM-SM, connecting DVMRP and PIM-DM flood-and-prune is becoming common.

In order to connect two multicast routing domains, a *Multicast Border Router* (MBR) needs to exist between the two domains. This router must implement a shared forwarding cache architecture[39]. In this model, each multicast routing protocol running on a MBR submits its forwarding cache entries to a shared cache. This cache is the "bridge" between the trees in the different domains.

In order that the appropriate trees are created in each domain (on either side of a MBR), signaling must exist to bring sources from one domain to receivers in the other domain. This is part of the complication in connecting flood-and-prune protocol domains to explicit join protocol domains. In an explicit join protocol such as PIM-SM, joins are sent by edge routers to either a source or a *Rendezvous Point* when a host joins. A flood-and-prune protocol works quite differently, in a sense assuming that packets are desired; trees are pruned when edge routers receive new source packet but have no local listeners.

The signaling aspect of joining two domains can be accomplished with a variety of means. There are many options, but two stand out as providing the best methods of connecting domains. The first is to use *Domain Wide Reports* (DWRs)[36] in flood-and-prune domains. DWRs are similar to IGMP reports except that they are sent on a domain-wide basis. When a border router receives a DWR report, it can join a group on behalf of an entire domain. The second solution is to use the *Multicast Source Discovery Protocol* (MSDP)[37]. MSDP is currently used to send source lists between PIM-SM domains. It can also be used to connect domains by having the MBR also participate in MSDP. Sources can then be learned from an explicit join protocol domain; the MBR can then join the sources and flood them into attached flood-and-prune protocols domains.

Address Allocation

The schemes to provide dynamic distributed address allocation have not been successful to date. But with many multicast services being limited to either a single domain or a single source, the pressure is off. Instead, source-specific addresses are unique in any case. For many-to-many multicast (sometimes known as *Internet Standard Multicast* [ISM]), the problem has also been alleviated by the use of GLOP[61], which allocates sections of the address space by mapping Autonomous System numbers of a provider into Class D prefixes. This is potentially inefficient, but solves the contention, collision, revocation, or resolution problem that *Multicast Address Set Claim* (MASC) and *Multicast Address Allocation* (MALLOC)[60] attempt to do in a distributed dynamic manner.

In the longer term this address allocation, as well as scalable solutions to many-to-many multicast in the local domain and interdomain, await further development on bidirectional trees ["Bi-dir PIM" and the *Border Gateway Multicast Protocol* (BGMP)], which we discuss next. It is likely that these will need IPv6 to scale to serious usage.

Bidirectional PIM-SM

The PIM-SM multicast routing protocol builds both source and shared trees for the distribution of multicast packets. PIM-SM shared trees are rooted at special routers called Rendezvous Points and are uni-directional in nature. Shared tree traffic always flows from the Rendezvous Point down to the leaf routers. In some types of multicast applications, namely many-to-many type applications, a unidirectional tree may be inefficient.

Other multicast protocols such as *Core Based Trees* (CBT) and BGMP provide bidirectional shared trees. Bidirectional trees[40] do not have these inefficiencies in many-to-many applications. In a bidirectional tree, traffic from a source is forwarded directly onto the shared tree at the closest point; the traffic is then forwarded both "up" and "down" the tree to all receivers. This is in contrast to a unidirectional tree when the source packets are sent first to the Rendezvous Point (or root) and then down the tree. Recently, two proposals have been submitted that add bidirectional tree capabilities to PIM-SM[40].

BGMP

BGMP[33] is a new inter-domain multicast routing protocol that addresses many of the scaling problems of earlier protocols. BGMP attempts to bring together many of the ideas of previous protocols and adds features that make it more service provider friendly. BGMP is designed to be a unified inter-domain multicast protocol in much the same way that the *Border Gateway Protocol* (BGP) is used for unicast routing.

BGMP is an inter-domain protocol in that it adopts particular design features of BGP familiar to providers. Two of these features follow: it uses TCP connections for the transfer of routing information and it has a state machine (with error notifications) similar to BGP.

In order to accommodate different applications and backward compatibility, BGMP can build three types of multicast trees, both unidirectional source and shared trees and bidirectional shared trees. Unidirectional trees are useful for single-source applications and for backward compatibility with other multicast routing protocols. Shared trees are useful for many-to-many applications (for example, multiplayer gaming, videoconferencing) and multicast forwarding state to scale for these types of applications.

One of the unique properties of BGMP is that its shared trees are rooted at an Autonomous System that is associated with the multicast group address of the tree. Having the root of the tree at the Autonomous System that is associated with the address is logical because there are likely members in that domain. Rooting the trees at an Autonomous System level also provides stability and inherent fault tolerance.

BGMP requires a way to discover which Autonomous Systems "own" which multicast addresses; this can be accomplished through the use of the MASC protocol or through globally assignable multicast addresses (for example, IPv6 multicast). The MASC protocol allocates temporary assignments from the IPv4 group D address space; it then distributes these assignments into *Multiprotocol BGP* (MBGP) so that BGMP will know which Autonomous System is associated with which group and, therefore, where to send join messages.

If globally assignable addresses are available, then BGMP can use any static address architecture for obtaining an Autonomous System from a multicast group address.

The combination of BGMP and a large multicast address space (for example, IPv6 address space) provide the best scaling for all types of multicast applications.

Transport and Congestion Control: Calling Down Traffic on a Site

Multicast is a multiplier. It gives an advantage to senders, but without their knowledge. Multicast (and its application level cousin, the CU-SeeMe reflector) can "attract" more traffic to a site than it can cope with on its Internet access link. (CU-SeeMe is a popular Macintosh- and PC-based Internet videoconferencing package that currently does not directly use IP multicast.) A user can do this by inadvertently joining a group for which there is a high-bandwidth sender, and then "going for a cup of tea." This problem will be averted through access control, or through mechanisms such as charging[58], which may result from the deployment of real-time traffic support.

The problem is seen as critical by ISPs who have a shared bottleneck in their access technology—this is the case for cable modem and in some cases for *Asymmetric Digital Subscriber Line* (ADSL), where a large number of fast lines converge on a slower interface to the backbone. Here, a single user may attract more traffic than this link can handle, without seeing a problem that he or she causes for other users (unicast or other multicast lower-capacity separate sessions using the same shared bottleneck). The use of IGMPv3 with authenticated join and con-figuration management would appear to be a possible solution to these woes. Alternatively, the use of TCP-friendly multicast congestion control (as envisaged for reliable multicast, but also as emerging in some *Real-Time Transport Protocol* (RTP)[4] applications), would also solve this problem.

Congestion Control

One of the critical areas to clarify is the role of congestion control in multicast transport protocols[1]. From an early stage, it was established that coexistence with TCP was a critical design goal for protocols that would operate in the wider Internet. Thus systems such as *TCP Friendly (Reliable) Multicast Congestion Control* (TFMCC)[8], *Pragmatic General Multicast Congestion Control* (PGMCC)[53], and receiver-driven congestion control[54] all extend the classic work by Raj Jain[15] and Van Jacobson[17] and subsequent evolution[16] on TCP congestion avoidance and control.

Recently, this line of thinking has even been extended back into the unicast world in the application of such control schemes to *User Datagram Protocol* (UDP)-like flows in the work on the *Datagram Congestion Control Protocol* (DCCP)[62], suitable for adaptive multimedia flows on RTP, for example.

Reliable Multicast

There is a clear requirement for some sort of analog to TCP for multicast applications that need a level of reliability. The *Internet Research Task Force's* (IRTF's) *Reliable Multicast Research Group* (RMRG) group[3] has developed numerous prototypical solutions to the problem, which turns out to be quite a large design space (not "one size fits all").

The IETF *Reliable Multicast Transport* (RMT) working group has now been chartered to develop single-source reliable multicast transport solutions that meet the current Internet constraints[1]. That group has developed a building block approach[12], which is based partly on abstracting components from existing work such as *Reliable Multicast Transport Protocol* (RMTP) II[18], *Receiver Driven Layered Congestion Control* (RLC)[7], *Multicast File Transfer Protocol* (MFTP)[28], *Pragmatic General Multicast* (PGM)[41], and many other protocols.

Some applications of RMT products are likely to be infrastructural rather than of direct use to the ISPs' customers—for example, distributing software to mirror sites seems to be one popular compelling use.

However, reliable multicast is sometimes regarded as something of an oxymoron. When people talk about "Reliable Multicast," they usually mean a single protocol at a single "layer" of a protocol stack, typically the transport layer (although we have seen people propose it in the network and even link [ATM!] layers too), that can act as any layered protocol can—to provide common functionality for applications (higher layers) that need it.

So what is wrong with that? Well, possibly three things (or more):

- *Fate sharing:* Fate sharing in unicast applications means that as long as there is a path that IP can find between two applications, then TCP can hang on to the connection as long as the parties like. However, if either party fails, the connection certainly fails.

  Fate sharing between multicast end points is a more subtle idea. Should "reliability" extend to supporting the connection fork recipients failing? Clearly this will be application specific (just as timing out on not getting liveliness out of a unicast connection is for TCP—we must permit per-recipient timeouts and failures).

- *Performance:* When A talks to B, the performance is limited by one path. Whatever can be done to improve the throughput (or delay bound) is done by IP (for example, load sharing the traffic over multiple paths). When A talks to B, C, D, E, or F, should the throughput or delay be that sustainable by the slowest or average?

- *Semantics:* As well as performance and failure modes, N-way reliable protocols can have different service models. We could support reliable one-to-n, reliable n-to-one, and reliable n-to-m.

Applications such as software distribution are cited as classic one-to-n requirements. Telemetry is given as an n-to-one reliable protocol. Shared whiteboards are cited as examples of n-to-m applications.

It is interesting to look at the reliability functions needed in these. The one-to-n and n-to-one protocols are effectively *simplex* bulk transfer applications. In other words, the service is one where reliability can be dealt with by "rounding up" the missing bits at the end of the transfer. Because this does not need to be especially timely, there is no need for this to be other than end to end, and application based. (Yes, we know telemetry could be time sensitive, but we are trying to illustrate major differences clearly for now.)

On the other hand, n-to-m processes such as whiteboards need timely recovery from outages. The implication is that the "service" is best done somewhat like the effect of having $n \times (m-1)/2$ TCP connections. If used in the WAN, the recovery may best be distributed, because requests for recovery will implode down the very links that are congested or error prone and cause the need for recovery.

Now there are different schemes for creating distributed recovery. If the application semantics are that operations (application data unit packets worth) are sequenced in a way that the application can index them, then any member of a multicast session can efficiently help any other member to recover (examples of this include Mark Handley's Network Text tool[16].) On the other hand, packet-based recovery can be done from data within the queues between network or transport and application, if they are kept at all members in much the same way as a sender in a unicast connection keeps a copy of all unacknowledged data.

The problem with this is that *because* it is multicast, we do not have a positive acknowledgement system. Therefore, there is no way to inform *all* end points when they can safely discard the data in the "retransmit" queue. Only the application really knows this!

Well, this is not to say that there is not an obvious toolkit for reliable multicast support—it would certainly be good to have RTP-style media timestamps (determined by the application, but filled in by the system). It would be good to have easy access to a timestamp-based receive queue so applications could use this to do all functions discussed previously. It might be advantageous to have virtual Token Ring, expanding ring search, token tree, and other toolkits to support retransmit "helper" selection.

Table 1 illustrates this in terms of where functions might be put to provide reliability (retransmit), sequencing, and performance (adaptive playout, say, versus end to end, versus hop-by-hop delay constraint).

Table 1: Reliable Multicast Semantics

	Recovery	Sequency	Dalliance
Network	not in our internet	ditto	int-serv
Transport	one–many	yes	adaptive
Application	many–many	operation semantics	adaptive

Router Assist for Reliable Multicast

As mentioned in previous sections, one of the difficulties in end-to-end multicast signaling is the "implosion" of signaling at a source from many receivers. This problem has been addressed in numerous ways, including the use of timers, the use of servers to aggregate signaling, and the use of router-assisted mechanisms. We now discuss three protocols that make use of router assistance in order to better scale end-to-end multicast protocols.

PGM[41] is a *negative acknowledgement* (NAK)-based router-assisted reliable multicast protocol. PGM uses routers to aggregate receiver-to-source signals (for example, the NAKs) as they flow toward the source. PGM router support also includes a subcasting ability whereby repairs will flow down only to receivers who have requested them.

Extending the ideas of router assist in PGM is the *Generic Multicast Transport Service* (GMTS). GMTS provides generic, fixed, simple services for any end-to-end multicast transport protocol. These services include such features as signal aggregation with predicates and sophisticated subcasting ability. GMTS was used as a basis for *Generic Router Assist* (GRA)[34], which is similar, IETF standards oriented, and a bit more streamlined.

Securing Multicast

Multicast security is more difficult than unicast security in several areas. The key exchange protocols used between unicast hosts do not scale to groups. Rekeying is required more often to maintain confidentiality as group membership changes. And the efficient authentication transforms used between two unicast hosts cannot protect traffic between mutually distrustful members of a group.

These problems are being worked on by the IETF *Multicast Security* (msec) and IRTF *Group Security* (gsec) working groups. Because of the wide range of application requirements in group communication, their work is based upon a building block approach similar to that of the RMT group.

The blocks being developed are data security transforms, group key management and group security association, and group policy management[49]. An application may use different blocks together to create a protocol that meets its specific requirements.

Data Security Transforms

A data security transforms block provides confidentiality and authentication services for data being transported between group members. Confidentiality is reasonably easy to provide using standard encryption algorithms. Authentication is more difficult, because the algorithms used in unicast protocols such as *IP Security* (IPSec) would not allow a group member to authenticate data as being from another specific group member. This is because the secret used to authenticate the traffic must be shared between all sending and receiving parties. Public-key signatures would solve this problem, but are an order of magnitude slower than symmetric authentication algorithms and hence especially unsuitable for real-time traffic and low-powered communications devices.

Instead, blocks such as the *Timed Efficient Stream Loss-tolerant Authentication Protocol* (TESLA)[55] are being developed that trade off small amounts of functionality (such as immediate rather than slightly delayed authentication) to retain the efficiency benefits of symmetric algorithms. TESLA senders use a hash chain of keys $k_{n...1}$ to sign data, where: $k_n = hash(k_{n-1})$

They release each key in the chain a short interval after the data the key has signed. As long as other group members received the data during that interval, they can be confident that the signature was made by the sender. If keys are lost during transmission, receivers can recompute any key earlier in the sequence simply by repeatedly applying the hash function used to any later key received. Finally, they can be sure that keys are coming from the sender because the first key in the sequence is digitally signed, while only the sender can know the later keys in the sequence (because by definition, a hash function must not be reversible).

Group Key Management and Group Security Association

To use data security transforms, group members need to possess the cryptographic keys necessary to encrypt or decrypt and sign or authenticate data. They also need to agree on parameters such as specific encryption algorithms. This building block allows this information to be shared between group members.

The Group Key Management architecture[47] provides a unified model for key management blocks. A central *Group Controller/Key Server* (GCKS) provides *Traffic Encrypting Keys* (TEKs) or *Key Encrypting Keys* (KEKs) to new group members after authenticating them with a unicast protocol. The GCKS may also delegate some of its functions to other entities, improving scalability.

In groups with simple security requirements, this may be the only communication required between a group member and GCKS. But if group changes need to be cryptographically enforced, further TEKs, encrypted using a KEK, may be provided to members by multicast or a more scalable protocol such as the *Logical Hierarchy of Keys* (LHK)[56] that does not require every rekey message to be sent to every group member. Alternatively, noninteractive mechanisms such as hash trees may be used to update keys[48]. Finally, group members may explicitly de-register with the GCKS using a one- or two-step message.

Three key management building blocks are being developed. The *Group Domain of Interpretation* (GDOI) builds on the *Internet Security Association Key Management Protocol* (ISAKMP)[52] to allow the creation and management of security associations for IPSec and other network or application layer protocols[46]. *Multimedia Internet Keying* (MIKEY) is targeted at real-time multimedia communications, particularly those using the Secure RTP, and can be tunneled over the *Session Initiation Protocol* (SIP)[45]. And a *Group Secure Association Key Management Protocol* (GSAKMP), along with a GSAKMP-Light profile, have also been developed[51].

Group Policy Management

The final building block defines policies such as which roles various entities may play in the group; who may hold group information such as cryptographic keys; the cryptographic algorithms used to protect group data; and proof that the creator of a given policy is authorized to do so. A group policy token is used to hold all of this information[50]. All or part of tokens can be made available to users in policy repositories or by using other out-of-band mechanisms.

Operational Deployment of Multicast

As mentioned previously, multicast seems to be difficult to deploy. One problem is that it has only recently moved from the research community (and typically implemented using tunnels) into the service community (running native IP multicast routing).

This means that debugging multicast sessions, applications, and routing is a common activity. However, because of the dynamic nature of multicast addresses and the anonymous nature of the multicast service model, debugging is somewhat more difficult than for the equivalent unicast case.

Fortunately, all current native multicast paths are at least computed from underlying unicast ones, and it is possible to use tools such as *mtrace* and *mrm* to query the underlying router system to try to figure out where things are going on. Of course, the relevant *Management Information Bases* (MIBs) need to be designed, but mere *Simple Network Management Protocol* (SNMP) access to the variables defined in these may not be enough.

Many multicast sessions are global, and not surprisingly, someone, somewhere, sometime in the session will have a problem. In a way, you only have to look at multicast as a way of sampling large pieces of the Internet at one time to see why it is difficult to understand. In fact, a research project called *Multicast-Based Inference of Network-Internal Characteristics* (MINC)[9, 57] is using that very observation to build tools of more general use.

MRM

One recent tool that has been developed to facilitate multicast monitoring and debugging is the *Multicast Reachability Monitor* (MRM)[32]. MRM consists of two parts; a MRM management station configures test senders and test receivers in multicast networks. A multicast test sender or test receiver is any server or router that supports the MRM protocol and can source or sink multicast traffic. MRM provides the ability to dynamically test particular multicast scenarios; this capability can be used for fault isolation and general monitoring of sessions.

MRM is typically used to configure MRM-capable routers as test senders and test receivers from a management station. Routers configured as test senders send multicast packets periodically to a configured multicast group at a configured rate. Routers configured as test receivers monitor traffic to a group and keep statistics that can be reported back via *RTP Control Protocol* (RTCP) packets. Test receivers can be configured to send RTCP reports when a given condition has been reached or when polled by a management station. Although the MRM protocol is simple itself, it provides powerful capabilities that can be used by future multicast debugging applications.

Research Ideas in Multicast Routing and Addressing

The seeming complexity exhibited by the full panoply of multicast protocols has led some people to develop doubts as to the eventual deployment of multicast. It is far too early to say whether these doubts are well founded. The slow pace of deployment is a symptom not just of this complexity, but also of the underlying complexity of handling growth and evolution of *any* type in such a large system as the Global Internet.

Having said that, it is worth mentioning four of the approaches that have been discussed in the Internet community recently:

- *Addressable Internet Multicast* (AIM), by Brian Levine, et al., attempts to provide explicit addressing of the multicast tree. The routers run a tree-walking algorithm to label all the branch points uniquely, and then make these labels available to end systems. This allows numerous interesting services or refinement of multicast services to be built. Of some particular interest would be the ability this service gives to end systems to do subcasting, which would be useful for some classes of reliable transport protocols.

- *Explicitly Requested Single-Source* (Express), by Hugh Holbrook et al., is aimed at optimizing multicast for a single source. The proposal includes additional features such as authentication and counting of receivers, which could be added to many other multicast protocols usefully. It is motivated by a perceived requirement from some ISPs for these additional features. Express makes use of an extended address (channel + group) to provide routing without global agreement on address assignment. A possible source of problem for AIM is the potential for unbounded growth in the size of identifiers for labeling subtree branch points.
- *Root Addressed Multicast Architecture* (RAMA), by Radia Perlman et al., is in some senses a generalization of Express type addressing, but it also requires bidirectional trees (CBT like, rather than current PIM-SM, although work on bidirectional PIM is under way too). The goal is to offer a single routing protocol for both intra- and interdomain. In fact, RAMA can be implemented by combining the address extensions proposed for Express, and two-level bidirectional PIM as an implementation of BGMP. RAMA and Express (and bidirectional PIM) require a mechanism for carrying additional information in multicast IP data packets.

  There are two critical problems for carrying this identifier that are difficult to solve in general: first, it takes new space in the IP packet, and this has to be accessed by both hosts and routers—that represents a deployment problem; secondly, in the general case, the extra field must be examined on the "fast path," in routers that have such a concept, and this takes valuable processing resources that may have to be taken away from some other forwarding task.
- *Connectionless Multicast* (CM) by Dirk Ooms, et al., is a proposal for small, very sparse groups to be implemented by carrying lists of IP unicast addresses in packets. The scheme is not simply a form of loose source routing, because it would make use of packet replication at appropriate branch points in the network. It may be well suited to IP telephony applications where a user starts with a unicast call, but then adds a third or fourth participant.
- The *L'Ecole Polytechnique Fédérale de Lausanne* (EPFL) work on *Distributed Core Multicast* (DCM) aims to address very large numbers of very small groups with mobile users, typical characteristics of mobile IP telephony users making conference or group calls.
- MIT has done some work on the use of wide-area "anycast" addresses for the core and Rendezvous Point. This results in a potential improvement in the availability of trees (and subtrees) for multicast delivery in the event of router or link outage. More importantly, it may be possible for a multicast group to survive network partitions (or lack of core reachability), a possibility that would make this an invaluable improvement to the service. It depends on the scalability of the wide-area anycast solution, which the MIT work shows is at least viable, and certainly worth more attention.

- *Yet Another Multicast* (YAM) routing protocol[30] was devised by Ken Carlberg of SAIC to address the possibility of forming different multicast trees based on some QoS metric—the idea is that IGMP is modified to provide a "one-to-many" join, and a receiver sends this with required performance parameters. Routers receiving the request over links that can provide this service respond. The receiver (sender of the one-to-many IGMP) selects the one to then commit the join to.
- *Quality of Service Sensitive Multicast Internet protoCol* (QoSMIC) is a development from YAM by Faloutsos[29] at Toronto, and slightly modifies the tree-building exercise.
- When multicast and *Multiprotocol Label Switching* (MPLS) are mentioned together, there is both confusion and surprise. MPLS can be used with multicast in two very different ways. The first method is by building multicast trees over MPLS traffic-engineered paths. Some multicast routing protocols already make use of unicast forwarding information for the construction of multicast trees. Using multicast traffic-engineered paths is simply an extension of this concept—with one caveat. Some multicast routing protocols use *Reverse Path Forwarding* (RPF) checks on incoming packets to prevent looping; this is accomplished by checking to see if the incoming interface is the "closest" to the source. With MPLS traffic engineering, RPF checks are difficult. A solution has not been presented at this time that addresses this problem.

  The second method for using multicast with MPLS is through the use of point-to-multipoint virtual circuits in much the same way as ATM point-to-multipoint virtual circuits. These are useful in cases where receivers are statically configured to a multicast address or multicast traffic is always to be delivered to a destination. Mapping dynamic memberships into a multipoint circuit has proven difficult, for example, with ATM. There are currently several Internet drafts that propose various solutions for MPLS and multicast[31].
- Several groups have been working on end system-only multicast schemes, probably most notably Carnegie-Mellon University[59].

Summary and Conclusions

In this article, we have looked at some of the newer ideas in the research and development community in the area of multicast. There is still a lot to be done to close the loop between network services, transport, and applications, but present research indicates that we will eventually achieve this goal.

IAN BROWN holds a BSc from The University of Newcastle upon Tyne and a PhD from University College London. His research has focused on network security and active networking. He is a member of the ACM, IEEE, and is a contributor to the Internet Engineering Task Force, particularly in the area of authorized emergency communications. He has also worked extensively on the social implications of technology, and is a trustee of Privacy International and advisory board member of the Foundation for Information Policy Research. His e-mail address is:
I.Brown@cs.ucl.ac.uk

BRAD CAIN is a Senior Consulting Engineer at Storigen Systems, where he contributes to product development in the areas of networking and storage technology. Prior to joining Storigen, Cain was chief scientist at Cereva Networks, where he worked on system architecture and new product development. Cain also worked at Mirror Image Internet, one of the first commercial Content Delivery Networks (CDNs), where he helped architect their content distribution system. Cain is a contributor in the IETF and IRTF in the areas of IP multicast, IP routing, MPLS, and content networking. He has published numerous papers in the areas of routing and multicast and has more than 40 patents pending in the areas of multicast, security, routing, and router architecture. Cain holds a masters and bachelors in electrical engineering from the University of Delaware.
E-mail: **Brad.Cain@storigen.com**

JON CROWCROFT is the Marconi Professor of Networked Systems at the University of Cambridge. Prior to that he was professor of networked systems at University College London (UCL) in the Computer Science Department. He is a member of the ACM, a Fellow of the British Computer Society, a Fellow of the IEE, and a Fellow of the Royal Academy of Engineering, as well as a senior member of the IEEE. He is a member of the IAB, and was general chair for ACM SIGCOMM from 1995 to 1999. He is on the editorial team for the ACM/IEEE *Transactions on Networks and Computer Communications,* as well as on the program committee for ACM SIGCOMM and IEEE Infocomm. He has published five books—the latest is *Linux TCP/IP Implementation,* published by Wiley in 2001.
E-mail: **Jon.Crowcroft@cl.cam.ac.uk**

MARK HANDLEY received his BSc in Computer Science with Electronic Engineering from University College London in 1988 and his PhD from UCL in 1997. For his PhD he studied multicast-based multimedia conferencing systems, and was technical director of the European Union funded "MICE" and "MERCI" multimedia conferencing projects. After two years working for the University of Southern California's Information Sciences Institute (ISI), he moved to Berkeley to join the new ICSI Center for Internet Research (formerly known as ACIRI). Most of his work is in the areas of scalable multimedia conferencing systems, reliable multicast protocols, multicast routing and address allocation, and network simulation and visualization. He is co-chair of the IRTF Reliable Multicast Research Group, and he previously chaired the IETF Multiparty Multimedia Session Control working group. E-mail: **mjh@icir.org**

Zero Configuration Networking

by Edgar Danielyan, Danielyan Consulting

Zero configuration networking may sound like an oxymoron to many who spend most of their time setting up and mending networks. But don't decide on a career change yet—although zero configuration networks exist and work, they don't work always and everywhere. In this article I describe the current state of the affairs in zero configuration IP networking, introduce Zeroconf, the suite of zero configuration IP protocols, and tell what they do and how they work. This article is only a brief introduction to zero configuration networking and Zeroconf, so if you are really interested in all the details, refer to the sources listed in the References section at the end of this article.

The best introduction to Zeroconf is the one from the *Zeroconf Working Group* of the *Internet Engineering Task Force* (IETF)[1]:

> "The goal of the Zero Configuration Networking (Zeroconf) is to enable networking in the absence of configuration and administration. Zero configuration networking is required for environments where administration is impractical or impossible, such as in the home or small office, embedded systems 'plugged together' as in an automobile, or to allow impromptu networks as between the devices of strangers on a train."

Essentially, to reduce network configuration to zero (or near zero) in *Internet Protocol* (IP) networks, it is necessary, inter alia, to:

- Distribute IP addresses (without a *Dynamic Host Configuration Protocol* [DHCP] server),
- Provide name resolution (without a *Domain Name System* [DNS] server),
- Find and list services (without a directory service), and
- Distribute multicast IP addresses, if necessary (without a multicast server).

These and other requirements are defined in an Internet Draft titled "Requirements for Automatic Configuration of IP Hosts" by Aidan Williams[2]. This document does not define Zeroconf protocols themselves but instead spells out the requirements that should be met to achieve effective and useful zero configuration IP networking. One of the most important requirements for any Zeroconf protocol is that it should not interfere with other protocols and it must be able to exist on the same network with other non-Zeroconf protocols and devices. Another requirement is "no less" security—Zeroconf protocols should not be less secure than existing non-Zeroconf protocols—more on this later. Although IPv6 addresses some of the requirements of zero configuration networking (such as automatic allocation of link-local addresses), other requirements have yet to be met for both IPv4 and IPv6.

Zeroconf IETF Working Group

The Zeroconf Working Group of the IETF is chaired by Erik Guttman of Sun Microsystems and Stuart Cheshire from Apple Computer, with Thomas Narten (IBM) and Erik Nordmark (Sun) serving as area directors. It was chartered in September 1999 and had its first meeting at the 46th IETF in Washington, D.C., in November 1999. Those interested in the work of Zeroconf WG may find the mailing list archive of the working group at:

`http://www.merit.edu/mail.archives/zeroconf/`

Where and When to Use Zeroconf

For a correct understanding of the applicability and usefulness of Zeroconf it is necessary to keep in mind that it is a *link-local* technology. Link-local addressing and naming are meaningful only in a particular network; link-local addresses and names are not global and are not unique globally. In this case it means that Zeroconf is intended for use in small wired or wireless local-area networks in situations and places where zero configuration is necessary. It is appropriate to use Zeroconf in such networks when there is no possibility (or it is inappropriate) to set up a working IP network using the traditional technologies such as DNS and DHCP. Zeroconf is not appropriate and should not be used in many cases, for example in:

- Medium or large networks
- Networks where a high degree of security and control is required
- Large public access networks
- Networks with low bandwidth and high latency (such as some wireless networks)

When inappropriately used, Zeroconf may bring more problems and headaches than it solves. In contrast, examples of correct and appropriate use would include:

- Home and small office networks
- Ad hoc networks at meetings and conferences (especially wireless networks)
- Two devices needing to spontaneously share or exchange information

Likewise, Zeroconf advantages from one viewpoint may become annoying problems from another. Consider, for instance, the automatic distribution and configuration of link-local IP addresses. For a home network user this is a blessing—no longer do you have to spend time creating an addressing scheme and setting the IP addresses and netmasks on devices that should just work. But for an enterprise network (especially an incorrectly configured one), sudden appearance of nodes with (yet) unfamiliar and strange (this is not your regular **`10.*`** or **`192.168.*`**) IP addresses may result in more than surprise and added workload for the network administrator.

Continuing in this manner, Multicast DNS (mDNS) that ends the misery of having to remember and type **`ftp 10.20.30.1`** every time you need to transfer files from or to your PC named Bobo and replaces it with just **`ftp bobo`** may result in strange behavior on some networks. The bottom line? Zeroconf is not a one-size-fits-all solution; it wasn't designed to be one, and will not work as one.

Zeroconf and Security

Security should occupy an important place in the minds of all networking professionals, so an introduction to zero configuration networking would be incomplete without a mention of its security position. Security goals of Zeroconf are defined in section 4, Security Considerations, of "Requirements for Automatic Configuration of IP Hosts"[2]:

"Zeroconf protocols are intended to operate in a local scope, in networks containing one or more IP subnets, and potentially in parallel with standard configured network protocols. Application protocols running on networks employing zeroconf protocols will be subject to the same sets of security issues identified for standard configured networks. Examples are: denial of service due to the unauthenticated nature of IPv4 ARP and lack of confidentiality unless IPSec-ESP, TLS, or similar is used. However, networks employing zeroconf protocols do have different security characteristics, and the subsequent sections attempt to draw out some of the implications.

Security schemes usually rely on some sort of configuration. Security mechanisms for zeroconf network protocols should be designed in keeping with the spirit of zeroconf, thus making it easy for the user to exchange keys, set policy, etc. It is preferable that a single security mechanism be employed that will allow simple configuration of all the various security parameters that may be required. Generally speaking, security mechanisms in IETF protocols are mandatory to implement. A particular implementation might permit a network administrator to turn off a particular security mechanism operationally. However, implementations should be "secure out of the box" and have a safe default configuration.

Zeroconf protocols MUST NOT be any less secure than related current IETF-Standard protocols. This consideration overrides the goal of allowing systems to obtain configuration automatically. Security threats to be considered iclude both active attacks (e.g. denial of service) and passive attacks (e.g. eavesdropping). Protocols that require confidentiality and/or integrity should include integrated confidentiality and/or integrity mechanisms or should specify the use of existing standards-track security mechanisms (e.g. TLS (RFC 2246), ESP (RFC 1827), AH (RFC 2402) appropriate to the threat."

Although this document does not address each and every aspect of security issues with Zeroconf, it sets requirements for Zeroconf protocols. As is the case with traditional IPv4 and IPv6, use of such techniques as *IP Security Architecture* (IPSec) or *Transport Layer Security* (TLS) may be appropriate in some cases. However, the nonstatic (or one may say nondurable) nature of both IP addresses and names in Zeroconf environment may pose a problem for IPSec and TLS deployment.

Dynamic Configuration of IPv4 Link-Local Addresses

Generally speaking, the first requirement that should be fulfilled before any useful IP communication can occur are the IP addresses of sender and recipient. The IP addresses are usually either assigned and set manually or provided by some other means such as DHCP or the *Point-to-Point Protocol* (PPP). However, neither of these is possible in zero configuration networks. Therefore, an automatic mechanism for dynamic configuration of IP addresses without any manual intervention or dependence on third-party service (that is, DHCP) is necessary. This mechanism already exists in IPv6 but not in IPv4. In "Dynamic Configuration of IPv4 Link-Local Addresses"[3], Stuart Cheshire, Bernard Aboba, and Erik Guttman describe a method that may be used in IPv4 networks to automatically assign IPv4 addresses valid for local communication on a particular interface. A special network **`169.254/16`** is reserved with the *Internet Assigned Numbers Authority* (IANA) for this purpose. It is necessary to highlight that **`169.254/16`** addresses are reserved for link-local use only. The document also addresses such issues as support for multiple addresses and multiple interfaces, continuous address conflict detection, effects of joining previously not interconnected networks, and other considerations.

IPv4 Address Conflict Detection

Address conflicts in IP networks are annoying problems that (needlessly) take time and effort to detect and rectify, so a separate document on address conflict detection was deemed necessary. "IPv4 Address Conflict Detection"[4] by Stuart Cheshire presents two things: first, a way to prevent this unfortunate situation of conflicting IP addresses from happening, and second, a way to detect address conflicts if they do happen even after all the precautions. Both of these are accomplished using the *Address Resolution Protocol* (ARP). Interestingly, in the Security Considerations section of the document the author states:

> "The ARP protocol [RFC 826] is insecure. A malicious host may send fraudulent ARP packets on the network, interfering with the correct operation of other hosts. For example, it is easy for a host to answer all ARP requests with responses giving its own hardware address, thereby claiming ownership of every address on the network.
>
> This specification makes this existing ARP vulnerability no worse, and in some ways makes it better: Instead of failing silently with no indication why, hosts implementing this specification are required to either attempt to reconfigure automatically, or if not that, at least inform the human user of what is happening."

Although some may argue about the question of whether or not it is effective, appropriate, and useful to "inform the human user" in this case, this solution nevertheless follows the principle of at least not worsening the current security situation of an existing protocol.

Zeroconf Multicast Address Allocation Protocol

The *Zeroconf Multicast Address Allocation Protocol* (ZMAAP) defined in[5] specifies a method for peer-to-peer allocation of *multicast addresses without a multicast* (MADCAP) server in small zero configuration networks. The word "small" is important here because ZMAAP is not scalable beyond small networks (and is not designed to be).

Multicast DNS

"Performing DNS queries via IP Multicast"[6] by Stuart Cheshire suggests some very useful ideas on how to use mDNS with maximum benefit and minimum hassle in zero configuration networks. In my opinion, the best thing about this proposal is that it does not require any changes to the DNS protocol (messages, resource record types, etc.) itself. Instead it concentrates on the use of multicast for name resolution in environments where no DNS servers exist (and where one would not reasonably expect them to). The goal is to have a working name resolution service without name servers. The document proposes to use **`local.arpa`** (although the exact choice of this special domain is not the goal of this document) as the link-local domain (like the **`169.254/16`** network for dynamic allocation of IPv4 link-local addresses described earlier in this article). For reverse address resolution, **`254.169.in-addr.arpa`** is also link-local. The multicast address **`224.0.0.251`** that is used for mDNS queries is registered by the IANA for this purpose. No delegation is performed within mDNS domain **`local.arpa`**. There is also no *Start of Authority* (SOA) record for the mDNS domain because of the nature of zero configuration networks where it is intended to be used—in particular, there is no mailbox responsible for the zone. Likewise, zone transfers are not applicable with mDNS zones. To summarize, any local link has its own local and private **`local.arpa`** and **`254 254.169.in-addr.arpa`** zones, which have only link-local significance in the particular Zeroconf network.

DNS Service Discovery

Like the multicast DNS solution described previously, the *DNS Service Discovery* (DNS-SD)[7] does not require any changes to the existing DNS protocol; thus it is completely compatible with the existing DNS server and client software.

What DNS-SD proposes is a naming scheme for DNS *Resource Records* (RRs) to allow for service discovery using the existing DNS—either the traditional or multicast DNS described in the previous paragraph. DNS-SD uses the SRV and PTR resource records to provide the required functionality. To cite from [7]:

"Service discovery requires a central aggregation server. DNS already has one: It's called a DNS server.

Service discovery requires a service registration protocol. DNS already has one: It's called DNS Dynamic Update.

Service discovery requires a security model. DNS already has one: It's called DNSSEC.

Service discovery requires a query protocol. DNS already has one: It's called DNS."

It is necessary to note that DNS-SD is compatible with mDNS and vice versa, but neither requires the other one to function. However, it is practical to use mDNS for service discovery (using DNS-SD) to have a single protocol and interface and not have to implement another protocol just for service discovery.

Industry Support

Any new technology needs industry support to succeed, and Zeroconf is no exception. Several major vendors have announced plans to support or already support Zeroconf in their products, including Apple, Epson, Hewlett-Packard, Lexmark, Philips, Canon, Xerox, Sybase, and World-Book. One can expect that more companies will Zeroconf-enable their products as the technology itself matures and hopefully becomes standardized and widespread.

Rendezvous

Rendezvous is Apple Computer's implementation of Zeroconf in its Darwin 6 and Mac OS X 10.2 ("Jaguar") operating systems. Apple has stated its full support for the Zeroconf and intent to completely replace the aging AppleTalk with Zeroconf-enabled Macs, without sacrificing the ease of use and transparency to end users provided by AppleTalk networks. A good example of Zeroconf's use in OS X would be the iChat instant messaging (IM) client, which comes with the Version 10.2 of Mac OS X. It works not only with *AOL Instant Messenger* (AIM) and Mac networks but may also be used between Zeroconf-enabled Macs in a Zeroconf network.

Coupled with Apple's implementation of IEEE 802.11b ("WiFi") in ad hoc mode, it permits a wireless zero configuration network that just works without any configuration or additional hardware or software.

Apple has also made the source code for the mDNS Responder, a part of Rendezvous implementing mDNS, freely available through the Darwin Open Source Project. Mac OS X software developers are encouraged to use Zeroconf, and there are documentation and application examples to facilitate this. More information about Rendezvous and Zeroconf on Macs is available from Apple's Web sites[9].

Summary

With computers and computer networks becoming more and more complex and sophisticated, some people (including the author of this article) believe that care should be taken by those in the know not to create more problems than we solve using these computers and networks. Yes, we want more features—but we also need to remember that most users of these features do not have doctorates in computer science and (surprise, surprise) don't even wish to. Zero configuration networking would probably help in this regard, minimizing and even eliminating in some cases the need to configure and administer small networks. Let me conclude by quoting once more from the Zeroconf Working Group:

> "It is important to understand that the purpose of Zeroconf is not solely to make current personal computer networking easier to use, though this is certainly a useful benefit. The long-term goal of Zeroconf is to enable the creation of entirely new kinds of networked products, products that today would simply not be commercially viable because of the inconvenience and support costs involved in setting up, configuring, and maintaining a network to allow them to operate."

Book Reviews

Ruling the Root

Ruling the Root: Internet Governance and the Taming of Cyberspace, by Milton L. Mueller, ISBN 0-262-13412-8, The MIT Press, 2002, **http://mitpress.mit.edu**

> "WASHINGTON, Apr. 1 /Governance Newswire/ — The organizations that create street names, assign addresses, and assign telephone numbers have issued a joint announcement: Henceforth any conversation not conducted in Bahasa Malayu will result in termination of the relevant address or telephone number assignment."

The above bit of fiction is not pure silliness. Fear of equivalent, Internet-related excesses is the essence of Milton Mueller's book, *Ruling the Root*. The Syracuse University professor believes that administration of Internet addresses and domain names provides a fulcrum for overall Internet governance. He says they create a "political economy" vulnerable to serious abuse. Domain name administration is equated with control over Internet content, because, "a domain name record [is] very much like an Internet driver's license" as if it provides permission to use the Net, and even authorizes the locations one may visit.

Organization

The book covers both IP address and domain name administration. The material on IP addresses is thin, perhaps because it is a well-managed area without significant controversy. This is in marked contrast to the recent history of debate on *Domain Name System* (DNS) oversight. So it might have been instructive to see a comparison between the two administrative models, beyond simply noting that domain names can be interesting.

Discussion covers Internet technology, the history and politics of DNS and IP administrative management structure, and the intellectual property aspects of name assignment conflicts. Mueller suggests a three-layer hierarchy: technical, economic, and policy. What is missing from this "architecture" and from the entire book is any concern for the pragmatic details of administration and operation of these global, mission-critical services. Yet such tasks are difficult to perform well, as Network Solutions repeatedly demonstrated over the years, by losing registrations and corrupting critical data files; and the effects of problems are large.

When *Star Trek's* Captain Picard commands, "make it so," we know that he fully appreciates the challenges in implementing his directive. However, for *Ruling the Root,* policy development is not concerned with the operational complexities.

Not surprisingly, the book often demonstrates a misunderstanding of constraints inherent in DNS technology, although the tutorial on basic Internet technology is adequate, in spite of making the common error about the "T" in TCP/IP.[1]

Differing Opinions

Other reviewers of the book have called it well written, insightful, and nuanced. Indeed the discussion of history that is fully documented and involves simple, clear, objective facts is quite good. The rest of the time Mueller presents biased and unfounded descriptions of Internet governance, motives, and decisions, while failing to distinguish between what is fact and what is his opinion.

Ruling the Root sees adversaries, conspiracies, and threats, and permits no balancing sense of diverse collaboration, constructive criticism, or productive compromise. The technical community is somewhat less suspect, but is deprecated with the usual cliche about its naivete. So Mueller misses the essential point that techies designed, built, operated, and grew this robust, survivable, equitable system for global operations and service governance.

Professor Mueller's treatment of the dominant DNS registry, *Network Solutions* (NSI), now VeriSign, is curiously superficial and soft. NSI benefited spectacularly from the National Science Foundation's decision to permit charging for domain names, and from the policies and delays in the formation of the *Internet Corporation for Assigned Names and Numbers* (ICANN), as well as ICANN's distraction away from its intended registry oversight function and toward abstract debates about Internet governance. Yet the book does not consider NSI's role in ICANN-related political processes.

Mueller fails to understand the history of the organization that managed the DNS from its inception, the *Internet Assigned Numbers Authority* (IANA) and Jon Postel's role in running it. IANA is incorrectly represented as a simple operations arm of the U.S. Government. The grass-roots basis for its real legitimacy is missed. Its policy role is missed. Its collaborative processes are denied. For example, Mueller tells us that the description of IANA in RFC 1083, published in 1988 meant, "a new world was being defined by the RFC." In reality it was simply documenting established practice, as is typical for operations RFCs.

Validation

Mueller's substantiation of his analyses is also problematic. The book must be read with careful attention to the actual authority of each source. Goals and agendas are often misstated. For example, he characterizes the pre-ICANN *International Forum for the White Paper* (IFWP) as "the real arena for arriving at a decision [about the details of the new organization]." Its actual goal was simply to be a forum for discussion. Discussion, not decision-making.[2]

The book claims that the pre-ICANN *International Ad Hoc Committee* (IAHC) was formed "to develop and implement a blueprint for a global governance structure for the domain name system." In fact, the IAHC was formed for "specifying and implementing policies and procedures relating to iTLDs (international top-level domains, now called 'generic' TLDs, or gTLDs)."[3] He claims, "They had asserted that the root was theirs to dispose of." To the contrary, the IAHC was explicitly subordinate to IANA, and had nothing at all to do with management of the DNS root or any non-gTLD part of the DNS. Interestingly, the endnote Mueller offers as substantiation disproves his characterization.

Ruling the Root is loaded with endnotes—27 pages of small print. However, even the formal citations are problematic. Note #55 cites a newspaper article as a primary source, as if it were definitive proof the person discussed in the article held a specific opinion. Mueller's Note #45 claims to substantiate that, "Postel himself... admitted...it is unclear who actually controls the name space." Yet the note is for *Internet Architecture Board* (IAB) minutes. Attributing it to Postel was a fabrication.

Back-room, deal-making, conspiracy explanations are offered without substantiation. Of changes to *Internet Engineering Task Force* (IETF) management, Mueller states: "The most important reason the IETF didn't institute voting was that Jon Postel and several other senior figures vowed that they would refuse to run for office." Postel never made such a vow, and the process to effect these IETF changes did not experience any such attempts at influence. Of Postel's instructing some root servers to retrieve copies of the DNS root from a non-NSI master, Mueller claims that Postel was "apparently concerned about the direction U.S. policy was taking."

No substantiation is offered, because the claim is false. Postel and others were concerned about NSI's reaction to its own loss of control. The switch was intended to see what it would take to move NSI out of the hierarchy. These are not small matters of nuance. They show a pattern of misrepresentation.

The Author

Professor Mueller's credibility would have been aided by disclosing his own affiliations. The only ICANN constituency (the Non Commercial Domain Name Holders Constituency) claiming to represent the non-commercial world focuses on the civil society concerns that dominate the public debate about ICANN. Professor Mueller's discussion of the group is quite thin and does not disclose the fact that he held a dominant management position in it. In his criticism of dispute-resolution activities, he neglects to mention that he is a paid arbitration panelist.

An important book should be read because it has factual detail and thoughtful insight. *Ruling the Root* is, instead, important because it so thoroughly embodies the difficulties that have emerged in discussing Internet policy. Because so many people take *Ruling the Root* seriously, it should be read. However, the serious problems of the book encourage borrowing it, rather than buying a copy. Based on the pattern noted in this review, a thorough audit of those problems would be appropriate for the relevant Syracuse University academic ethics committee.

http://www.ifwp.org/

[3] **http://www.iahc.org/iahc-charter.html**

[4] Factual claims in the review that do not have citations are based on the reviewer's direct experience. Dave Crocker wrote the first Internet standard for domain name syntax (RFC 822). He also was the IETF area director for initial work on DNS security. More recently he was one of Jon Postel's appointees to the IAHC. He naively thought that its work should be conducted in the manner that had been typical for Internet administration. So the last few years of charged, global politicization have been an education. He must also note that he was once Jon Postel's officemate.

High-Speed Networks and Internets

High-Speed Networks and Internets: Performance and Quality of Service, 2nd ed., by William Stallings, ISBN 0-13-032221-0, Prentice Hall, 2002. **http://www.prenhall.com/stallings**

This thoroughly updated classic covers topics of traffic engineering, queuing, and traffic modeling. The book gives a complete look around the protocols of the next generation: *Resource Reservation Protocol* (RSVP), *Multiprotocol Label Switching* (MPLS), and *Real-Time Transport Protocol* (RTP). It gives the keys to understand the way Frame Relay, TCP, and ATM react to congestion and flow control. The book also deals with new trends and standards that will lead the telecommunications industry in the following years. A very useful book, from the same author of traditional titles such as: Data Communications, Cryptography, Computer Architecture, and many more.

Organization

High-Speed Networks is divided into seven parts. The first one discusses the basic background needed to understand the rest of the book. Following the introduction, the second chapter goes on with the classical: the *Open System Interconnection* (OSI) model and the TCP/IP suite.

Part II explains packet-switching technologies in detail. The forth chapter explains the architecture of Frame Relay, and the next one focuses on ATM, including its operation and the adaptation layers. Chapter 6 works on high speed LANs, covering Fast Ethernet and Gigabit Ethernet, with the different media supported by each.

The third part is one of the most important; chapter 7 presents an overview of probability and stochastic processes. Although it is a brief one, it is useful to make revision of some concepts. The next chapter works on queuing analysis, introducing the basic elements of a queuing model. It explains the topics with plenty of examples: M/M/1, multiserver queues, and networks of queues, presenting all the formulas. Chapter 9 is dedicated to self-similar traffic. As recent studies indicate, traffic on high speed networks does not have the characteristics needed for the queuing theory. It introduces and explains the concept of self-similarity. Then the author applies this concept to data traffic analysis and examines performance implications. Based on papers on this subject, Stallings explains this new approach to traffic modeling not analyzed before.

The forth part focuses on another main topic: congestion and traffic management. Chapter 10 explains the effects of congestion and the different ways to control and avoid it. In the following chapter the author discusses control mechanisms at the link level. He examines different ways used by protocols to handle flow control: *Stop and Wait, Sliding Window,* and *Go back N-ARQ*. An analysis of the performance gained by using *Automatic Repeat Request* (ARQ) techniques follows.

These chapters give a detailed description of the different ways that communications can be handled. Chapter 12 focuses on transport-level traffic management. It explains TCP flow control in detail, including the retransmission strategy. The way TCP avoids congestion is discussed thoroughly. The next chapter continues with congestion control in ATM networks. The framework for traffic control is explained in detail, with sections dedicated to *Available-Bit-Rate* (ABR) and *Guaranteed-Frame-Rate* (GFR) traffic management.

The next part of the book is about Internet routing. Chapter 14 presents the algorithms used to compute the minimum path, and introduces some elementary concepts in graph theory. Later the author concentrates on Interior routing protocols, analyzing the *Routing Information Protocol* (RIP) and *Open Shortest Path First* (OSPF), the most important ones. Next the book discusses exterior routing protocols and multicast. The author describes in a simple way these addressing schemes and the related protocols.

The following section is dedicated to *Quality of Service* (QoS) in IP networks. The first chapter discusses integrated services, with coverage of queuing disciplines such as *Weighted Fair Queuing* (WFQ). A review of the Differentiated Services architecture follows.

After discussing the concepts, the author examines the protocols that support QoS: RSVP, MPLS, and RTP. He explains the philosophy behind each protocol, its characteristics, and its implementation.

In the final part of the book, the author changes the subject to compression. In Chapter 19 he presents an overview of information theory, discussing typical areas such as entropy. The next chapter continues with loss-less compression, facsimile compression, and others. It discusses the Lempel-Ziv algorithm used in PKZIP. The final chapter reviews lossy compression, explaining the discrete cosine transform, a key component of the *Joint Photographics Expert Group* (JPEG) and *Motion Picture Experts Group* (MPEG) standards.

Two very interesting appendices end the book: one for Internet standards and the standardization process and the other one dedicated to sockets, containing source code. Although the book is not dedicated to programming, the inclusion of TCP sockets can be useful to understand its implementation.

A book worth reading

We are facing an essential book for networking professionals, designers, and engineers. It covers unusual topics such as self-similar traffic and data compression. It is the basement for the design of any high speed network. As Internet traffic continues to grow, the optimization of network resources becomes a critical topic. Also, more and more voice traffic is carried over packet networks, congestion being one of its worst enemies. The time-sensitive traffic needs attention, and this book provides the tools to manage it.

In addition to its solid coverage of topics, the book has plenty of bibliography and many links to the principal sites for each chapter. With no doubt this is a very useful book, from the well-known technical author William Stallings.

Would You Like to Review a Book for IPJ?

We receive numerous books on computer networking from all the major publishers. If you've got a specific book you are interested in reviewing, please contact us and we will make sure a copy is mailed to you. The book is yours to keep if you send us a review. We accept reviews of new titles, as well as some of the "networking classics." Contact us at **ipj@cisco.com** for more information.

Letters to the Editor

ENUM

Ole,

As the co-chair of the ENUM work group in the IETF, I was delighted with Geoff Huston's article. (*The Internet Protocol Journal,* Volume 5, No. 2, June 2002, page 13).

I would like to point out and clarify several other issues raised by the Letters to the Editor published in the subsequent issue.

First, as a practical matter though the North American Numbering Plan uses a single country code "1," there will not be a single administration of ENUM within "1." The agreements between the IAB and the ITU on the administration of **e164.arpa** clearly indicate that these resources will be administered on a nation-state basis.
www.iab.org/DOCUMENTS/enum-pr.html
www.iab.org/DOCUMENTS/sg2-liaison-e164-sep-02.html

The United States, Canada, Bermuda, and the 18 countries of the NANP will be free to administer their numbering resources as they so choose through the use of 1 + NPA (area codes) zones within the root of **e164.arpa**.

Dr. Deleuze writes, "E.164 numbers are really telephone addresses. They are tied to telephone network topology and are surely not user friendly. There are no user-friendly names in the telephone system."

In fact, this is not exactly correct either. Since the advent of Number Portability by several national telephone administrations, including the United States, telephone numbers are no longer tied to the underlying network or routing structure of the PSTN. Actual routing of phone calls in the United States is done on Local Routing Numbers for all landline calls and, beginning in November of 2003, for wireless calls as well.

Phone numbers even now are essentially names, much like domain names in the Internet. In the United States, phone numbers can be taken or "ported" to any wireline service provider within proscribed geographic boundaries, in 2003 between wireless service providers and from wireline to wireless providers as well.

I partially take issue with Dr. Deleuze's thought that telephone numbers are not "user-friendly." Phone numbers are readily identifiable, easy to use, and are not tied to culture or language, problems we have not yet solved with domain names.

—Richard Shockey, NeuStar Inc.
rich.shockey@NeuStar.com

Visitor Networks

Dear Editor,

The September 2002 issue of IPJ featured a very interesting, comprehensive article on visitor networks. One aspect I found not mentioned, however, is the danger of users in such scenarios falling victim to fake visitor gateways. In public wireless hot spots, as they are increasingly being setup at numerous locations these days, attackers could employ their own mobile WLAN device to direct visitors trying to log on to the hot spot to their own fake login page, enabling them to easily collect their login details such as credit card information. Using encryption does not help here as long as the gateway does not need to authenticate itself to the customer's mobile device. The average user should not have a chance to realize whether he or she is connected to a legitimate or a fake login page—if he or she is aware of that potential danger at all. Given the fact that all such an attack would need, apart from readily available equipment such as a portable computer with a WLAN card, is some small piece of appropriate software and that it would be quite difficult to detect,that kind of threat unfortunately should be quite realistic in such environments.

—Dr. Georg Schwarz
Detecon International GmbH, Berlin, Germany
Georg.Schwarz@detecon.com

The author responds:

This is a good point that was not discussed in the article. There are actually at least three cases that visitors need to worry about. The first is, as you mentioned, that the service provider is not who they say they are. This can be dealt with by using SSL certificates assuming the visitor is conscious of the URL that he/she is being directed to and knows that it belongs to the real service provider. If the visitor has no idea who is a reasonable service provider, this is a different class of problem, very similar to what has happened with public telephones that accept standard calling and credit cards—someone makes a call, receives the service but then gets charged an outrageous rate. The third case is a man-in-the-middle attack or passive snooping where someone with a laptop as you describe is able to grab traffic and gather passwords.

Some basic advice to visitors is for services that require subscription, although possibly inconvenient, never subscribe on a potentially compromised connection. That way, only the service provider-assigned username and password is compromised, instead of more sensitive personal information related to the account. Connections using 802.1x authentication with EAP-TLS provide mutual authentication and are in the long run, a better solution than redirection of web pages. No matter what kind of security one has, inevitably there will be legally legitimate providers that will take advantage of visitors and in that case it's just "buyer beware."

—Dory Leifer
leifer@del.com

Wireless Security

Hi Ole,

Again, I found the latest issue of IPJ quite enlightening and useful. However, I do have one comment regarding the article by Greg Scholz on "An Architecture for Securing Wireless Networks." Although the use of source IP addresses to provide policy group membership on the firewall works in most cases, some client OSs and some IPSec VPN boxes allow the source address (even if it is the endpoint address of the tunnel, not the "real" address of the host) to be changed,provided the source address of the enciphered traffic does not change. This would allow users to change the policy group they belong to. A better solution is to use a VPN box that can associate groups of IPSec tunnels to VLANs. Then the firewall could be configured to allow policy group membership based on VLANs. This takes all determination of policy group membership off the client host and places it in the domain of trust of the VPN and firewall boxes.

From The Editor

Even the most carefully designed and operated IP network is subject to any number of performance problems ranging from overloaded links and mis-configured routers to server failures. For these situations, the network manager has several diagnostic tools as options. Geoff Huston gives us an overview in an article entitled "Measuring IP Network Performance."

Voice over IP (VoIP) is an emerging application, as well as a rapidly growing market. Use of the corporate network or the Internet at large to carry telephone traffic has many advantages, not the least economic ones. A successful VoIP network must not only support IP-based telephones, but also provide a means of seamlessly integrating the IP-based network with traditional telephone networks. At the core of VoIP lies the *Session Initiation Protocol* (SIP) and a few related protocols. Bill Stallings describes SIP in our second article.

Book reviews published in *The Internet Protocol Journal* can rarely be characterized as "controversial." However, when the book in question deals with ICANN, it is perhaps not surprising that strong opinions emerge. Thus, following the review of *Ruling the Root* in our last issue, we received a letter from the author that is included in our "Letters to the Editor" section (along with a response from the book reviewer). I would like to take this opportunity to remind our readers that book reviews do represent the *opinion* of the reviewer and should be read in that light.

Our online subscription system has been up and running for a couple of months. Please give it a try at: **www.cisco.com/ipj**.

ole@cisco.com

Measuring IP Network Performance

by Geoff Huston, Telstra

If you are involved in the operation of an IP network, a question you may hear is: "How *good* is your network?" Or, to put it another way, how can you measure and monitor the quality of the service that you are offering to your customers? And how can your customers monitor the quality of the service you provide to them?

These questions have been lurking behind many public and enterprise IP networks for many years now. With the increasing levels of deployment of various forms of high-speed (or broadband) services within today's Internet there is new impetus to find some usable answers that allow both providers and users to place some objective benchmarks against the service offerings. With the lift in access speed with broadband services, there is an associated expectation on the part of the end user or service customer about the performance of the Internet service. It should be "better" in some fashion, where "better" relates to the performance of the network and the service profile that is offered to network applications. And not only is there an expectation of "better" performance, it should be measurable. This article looks at network performance and explores its definition and measurement.

A Functional Definition of Network Performance

An informal functional approach to a definition of network performance is measuring the speed of the network. How fast is the network? Or, what is the elapsed time for a particular network transaction? Or, how quickly can I download a data file? This measurement of time for a network transaction to complete certainly relates to the speed of the network, and speed is a good network performance benchmark, but is speed everything?

When looking at the broad spectrum of performance, the answer is that speed is not everything. The ability of a network to support transactions that include the transfer of large volumes of data, as well as supporting a large number of simultaneous transactions, is also part of the overall picture of network load and hence of network performance. But large data sets is not everything in performance. Consideration should also be given to the class of network applications where the data is implicitly clocked according to some external clock source. Such real-time applications include interactive voice and video, and their performance requirements include the total delay between the end points, or latency, as well as the small-scale variation of this latency, or *jitter*. Such performance measurements also include the ratio of discarded packets to the total number of packets sent, or loss rate, as well as the extent to which a sequence of packets is reordered within the network, or even duplicated by the network. Taken together, this set of performance factors can be considered as a form of the amount of distortion of the original real-time signal.

Accordingly, a functional description of network performance encompasses a description of speed, capacity, and distortion of transactions that are carried across the network. This informal description of what

constitutes network performance certainly feels to be on the correct path, given that if one knew the latency, available bandwidth, loss, and jitter rates and packet reorder probability as a profile of network performance between two network end points, as well as the characteristics of the network transaction, it is possible to make a reasonable prediction relating to the performance of the transaction.

Taking this informal definition, the next step is to create a more rigorous framework for measuring performance. For any single network path between an entry and egress point, it is possible to measure the path latency, available peak bandwidth, loss rates, jitter profile, and reorder probability. But there is a difference between a description of the performance of a particular path across a network and the performance of the network as an aggregate entity. Given a set of per-path performance measurements, how can you construct a view of the performance of the network? A common methodology is to take a relatively complete set of path measurements across a network and then combine them to create an average metric. Although this accomplishes a useful reduction in the size of the data, there is also a loss of information. The average network performance measurements have little relationship to the performance of any individual path.

There are various ways to improve this loss of information, including weighting the individual path measurements by the amount of traffic passed along the path. Such techniques are indeed to ensure that paths that use far-flung network outliers that carry relatively low volumes of traffic have a much lower impact on the overall network performance metric than the major network transit paths.

Measuring Network Performance

Given these performance indicators, the next step is to determine how these indicators may be measured, and how the resulting measurements can be meaningfully interpreted. At this point it is useful to look at numerous popular network management and measurement tools and examine their ability to provide useful measurements. There are two basic approaches to this task; one is to collect management information from the active elements of the network using a management protocol, and from this information make some inferences about network performance. This can be termed a *passive approach* to performance measurement, in that the approach attempts to measure the performance of the network without disturbing its operation. The second approach is to use an active approach and inject test traffic into the network and measure its performance in some fashion, and relate the performance of the test traffic to the performance of the network in carrying the normal payload.

Measuring Performance with SNMP

In IP networks the ubiquitous network management tool is the *Simple Network Management Protocol* (SNMP). There is no doubt that SNMP can provide a wealth of data about the operational status of each management network element, but can it tell you anything about the overall network performance?

The operation of SNMP is a *polling* operation, where a management station directs periodic polls to various managed elements and collects the responses. These responses are used to update a view of the operating status of the network.

The most basic tool for measuring network performance is the periodic measurement of the interface byte counters. Such measurements can provide a picture of the current traffic levels on the network link, and when related to the total capacity of the link, the relative link loading level can be provided. As a performance indicator this relative link loading level can provide some indication of link performance, in that a relatively lightly loaded link (such as a load of 5 to 10 percent of total available capacity) would normally indicate a link that has no significant performance implications, whereas a link operating at 100 percent of total available capacity would likely be experiencing high levels of packet drop, queuing delay, and potentially a high jitter level. (Figure 1) In between these two extremes there are performance implications of increasing the load. Of course it should be noted that the characteristics of the link have a bearing on the interpretation of the load levels, and a low-latency 10-Gbps link operating at 90-percent load will have very significantly lower levels of performance degradation than a 2-Mbps high-latency link under the same 90-percent load. (Figure 2)

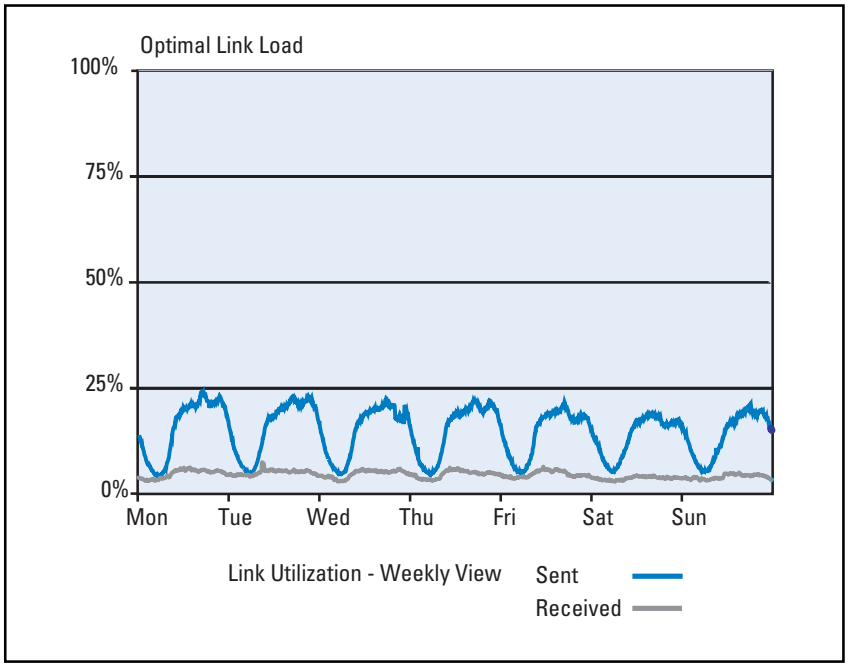

Figure 1a: Relative Link Loading – An Optimally Loaded Link

Figure 1b: Relative Link Loading – A Maximally Loaded Link

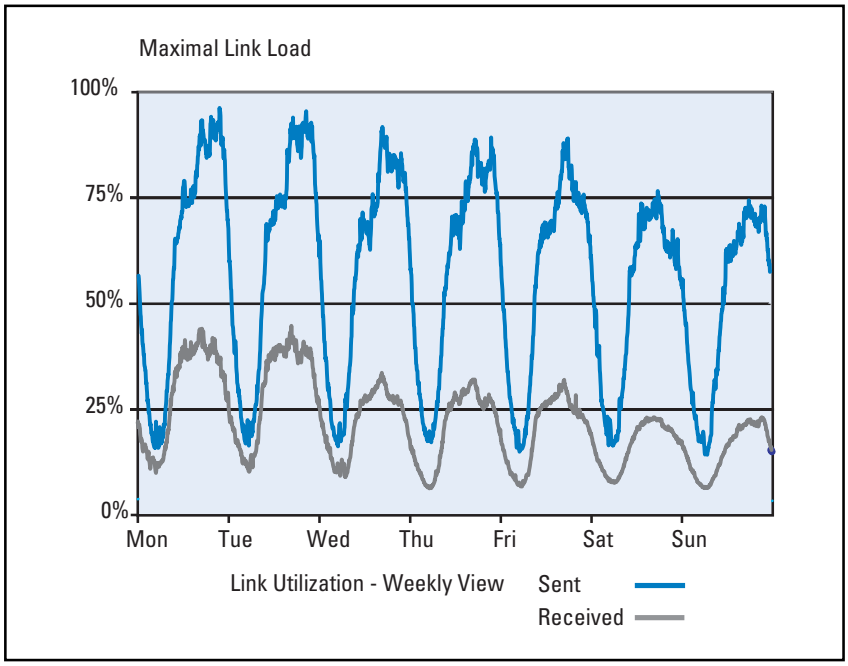

Figure 1c: Relative Link Loading – Highly Degraded Link

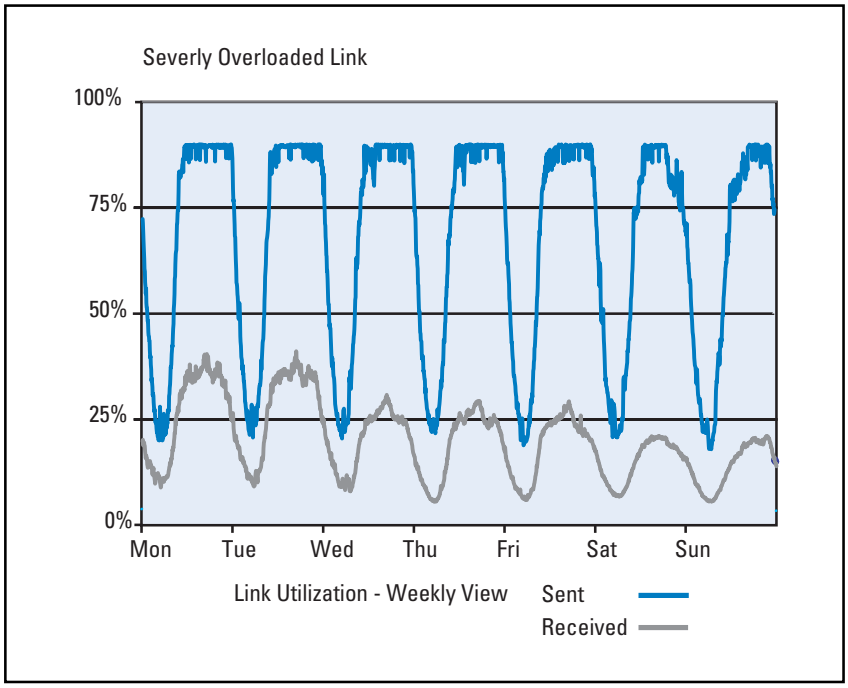

Figure 2: Queuing Delay Simulation (David Meyer, Sprint, November 2002)

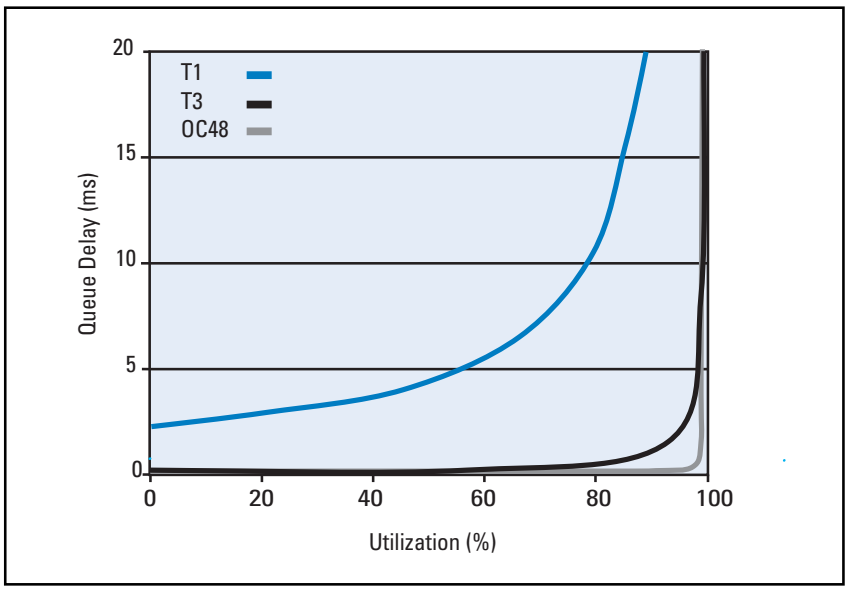


Relative traffic load on each link can be complemented by measurement of performance-related SNMP counters. A management system can poll each active network element to retrieve the number of packets dropped for each interface, and the number of packets successfully forwarded. From these two data items, the relative drop proportion of packets can be calculated on an element-by-element and potentially a link-by-link basis, and a series of element measures can provide a per-path drop proportion by combining the individual packet-forwarding measurements for the interfaces on the path.

Because some count of relative packet drop rate can be gathered from each network element, with the additional input of the current forwarding state of the network it is possible to predict the path a packet will take through the network, and hence estimate the path probability of drop. However, this information is still well short of being a reliable measurement of service performance.

Queuing delay is somewhat more challenging to measure on an element-by-element basis using element polling with SNMP. In theory, the polling system could use a rapid sequence of polling the output queue length of a router and estimating the queuing delay based on an average packet size estimate, together with the knowledge of the available output capacity. Of course, such a measurement methodology assumes a simple *first-in, first-out* (FIFO) queuing discipline, a queue size that varies slowly over time, and slow link speeds. Such assumptions are rarely valid in today's IP networks. As the link speed increases, the queue size may oscillate with a relatively high frequency as a function of both the number and capacity of the input systems and of the capacity of the output system. In general, queuing delay is not easily measured using network element polling.

There is no ready way for a polling mechanism to detect and count the incidence of reordered packets. Packet reordering occurs in many situations, including the use of parallel switching fabrics within a single network element and the use of parallel links between routers.

IP routers are not typically designed to detect, let alone correct, packet reordering and because they do not detect this condition, they cannot report on the incidence of reordering via SNMP polling.

The generic approach of network management polling systems is that the polling agent, the network management station, is configured with an internal model of the network; status information, gathered through element polling, is integrated to the network model. The correlation of the status of the model to the status of the network itself is intended to be accurate enough to allow operational anomalies in the network to be recognized and flagged. The challenge is that a sequence of snapshots of element status values cannot readily be reconstructed into a comprehensive view of the performance of the network as an entire system, or even as a collection of edge-to-edge paths. Measurement techniques using polling and modeling can track the performance of the individual elements of the network, but they cannot track per-path service levels across the network. The network-element polling approach can indicate whether or not each network element is operating within the configured operational parameters, and alert the network operator when there are local anomalies to this condition. But such a view is best described as *network centric,* rather than service centric. An implicit assumption is that if the network is operating within the configured parameters, then all service-level commitments are being met. This assumption may not be well founded.

The complementary approach to performance instrumentation of network elements is active network probing. This requires the injection of marked packets into the data stream; collection of the packets at a later time; and correlation of the entry and exit packets to infer some information regarding delay, drop, and fragmentation conditions for the path traversed by the packet. The most common probe tools in the network today are *ping* and *traceroute*.

Measuring Performance with Ping

The best known, and most widely used active measurement tool is *ping*. Ping is a very simple tool: a sender generates an *Internet Control Message Protocol* (ICMP) echo request packet, and directs it to a target system. As the packet is sent, the sender starts a timer. The target system simply reverses the ICMP headers and sends the packet back to the sender as an ICMP echo reply. When the packet arrives at the original sender's system, the timer is halted and the elapsed time is reported. An example ping output is shown in Figure 3.

Figure 3: Example Ping Report

```
% ping www.iab.org
PING www.iab.org (132.151.6.25): 56 data bytes
64 bytes from 132.151.6.25: icmp_seq=0 ttl=44 time=254.409 ms
64 bytes from 132.151.6.25: icmp_seq=1 ttl=44 time=254.197 ms
64 bytes from 132.151.6.25: icmp_seq=2 ttl=44 time=255.238 ms
64 bytes from 132.151.6.25: icmp_seq=3 ttl=44 time=255.874 ms
--- www.iab.org ping statistics ---
4 packets transmitted, 4 packets received, 0% packet loss
round-trip min/avg/max/stddev = 254.197/254.930/255.874/0.670 ms
```

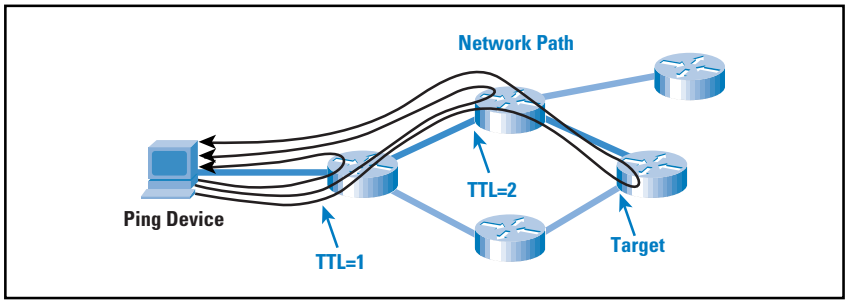
This simple active sampling technique can reveal a wealth of information. A ping response indicates that the target host is connected to the network, is reachable from the query agent, and is in a sufficiently functional state to respond to the ping packet. In itself, this response is useful information, indicating that a functional network path to the target host exists. Failure to respond is not so informative because it cannot be reliably inferred that the target host is not available. The ping packet, or perhaps its response, may have been discarded within the network because of transient congestion, or the network may not have a path to the target host, or the network may not have a path back to the ping sending host, or there may be some form of firewall in the end-to-end path that blocks the ICMP packet from being delivered.

However, if you can ping a remote IP address, then you can obtain numerous performance metrics. Beyond simple reachability, further information can be inferred by the ping approach with some basic extensions to our simple ping model. If a sequence of labeled ping packets is generated, the elapsed time for a response to be received for each packet can be recorded, along with the count of dropped packets, duplicated packets, and packets that have been reordered by the network. Careful interpretation of the response times and their variance can provide an indication of the load being experienced on the network path between the query agent and the target. Load will manifest a condition of increased delay and increased variance, due to the interaction of the router buffers with the traffic flows along the path elements as load increases. When a router buffer overflows, the router is forced to discard packets; and under such conditions, increased ping loss is observed. In addition to indications of network load, high erratic delay and loss within a sequence of ping packets may be symptomatic of routing instability with the network path oscillating between many path states.

A typical use of ping is to regularly test numerous paths to establish a baseline of path metrics. This enables a comparison of a specific ping result to these base metrics to give an indication of current path load within the network.

Of course, it is possible to interpret too much from ping results, particularly when pinging routers within a network. Many router architectures use fast switching paths for data packets, whereas the central processing unit of the router may be used to process ping requests. The ping response process may be given a low scheduling priority because router operations represent a more critical router function. It is possible that extended delays and loss, as reported by a ping test, may be related to the processor load or scheduling algorithm of the target router processor rather than to the condition of the network path. (Figure 4)

Figure 4: Ping Path



Ping sequences do not necessarily mimic packet flow behavior of applications. Typical TCP flow behavior is prone to cluster into bursts of packet transmissions on each epoch of the round-trip time. Routers may optimize their cache management, switching behavior, and queue management to take advantage of this behavior. Ping packets may not be clustered; instead, an evenly spaced pacing is used, meaning that the observed metrics of a sequence of ping packets may not exercise such router optimizations. Accordingly, the ping results may not necessarily reflect an anticipation of application performance along the same path. Also a ping test does not measure a simple path between two points. The ping test measures the time to send a packet to a target system and for the target to respond back to the sender. Ping is measuring a loop rather than a simple path.

With these caveats in mind, monitoring a network through regular ping tests along the major network paths can yield useful information regarding the status of the network service performance.

Many refinements to ping can extend its utility. Ping can use *loose source routing* to test the reachability of one host to another, directing the packet from the query host to the loose source routed host, then to the target host and back via the same path through the specified approach. However, many networks disable support for loose source routing, given that it can be exploited in some forms of security attacks. Consequently, the failure of a loose source routed ping may not be a conclusive indication of a network fault.

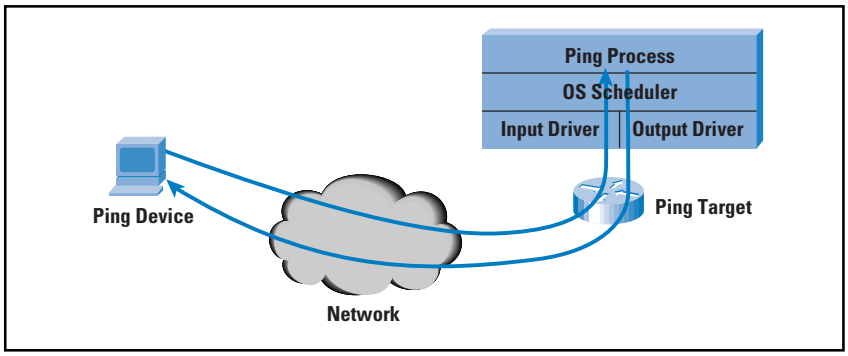
Ping also can be used in a rudimentary way to discover the provisioned capacity of network links. By varying the packet length and comparing the ping times of one router to the next-hop router on a path, the bandwidth of the link can be deduced with some degree of approximation required because of a background queue-induced level of network jitter.

A more sophisticated variation of ping is to pace the transmission of packets from the received packets, mimicking the behavior of the TCP flow control algorithms with *Slow Start* and subsequent congestion avoidance. *Treno* is such a tool. In Treno, the transmission of ping packets is managed by the TCP Reno flow-control algorithm, such that further ping packets are triggered by the reception of responses to earlier packets, and the triggering of further packets is managed by an implementation of the TCP control function. Such a tool can indicate available flow rate-managed capacity on a chosen path.

Path Discovery Using Traceroute

The second common ICMP-based network management tool, *traceroute*, devised by Van Jacobson, is based on the ICMP *Time Exceeded* message. Here, a sequence of *User Datagram Protocol* (UDP) packets are generated to the target host, each with an increased value of the *Time To Live* (TTL) field in the IP header. This generates a sequence of ICMP Time Exceeded messages sourced from the router where the TTL expired. These source addresses are those of the routers, in turn, on the path from the source to the destination. (Figure 5)

Figure 5: Traceroute Path



Like ping, traceroute measures the elapsed time between the packet transmission and the reception of the corresponding ICMP packet. In this way, the complete output of a traceroute execution exposes not only the elements of the path to the destination, but also the delay and loss characteristics of each partial path element. Traceroute also can be used with loose source route options to uncover the path between two remote hosts. The same caveats mentioned in the ping description relating to the relative paucity in deployment of support for loose source routing apply. An example of a traceroute report is shown in Figure 6.

Notes:
1) There are interprovider handovers at hops 7, 9, and 13.
2) There is a sudden jump in response times at hop 8. The additional 182 ms of round-trip latency corresponds to a 36,000-km submarine cable path. This can be explained by the hop-7 to hop-8 segment, including a submarine cable path between Australia and the United States.

Traceroute is an excellent tool for reporting on the state of the routing system. It operates as an excellent "sanity check" of the match between the design intent of the routing system and the operational behavior of the network.

The caveat to keep in mind when interpreting traceroute output has to do with asymmetric routes within the network. Whereas the per-hop responses expose the routing path taken in the forward direction to the target host, the delay and loss metrics are measured across the forward and reverse paths for each step in the forward path. The reverse path is not explicitly visible to traceroute.

One-Way Measurements

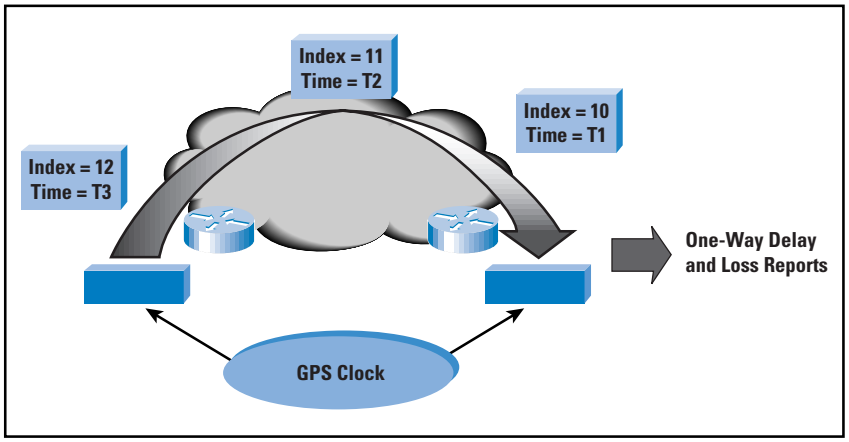
Round-trip probes, such as ping and traceroute, are suited to measuring the total network path between two ends of a transaction, but how can a network provider measure the characteristics of a component of the total end-to-end path? In such a case the network provider is interested in the performance of a set of unidirectional transit paths from an network ingress point to an egress point. There are now some techniques that perform a one-way delay and loss measurement, and they are suited to measuring the service parameters of individual transit paths across a network. A one-way approach does not use a single network management system, but relies on the deployment of probe senders and receivers using synchronized clocks.

The one-way methodology is relatively straightforward. The sender records the precise time a certain bit of the probe packet was transmitted into the network; the receiver records the precise time that same bit arrived at the receiver. Precisely synchronizing the clocks of the two systems is an interesting problem, and initial implementations of this approach have used *Global Positioning System* (GPS) satellite receivers as a synchronized clock source.

One of the noted problems with the use of GPS was that computers are generally located within machine rooms and a clear GPS signal is normally available only on a rooftop. Later implementations of this approach have used the clock associated with the *Code Division Multiple Access* (CDMA) mobile telephone network as a highly accurate, synchronized, distributed clock source, with the advantage that the time signal is usually available close to the measurement unit.

Consequent correlation of the sender's and receiver's data from repeated probes can reveal the one-way delay and loss patterns between sender and receiver. To correlate this to a service level requires the packets to travel along the same path as the service flow and with the same scheduling response from the network.

Figure 7: One-Way Measurements



Ping and traceroute are ubiquitous tools. Almost every device can support sending ping and traceroute probes, and, by default almost every device, including network routers, will respond to a ping or traceroute probe. One-way measurements are a different matter, and such measurements normally require the use of dedicated devices in order to undertake the clocking of the probes with the required level of precision (Figure 7).

Choosing the Right Time Base

Whether it is an active or passive measurement regime, the next basic decision is the time base to use for the measurements. Many applications are very sensitive to short-lived transient network conditions. This may take the form of a burst of packet loss, or a period of packet reordering, or a switch to a longer round trip time. TCP may react by halving its sending rate, or by entering an extended wait state while awaiting the retransmission timer to expire. In either case it will take numerous round trip time intervals for the transport session to recover, and this may impact the behavior of the application. On the other hand, a periodic network probe may miss the transient event altogether and report no abnormalities whatsoever.

IP networks have bursty traffic sources, and there is a marked self-similarity in the traffic patterns. This appears to be consistent over a wide range of networks, where large-capacity systems tend to observe large burst patterns and smaller systems also see bursts of a similar proportionate size. So the question is, what time interval for measurements can provide meaningful aggregation of information, while at the same time be sensitive enough to report on the outcomes of transient bursts within the network? Intuitively a measurement time base of hourly measurements is very insensitive to capturing transient bursts, whereas a time base of a millisecond would generate a massive amount of data, a scenario that would tend to smother the identification of abnormalities. Interestingly enough, the choice of a measurement base has little to do with the capacity of the links within a network, but it has a close relationship to the average routing trip time of the individual transport sessions that are active within the network.

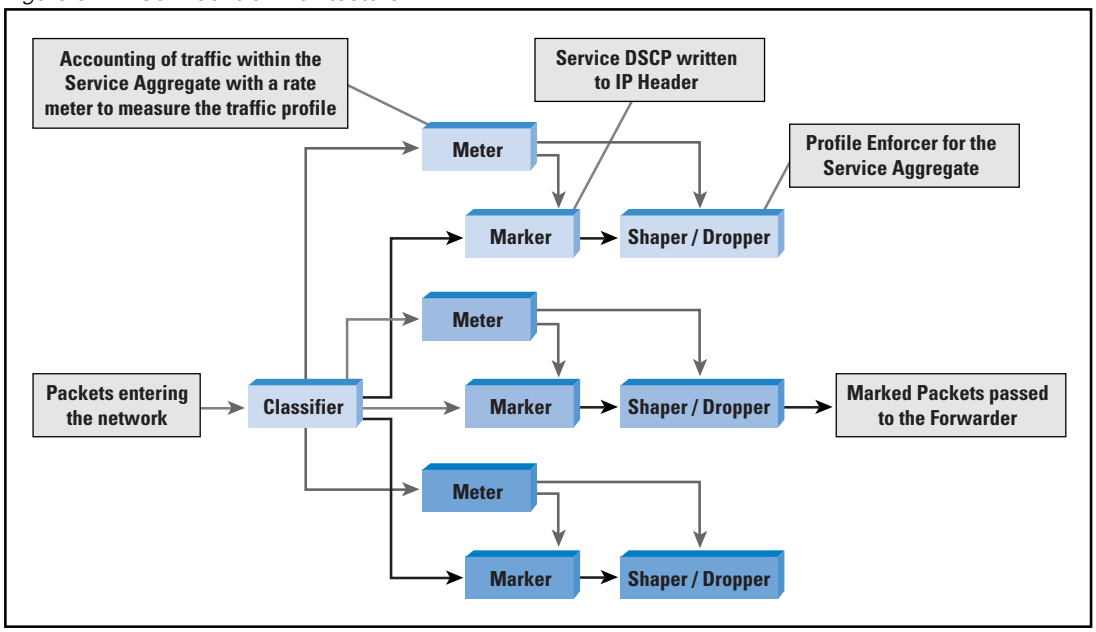
The profile of IP networks is one that is dominated by TCP traffic, and TCP traffic uses a transport control mechanism where the returning stream of *acknowledgement* (ACK) packets governs the actions of the sender. This implies that network-based distortion in the forward data path will not be signaled back to the sender for one complete round-trip time interval, and the consequent adaptation of the sender to the conditions of the network will take numerous additional round-trip times. The implication is that in order to capture a comprehensive view of network performance, a time base of 1 to 2 seconds is appropriate. However, for large networks, such a view generates a massive amount of data. It appears that many networks use a measurement time base of about 60 to 300 seconds, representing an acceptable compromise between sensitivity of the measurement system and the consequent volume of measurement data to analyze.

What About QoS Networks?

So far the assumption has been that the network operates with a single service level and that probes of the network operate at the same service level as the network payload. This is certainly a common situation, but the total picture is slightly broader. When the network provider attempts to create a premium response for certain classes of traffic, and where the customer is paying a premium tariff to use such a premium service, the question of performance becomes a matter of deep concern to both the provider and the customer. After all, the customer is now paying a premium for improved performance, so it would help all concerned if this could be clearly defined and measured.

Solutions exist in both the passive and active polling domains. In the case of SNMP there is a monitoring framework (or Management Information Base, MIB) relating to the *Differentiated Services* (DiffServ) model of *Quality of Service* (QoS), and also MIBs relating to the *Integrated Services* (IntServ) QoS model. For the DiffServ MIB, it is first necessary to define an abstract model of the operation of a DiffServ admission router, by looking at the major functional blocks of the router. The first of these blocks is the definition of the supported behavior aggregates provided by the network. Within the network path, the initial active path element is the traffic classification module, which can be modeled as a set of filters and an associated set of output streams. The output stream is passed to the traffic-conditioning elements, which are the traffic meters and the associated action elements. Many meter profiles can be used in the model: an average data rate, an exponential weighted moving average of one of numerous various traffic profiles that can be expressed by a set of token-bucket parameters using an average rate, a peak rate, and a burst size. More elaborate meter specifications can be constructed using a multilevel token-bucket specification. From the meter, the traffic is passed through an action filter, which may mark the packets and shape the traffic profile through queues or discard operations. Together, this sequence of components forms a *traffic conditioning block*. The traffic is then passed into a queue through the use of a queuing discipline that applies the desired service behavior. (Figure 8)

Figure 8: DIffServ Control Architecture



From this generic model it is possible to define instrumentation for SNMP polling, where each of these five components—the behavior aggregate, the classifier, the meter, profile actions, and the queuing discipline—correspond to a MIB table. With this structure it is possible to parameterize both the specific configuration of the DiffServ network element and its dynamic state. This MIB is intended to describe the configuration and operation of both edge and interior DiffServ network elements, the difference being that interior elements use just a behavior aggregate classifier and a queue manager within the management model, whereas the edge elements use all components of the model.

A comparable MIB is defined for the IntServ architecture and an additional MIB for the operation of guaranteed services. The IntServ MIB defines the per-element reservation table used to determine the current reservation state, an indication of whether or not the router can accept further flow reservations, and the reservation characteristics of each current flow. No performance polling parameters or accounting parameters are included in the MIB. The guaranteed services MIB adds to this definition with a per-interface definition of a backlog. This is a means of expressing *packet quantization delay*, a delay term, which is the packet propagation delay over the interface, and a slack term, which is the amount of slack in the reservation that can be used without redefining the reservation. Again, these are per-element status definitions, and they do not include performance or accounting data items.

The IntServ MIB is being further defined as a *Resource Reservation Protocol* (RSVP) MIB for the operation of IntServ network elements[14]. There are a larger number of objects within the MIB, including General Objects, Session Statistics Table, Session Sender Table, Reservation Requests Received Table, Reservation Requests Forwarded Table, RSVP Interface Attributes Table, and an RSVP Neighbor Table.

Interestingly, the MIB proposes a writeable RSVP reservation table to allow the network manager to manually create a reservation state that can be removed only through a comparable manual operation. The MIB enables a management system to poll the IntServ network element to retrieve the status of every active IntServ reserved flow and the operational characteristics of the flow, as seen by the network element.

In a QoS DiffServ environment, ping and traceroute pose some interesting engineering issues. Ping sends an ICMP packet. The network QoS admission filters may choose a different classification for these packets from that chosen for normal data-flow TCP or UDP protocol packets; as a result, the probe packet may be scheduled differently or even take a completely different path to the network. In an IntServ QoS network, the common classification condition for a flow is a combination of the IP header source and destination addresses and the TCP or UDP header source and destination port addresses. The ping probe packet cannot reproduce this complete flow description, and therefore cannot, by default, be inserted into the flow path that it is attempting to measure. With traceroute, the packet does have a UDP protocol address, but it uses a constant port address by default, causing a similar problem of attempting to be inserted to an IntServ flow. DiffServ encounters similar problems when attempting to pass the probe packet into the network via the DiffServ admission classification systems. Inside the network, it is possible to insert the probe packet into the network with the IP *Differentiated Services Code Point* (DSCP) field set to the DiffServ behavior aggregate that is being measured.

The measurement of delay and loss taken by ping and traceroute is a cumulative value of both the forward and return path delay and loss. When attempting to measure unidirectional flow-path behavior, such as an IntServ flow path, this measurement is of dubious value, given the level of uncertainty as to which part of the path, forward or reverse, contributed to the ping or traceroute delay and loss reports.

For one-way delay measurements, in DiffServ networks, this can be done within the network, setting the DSCP field to the value of the service aggregate being monitored. Of course, from the customer's perspective, the DiffServ network service profile includes the admission traffic-conditioning block, and the interior one-way measurements are only part of the delivered service. In the IntServ network, the packets have to be structured to take the same path as the elevated service flows; they are classified by each element as part of the collection of such elevated service flows for the purposes of scheduling.

Measuring Performance—The Client Perspective

From the client's perspective, the measurement choices are more limited. A client does not normally enjoy the ability to poll network elements within a provider's network. One way for a client to measure service quality is to instigate probing of the network path, whereby a sender can pass a probe packet into the network and measure the characteristics of the response. Of course, the problems of inserting probe packets into the service flow remain, as do the issues of unidirectional elevated service flows with bidirectional probes.

However, the client does have the advantage of being able to monitor and manipulate the characteristics of the service flow itself. For TCP sessions, the client can monitor the packet retransmission rate, the maximum burst capacity, the average throughput, the *round-trip time* (RTT), RTT variance, and misordered packets, by monitoring the state of the outbound data flow and relating it to the inbound ACK flow. For UDP sessions, there is no corresponding transport-level feedback information flow to the sender as a part of the transport protocol itself. The receiver can measure the service quality of the received datastream using information provided in the *Real-Time Protocol* (RTP) information feedback fields—if RTP is being used for real-time data or as an application-related tool for other application types. If sender and receiver work in concert, the receiver can generate periodic quality reports and pass these summaries back to the sender. Such applications can confirm whether an application is receiving a specified level of service. This approach treats the network like a black box; no attempt is made to identify the precise nature or source of events that disrupt the delivered service quality. There are no standardized approaches to this activity, but numerous analysis tools are available for host platforms that perform these measurements.

Though the client can measure and conform service quality on a per-application level of granularity, the second part of the client's motivation in measuring service quality is more difficult to address. The basic question is whether the service delivered in response to a premium service request is sufficiently differentiated from a best-effort service transaction. Without necessarily conducting the transaction a second time, the best approach is to use either one-way delay probes, for unidirectional traffic, or a bulk TCP capacity probe, to establish some indication of the relativity in performance. From a client perspective none of these are simple to set up, and the dilemma that the customer often faces is the basic question of whether the cost of operating the measurement setup is adequately offset by the value of the resulting answers.

Measuring Networks—Looking for Problems

So far we have been looking at the ways of measuring network performance as a general task. Of course degraded performance does not happen by accident (well, sometimes accidents do happen), and it makes the measurement task easier if you can identify precisely what it is that you are looking for. This approach requires identification of the various situations that can impact network performance and then set up network measurement and monitoring systems that are tuned to identify these situations.

Within this approach, the motives for network measurement are concerned with identification of traffic load patterns that cause uneven network load, monitoring, and verification of service-level agreements, detection of abnormal network load that may be a signature of an attack, forecasting and capacity planning, and routing stability.

The objective here is to create a stable and well-understood model of the operational characteristics of the network, and then analyze the situations that could disrupt this stable state and the implications in terms of delivered performance under such conditions.

Such an approach could be described in terms of opposites—instead of measuring network performance, the approach is measuring the network to identify the conditions that cause nonperformance at particular times within particular network paths. As a performance management technique, this approach has been very effective—rather than taking a larger amount of performance data and merging and averaging it into a relatively meaningless index, the approach is to isolate those circumstances where performance is compromised and report on these exceptions rather than on the remainder of the time.

Of course measuring what is "normal" may involve more than assembling a benchmark set of SNMP-derived polling data and a collection of latency, loss, and jitter profiles obtained from analysis of large volumes of ping data. One additional tool is the router itself. Because the router uses many IP packet header fields to switch each packet, one approach is to get the router to assemble and aggregate information about the characteristics of traffic that has been passed through the router, and send these aggregated reports to a network management station for further analysis. *NetFlow* is the most common tool to undertake this form of reporting. Like SNMP, NetFlow can report on the characteristics of traffic as it passes a point in the network. For measuring end-to-end performance of individual applications, NetFlow has the same limitations as SNMP. The analogy is one of standing on a street corner counting cars that go past and from that measurement attempting to derive the average time for a commuter to drive to or from work. However, the value of NetFlow is that in this context of performance measurement, it can be used to derive a picture of the baseline characteristics of the network, including identification of the endpoints of the traffic flows. Extending the car analogy further, NetFlow can provide an indication of the origins and ultimate destinations of the cars as they pass the monitoring point. This information is useful in terms of designing networks that are adequately configured to handle the transit traffic load. In addition, with careful analysis, NetFlow can be used to identify exceptional traffic conditions. The advantage here is that NetFlow data can be used to identify both the abnormal traffic load and also provide some indication of the endpoints of the abnormal flows. In this way, NetFlow can be deployed as both a baseline network traffic profile benchmarking tool and a performance exception diagnosis tool.

This approach of capturing the packet header information as the traffic passes a monitoring point in the network has been implemented in numerous ways, and NetFlow is not the only data-collection tool in this space. One interesting approach has been used by NeTraMet, an implementation of the *Internet Engineering Task Force's* (IETF's) *Realtime Traffic Flow Measurement* architecture for traffic flow measurement.

The feature here is a powerful ruleset within the tool that allows the flow collector to be configured to collect information about particular traffic flows and their characteristics. In the context of measuring performance, one of the abilities of the tool is to match the outbound data flow with the inbound acknowledgement stream, allowing an analyzer some ability to infer end-to-end performance of the application based on the collected information.

Where to Go from Here

It is clear that the picture is so far very incomplete. The active probe measurements require either some latitude of interpretation or dedicated instrumentation to take measurements with some necessary level of frequency and precision. The passive approach of probing the active switching elements of the network is constrained by a very basic model of the switching system, so that the collectable values provide only a very indirect relationship to the manner in which the switching element is generating queuing delays and traffic flow instability.

Perhaps what is also increasingly unclear is the relationship between performance and networks in any case. The last few years have seen a massive swing in public Internet platforms away from networks where some level of congestion and contention was anticipated to networks that are extensively overprovisioned, and there packet jitter and loss are simply not encountered. With the ever-decreasing cost of transmission bandwidth in many markets, this environment of abundant network capacity is now also finding its way into various enterprise network sectors. In such worlds of abundant supply and overengineering of networks, there is really little left to measure within the network. The entire question of performance then becomes a question phrased much closer to home: how well is your system tuned to make the most of its resources and those of the server? Often the entire issue with performance is a situation of abundant network resources, abundant local memory and processing resources, and poor tuning of the transport protocol stack. That is, of course, quite properly the subject of another article.

Further Reading

The Internet offers a wealth of material on the topic of network measurement, and the major exercise is undertaking some filtering to get a broad collection of material that encompasses a range of perspectives on this topic. The following sources were used to prepare this article, and are recommended as starting points for further exploration of this topic.

The Session Initiation Protocol

by William Stallings

The *Session Initiation Protocol* (SIP), defined in RFC 3261[6], is an application level signaling protocol for setting up, modifying, and terminating real-time sessions between participants over an IP data network. SIP can support any type of single-media or multimedia session, including teleconferencing.

SIP is just one component in the set of protocols and services needed to support multimedia exchanges over the Internet. SIP is the signaling protocol that enables one party to place a call to another party and to negotiate the parameters of a multimedia session. The actual audio, video, or other multimedia content is exchanged between session participants using an appropriate transport protocol. In many cases, the transport protocol to use is the *Real-Time Transport Protocol* (RTP). Directory access and lookup protocols are also needed.

The key driving force behind SIP is to enable Internet telephony, also referred to as *Voice over IP* (VoIP). There is wide industry acceptance that SIP will be the standard IP signaling mechanism for voice and multimedia calling services. Further, as older *Private Branch Exchanges* (PBXs) and network switches are phased out, industry is moving toward a voice networking model that is SIP signaled, IP based, and packet switched, not only in the wide area but also on the customer premises[2, 3].

SIP supports five facets of establishing and terminating multimedia communications:

- *User location:* Users can move to other locations and access their telephony or other application features from remote locations.
- *User availability:* This step involves determination of the willingness of the called party to engage in communications.
- *User capabilities:* In this step, the media and media parameters to be used are determined.
- *Session setup:* Point-to-point and multiparty calls are set up, with agreed session parameters.
- *Session management:* This step includes transfer and termination of sessions, modifying session parameters, and invoking services.

SIP employs design elements developed for earlier protocols. SIP is based on an HTTP-like request/response transaction model. Each transaction consists of a client request that invokes a particular method, or function, on the server and at least one response. SIP uses most of the header fields, encoding rules, and status codes of HTTP. This provides a readable text-based format for displaying information. SIP incorporates the use of a *Session Description Protocol* (SDP), which defines session content using a set of types similar to those used in *Multipurpose Internet Mail Extensions* (MIME).

SIP Components and Protocols

A system using SIP can be viewed as consisting of components defined on two dimensions: client/server and individual network elements. RFC 3261 defines client and server as follows:

- *Client:* A client is any network element that sends SIP requests and receives SIP responses. Clients may or may not interact directly with a human user. User agent clients and proxies are clients.
- *Server:* A server is a network element that receives requests in order to service them and sends back responses to those requests. Examples of servers are proxies, user agent servers, redirect servers, and registrars.

The individual elements of a standard SIP configuration include the following:

- *User Agent:* The user agent resides in every SIP end station. It acts in two roles:
  - User Agent Client (UAC): Issues SIP requests
  - User Agent Server (UAS): Receives SIP requests and generates a response that accepts, rejects, or redirects the request
- *Redirect Server:* The redirect server is used during session initiation to determine the address of the called device. The redirect server returns this information to the calling device, directing the UAC to contact an alternate *Universal Resource Identifier* (URI). A URI is a generic identifier used to name any resource on the Internet. The URL used for Web addresses is a type of URI. See RFC 2396[1] for more detail.
- *Proxy Server:* The proxy server is an intermediary entity that acts as both a server and a client for the purpose of making requests on behalf of other clients. A proxy server primarily plays the role of routing, meaning that its job is to ensure that a request is sent to another entity closer to the targeted user. Proxies are also useful for enforcing policy (for example, making sure a user is allowed to make a call). A proxy interprets, and, if necessary, rewrites specific parts of a request message before forwarding it.
- *Registrar:* A registrar is a server that accepts REGISTER requests and places the information it receives (the SIP address and associated IP address of the registering device) in those requests into the location service for the domain it handles.
- *Location Service:* A location service is used by a SIP redirect or proxy server to obtain information about a callee's possible location(s). For this purpose, the location service maintains a database of SIP-address/IP-address mappings.

The various servers are defined in RFC 3261 as logical devices. They may be implemented as separate servers configured on the Internet or they may be combined into a single application that resides in a physical server.

Figure 1: SIP Components and Protocols

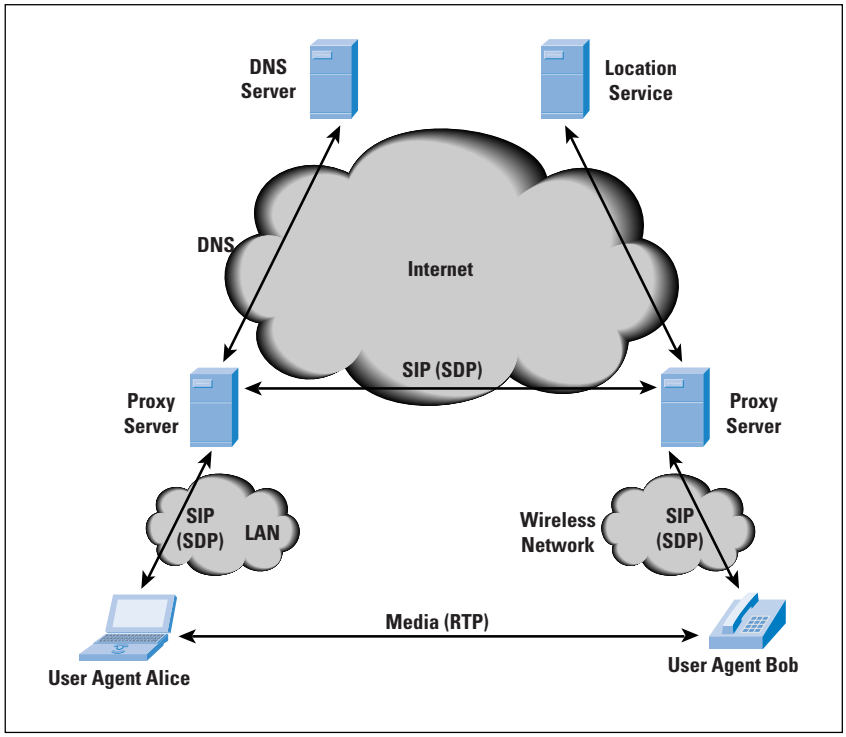

Figure 1 shows how some of the SIP components relate to one another and the protocols that are employed. A user agent acting as a client (in this case UAC Alice) uses SIP to set up a session with a user agent that acts as a server (in this case UAS Bob). The session initiation dialogue uses SIP and involves one or more proxy servers to forward requests and responses between the two user agents. The user agents also make use of the SDP, which is used to describe the media session.

The proxy servers may also act as redirect servers as needed. If redirection is done, a proxy server needs to consult the location service database, which may or may not be colocated with a proxy server. The communication between the proxy server and the location service is beyond the scope of the SIP standard. The *Domain Name System* (DNS) is also an important part of SIP operation. Typically, a UAC makes a request using the domain name of the UAS, rather than an IP address. A proxy server needs to consult a DNS server to find a proxy server for the target domain.

SIP often runs on top of the *User Datagram Protocol* (UDP) for performance reasons, and provides its own reliability mechanisms, but may also use TCP. If a secure, encrypted transport mechanism is desired, SIP messages may alternatively be carried over the *Transport Layer Security* (TLS) protocol.

Associated with SIP is the SDP, defined in RFC 2327[4]. SIP is used to invite one or more participants to a session, while the SDP-encoded body of the SIP message contains information about what media encodings (for example, voice, video) the parties can and will use. After this information is exchanged and acknowledged, all participants are aware of the participants' IP addresses, available transmission capacity, and media type. Then, data transmission begins, using an appropriate transport protocol. Typically, the RTP is used. Throughout the session, participants can make changes to session parameters, such as new media types or new parties to the session, using SIP messages.

SIP Universal Resource Indicators

A resource within a SIP configuration is identified by a URI. Examples of communications resources include the following:

- A user of an online service
- An appearance on a multiline phone
- A mailbox on a messaging system
- A telephone number at a gateway service
- A group (such as "sales" or "help desk") in an organization

SIP URIs have a format based on e-mail address formats, namely **`user@domain`**. There are two common schemes. An ordinary SIP URI is of the form:

```
sip:bob@biloxi.com
```

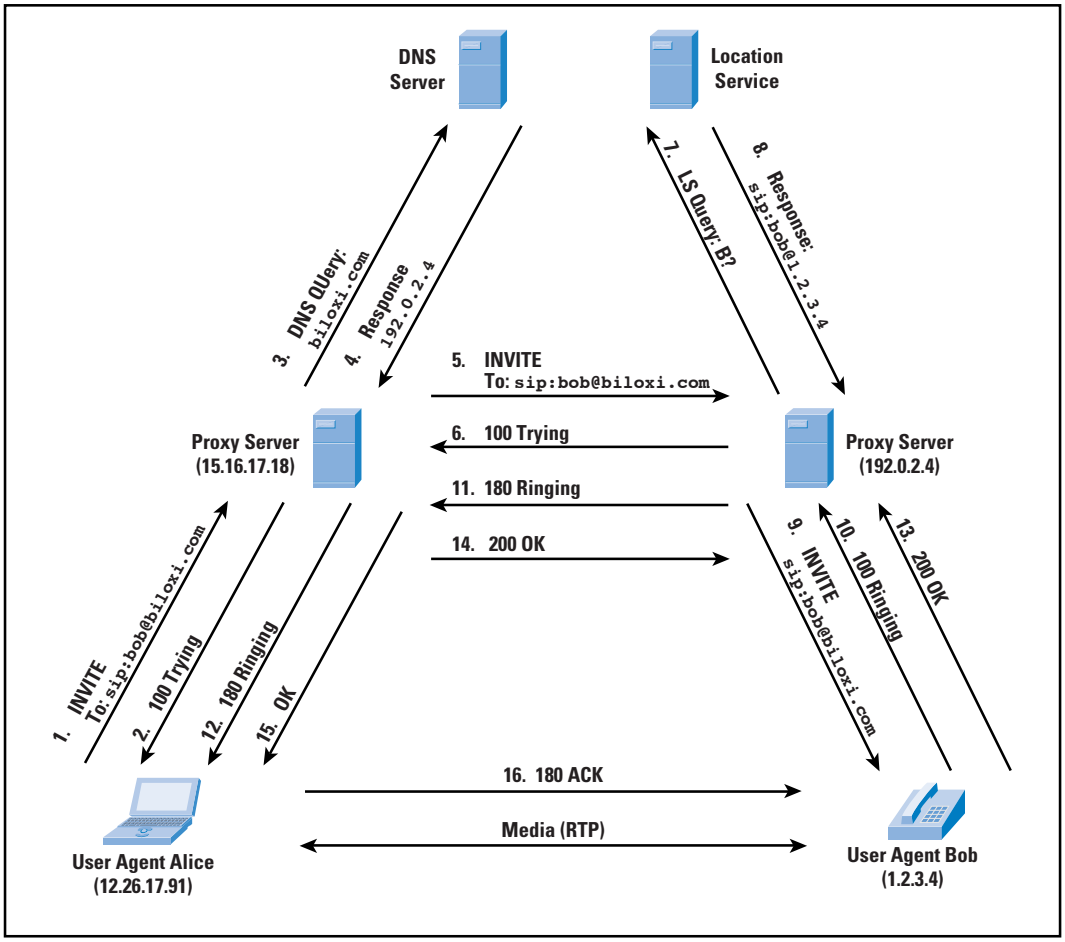
The URI may also include a password, port number, and related parameters. If secure transmission is required, "**`sip:`**" is replaced by "**`sips:.`**" In the latter case, SIP messages are transported over TLS.

Examples of Operation

The SIP specification is quite complex; the main document, RFC 3261, is 269 pages long. To give some feel for its operation, we present a few examples.

Figure 2 shows a successful attempt by user Alice to establish a session with user Bob, whose URI is **`bob@biloxi.com.`**[9] Alice's UAC is configured to communicate with a proxy server (the outbound server) in its domain and begins by sending an INVITE message to the proxy server that indicates its desire to invite Bob's UAS into a session (1); the server acknowledges the request (2). Although Bob's UAS is identified by its URI, the outbound proxy server needs to account for the possibility that Bob is not currently available or that Bob has moved. Accordingly, the outbound proxy server should forward the INVITE request to the proxy server that is responsible for the domain **`biloxi.com.`** The outbound proxy thus consults a local DNS server to obtain the IP address of the **`biloxi.com`** proxy server (3), by asking for the DNS SRV resource record that contains information on the proxy server for **`biloxi.com.`**

Figure 2: SIP Successful Call Setup

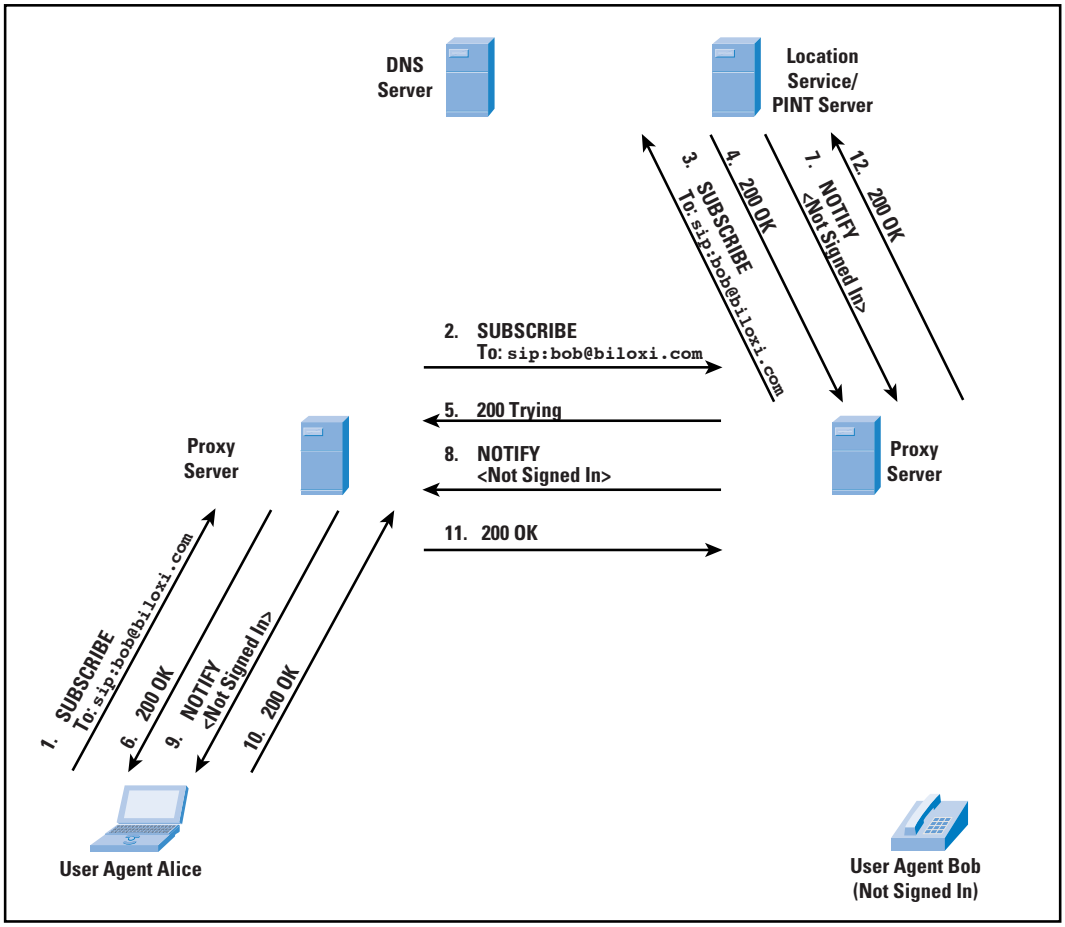


The DNS server responds (4) with the IP address of the **`biloxi.com`** proxy server (the inbound server). Alice's proxy server can now forward the INVITE message to the inbound proxy server (5), which acknowledges the message (6). The inbound proxy server now consults a location server to determine Bob's location Bob (7), and the location server responds with Bob's location, indicating that Bob is signed in, and therefore available for SIP messages (8).

The proxy server can now send the INVITE message on to Bob (9). A ringing response is sent from Bob back to Alice (10, 11, 12) while the UAS at Bob is alerting the local media application (for example, telephony). When the media application accepts the call, Bob's UAS sends back an OK response to Alice (13, 14, 15).

Finally, Alice's UAC sends an acknowledgement message to Bob's UAS to confirm the reception of the final response (16). In this example, the ACK is sent directly from Alice to Bob, bypassing the two proxies. This occurs because the endpoints have learned each other's address from the INVITE/200 (OK) exchange, which was not known when the initial INVITE was sent. The media session has now begun, and Alice and Bob can exchange data over one or more RTP connections.

Figure 3: SIP Presence Example

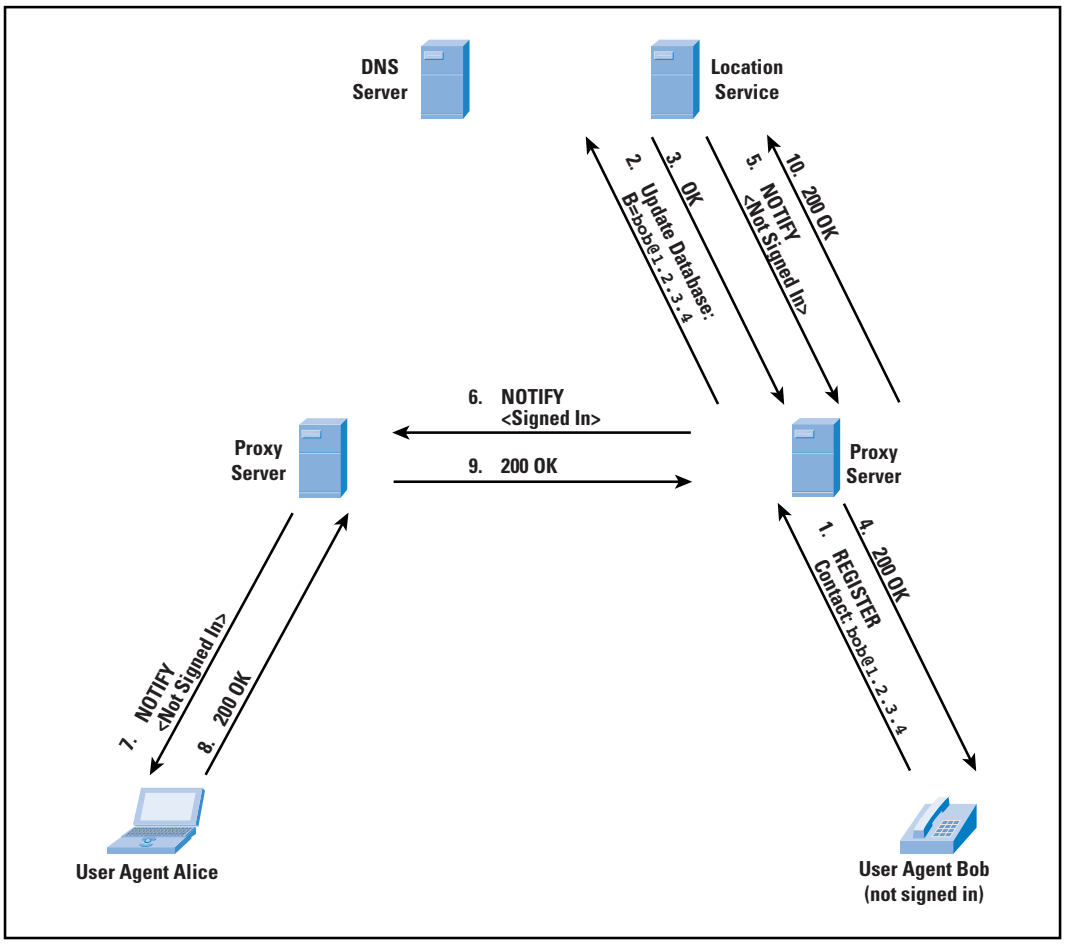


The next example (Figure 3) makes use of two message types that are not yet part of the SIP standard but that are documented in RFC 2848[5] and are likely to be incorporated in a later revision of SIP. These message types support telephony applications. Suppose that in the preceding example, Alice was informed that Bob was not available. Alice's UAC can then issue a SUBSCRIBE message (1), indicating that it wants to be informed when Bob is available.

This request is forwarded through the two proxies in our example to a PINT (*Public Switched Telephone Network [PSTN]-Internet Networking*) server (2, 3). A PINT server acts as a gateway between an IP network from which comes a request to place a telephone call and a telephone network that executes the call by connecting to the destination telephone. In this example, we assume that the PINT server logic is colocated with the location service. It could also be the case that Bob is attached to the Internet rather than a PSTN, in which case the equivalent of PINT logic is needed to handle SUBSCRIBE requests. In this example, we assume the latter and assume that the PINT functionality is implemented in the location service. In any case, the location service authorizes subscription by returning an OK message (4), which is passed back to Alice (5, 6). The location service then immediately sends a NOTIFY message with Bob's current status of not signed in (7, 8, 9), which Alice's UAC acknowledges (10, 11, 12).

Figure 4 continues the example of Figure 3. Bob signs on by sending a REGISTER message to the proxy in its domain (1). The proxy updates the database at the location service to reflect registration (2). The update is confirmed to the proxy (3), which confirms the registration to Bob (4). The PINT functionality learns of Bob's new status from the location server (here we assume that they are colocated) and sends a NOTIFY message containing Bob's new status (5), which is forwarded to Alice (6, 7). Alice's UAC acknowledges receipt of the notification (8, 9, 10).

Figure 4: SIP Registration and Notification Example



SIP Messages

As was mentioned, SIP is a text-based protocol with a syntax similar to that of HTTP. There are two different types of SIP messages, *requests* and *responses*. The format difference between the two types of messages is seen in the first line. The first line of a request has a method, defining the nature of the request and a Request-URI, indicating where the request should be sent. The first line of a response has a response code. All messages include a header, consisting of a number of lines, each line beginning with a header label. A message can also contain a body such as an SDP media description.

For SIP requests, RFC 3261 defines the following methods:

- *REGISTER:* Used by a user agent to notify a SIP configuration of its current IP address and the URLs for which it would like to receive calls
- *INVITE:* Used to establish a media session between user agents
- *ACK:* Confirms reliable message exchanges
- *CANCEL:* Terminates a pending request, but does not undo a completed call
- *BYE:* Terminates a session between two users in a conference
- *OPTIONS:* Solicits information about the capabilities of the callee, but does not set up a call

For example, the header of message (1) in Figure 2 might look like the following:

```
INVITE sip:bob@biloxi.com SIP/2.0
Via: SIP/2.0/UDP 12.26.17.91:5060
Max-Forwards: 70
To: Bob <sip:bob@biloxi.com
From: Alice <sip:alice@atlanta.com;tag=1928301774
Call-ID: a84b4c76e66710@12.26.17.91
CSeq: 314159 INVITE
Contact: <sip:alice@atlanta.com>
Content-Type: application/sdp
Content-Length: 142
```

The first line contains the method name (**INVITE**), a SIP URI, and the version number of SIP that is used. The lines that follow are a list of header fields. This example contains the minimum required set.

The **Via** headers show the path the request has taken in the SIP configuration (source and intervening proxies), and are used to route responses back along the same path. As the INVITE message leaves, there is only the header inserted by Alice. The line contains the IP address (**12.26.17.91**), port number (**5060**), and transport protocol (**UDP**) that Alice wants Bob to use in his response.

The **Max-Forwards** header limits the number of hops a request can make on the way to its destination. It consists of an integer that is decremented by one by each proxy that forwards the request. If the **Max-Forwards** value reaches 0 before the request reaches its destination, it is rejected with a 483 (**Too Many Hops**) error response.

The **To** header field contains a display name (Bob) and a SIP or SIPS URI (**sip:bob@biloxi.com**) toward which the request was originally directed. The **From** header field also contains a display name (Alice) and a SIP or SIPS URI (**sip:alice@atlanta.com**) that indicate the originator of the request. This header field also has a **tag** parameter that contains a random string (**1928301774**) that was added to the URI by the UAC. It is used to identify the session.

The **`Call-ID`** header field contains a globally unique identifier for this call, generated by the combination of a random string and the host name or IP address. The combination of the **`To`** tag, **`From`** tag, and **`Call-ID`** completely defines a peer-to-peer SIP relationship between Alice and Bob and is referred to as a dialog.

The **`CSeq`** or *Command Sequence* header field contains an integer and a method name. The CSeq number is initialized at the start of a call (**`314159`** in this example), incremented for each new request within a dialog, and is a traditional sequence number. The CSeq is used to distinguish a retransmission from a new request.

The **`Contact`** header field contains a SIP URI for direct communication between user agents. Whereas the **`Via`** header field tells other elements where to send the response, the **`Contact`** header field tells other elements where to send future requests for this dialog.

The **`Content-Type`** header field indicates the type of the message body. The **`Content-Length`** header field gives the length in octets of the message body.

The SIP response types defined in RFC 3261 are in the following categories:

- *Provisional* (1xx): The request was received and is being processed.
- *Success* (2xx): The action was successfully received, understood, and accepted.
- *Redirection* (3xx): Further action needs to be taken in order to complete the request.
- *Client Error* (4xx): The request contains bad syntax or cannot be fulfilled at this server.
- *Server Error* (5xx): The server failed to fulfill an apparently valid request.
- *Global Failure* (6xx): The request cannot be fulfilled at any server.

For example, the header of message (13) in Figure 2 might look like the following:

```
SIP/2.0 200 OK
Via: SIP/2.0/UDP server10.biloxi.com
Via: SIP/2.0/UDP bigbox3.site3.atlanta.com
Via: SIP/2.0/UDP 12.26.17.91:5060
To: Bob <sip:bob@biloxi.com;tag=a6c85cf
From: Alice <sip:alice@atlanta.com;tag=1928301774
Call-ID: a84b4c76e66710@12.26.17.91
CSeq: 314159 INVITE
Contact: <sip:bob@biloxi.com>
Content-Type: application/sdp
Content-Length: 131
```

The first line contains the version number of SIP that is used and the response code and name. The lines that follow are a list of header fields. The **`Via`**, **`To`**, **`From`**, **`Call-ID`**, and **`CSeq`** header fields are copied from the INVITE request. (There are three **`Via`** header field values—one added by Alice's SIP UAC, one added by the **`atlanta.com`** proxy, and one added by the **`biloxi.com`** proxy.) Bob's SIP phone has added a **`tag`** parameter to the **`To`** header field. This tag is incorporated by both endpoints into the dialog and is included in all future requests and responses in this call.

Session Description Protocol

The *Session Description Protocol* (SDP), defined in RFC 2327, describes the content of sessions, including telephony, Internet radio, and multimedia applications. SDP includes information about[8]:

- *Media streams:* A session can include multiple streams of differing content. SDP currently defines audio, video, data, control, and application as stream types, similar to the MIME types used for Internet mail.
- *Addresses:* SDP indicates the destination addresses, which may be a multicast address, for a media stream.
- *Ports:* For each stream, the UDP port numbers for sending and receiving are specified.
- *Payload types:* For each media stream type in use (for example, telephony), the payload type indicates the media formats that can be used during the session.
- *Start and stop times:* These apply to broadcast sessions, for example, a television or radio program. The start, stop, and repeat times of the session are indicated.
- *Originator:* For broadcast sessions, the originator is specified, with contact information. This may be useful if a receiver encounters technical difficulties.

Although SDP provides the capability to describe multimedia content, it lacks the mechanisms by which two parties agree on the parameters to be used. RFC 3264[7] remedies this lack by defining a simple offer/answer model, by which two parties exchange SDP messages to reach agreement on the nature of the multimedia content to be transmitted.

Letters to the Editor

Ruling the Root

Ole,

As a matter of principle, I don't mind having my book *Ruling the Root* reviewed by David Crocker. Mr. Crocker was a significant figure in some of the key events covered in the book. His assessment and opinion of the book had the potential to be quite interesting.

One can only be disappointed with the results, however. The review reveals an inability to rise above partisan sniping and engage rationally with an different view. That, as a matter of policy, is why serious journals don't publish unsolicited reviews of books. Unsolicited reviewers tend to fall into one of two types: unabashed promoters with a personal interest in the success of the book, or people with an axe to grind trying to shoot down a perceived enemy.

I offer a rebuttal only because I think it is vital that the Internet technical community, the presumed readers of *The Internet Protocol Journal,* achieve a higher standard in their discussion of Internet-related policy issues.

Ruling the Root is a serious attempt to analyze the intersection of technology and policy. It offers a way of understanding that intersection based on theories of institutions and property rights. I know that this intersection irritates many engineers, who often harbor a wish that it would go away. By now we should know that it won't. Technical systems raise political issues. Technical people, economists, lawyers, and policy analysts, therefore, must be able to engage in rational dialogue about institutional issues, even when the discussion comes uncomfortably close to home. If we can't, the world is in big trouble.

The review completely misses this big picture. It begins with an attempt to belittle the policy significance of domain name management by inventing a mythical decree that all street names have to be in an obscure language. Crocker's attempt at humor falls flat, given today's headlines. Virtually the same day his review was published a German registrar was ordered to take a domain name away from a Web site with objectionable content. Not too long after, an ICANN Task Force published a WHOIS policy proposal that allows domain names to be shut down after 15 days if someone challenges the accuracy of the contact information, raising issues of privacy and harassment. ICANN regulates the prices of registries and entry into the market for domain name services. No one, not even ICANN itself these days, pretends that domain name administration is an exclusively technical matter.

Instead of engaging on those terms, the review concentrated on factual nitpicking. Take this one: "...the book does not consider NSI's role in ICANN-related political processes." This is an astoundingly inaccurate statement. The index of the book under "Network Solutions" contains 33 listings under 5 separate headings.

The book analyzes at length NSI's origins and ownership changes, its opposition to the IAHC and gTLD-MoU, its implied threat to establish a new root, and its policy conflicts with ICANN and the U.S. Department of Commerce.

Crocker claims that I "[characterize] the pre-ICANN *International Forum for the White Paper* (IFWP) as 'the real arena for arriving at a decision [about the details of the new organization].'" His use of a sentence fragment covers up what appears to be a deliberate distortion. I really wrote that some people viewed the IFWP in that way, while others, notably Joe Sims, Jon Postel, and the Information Technology Association of America, did not; see pages 176–178. I wrote at length about how that basic lack of agreement between adherents of IFWP and followers of IANA over legitimacy led to lasting conflict over ICANN's formation.

Crocker was one of Jon Postel's appointees to the *International Ad Hoc Committee* (IAHC). The review takes issue with my characterization of the IAHC, but unfortunately only to maintain Crocker's fictional self-conceptions. He denies that the IAHC ever claimed that "the root was theirs to dispose of." He also denies that IAHC was intended to be the seed of an alternative DNS governance structure. He's wrong on both counts. There is a voluminous record on this question, comprising contemporary news accounts, e-mail list archives, and my own recorded interviews with principal figures such as Don Heath.

Crocker's assertion that IAHC was "explicitly subordinate to IANA" is rather disingenuous, because IANA's U.S. government funding was ending and IAHC was explicitly perceived by Postel and ISOC as a mechanism for continuing its funding. So IAHC was intended to be the governance and support structure for IANA, just as ICANN now is. Indeed, today's ICANN has many features in common with the IAHC proposal, such as the shared registry concept, the slant toward intellectual property interests, the treatment of TLDs as "public resources," and a compulsory and uniform dispute resolution procedure.

What is really at issue here? It is this: Crocker cannot accept the simple fact that a political battle was under way for control of the root, and Postel/IAHC, as well as NSI and the U.S. government, were contenders for that control. Crocker's review challenges the claim in the book that Postel's root redirection exercise in January 1998 was "apparently" based on "concerns about the direction U.S. policy was taking." This judgment was based on interviews with people who were involved with Postel's effort. Of course I cannot read Postel's mind, but neither can David Crocker. My interpretation of why Postel acted is based on the timing and on evidence drawn from first-hand participants. Crocker offers an alternative interpretation, plausible but based on nothing but his own assertion. There is plenty of room for legitimate debate about historical interpretations. Such debate is useful, however, only if it is aimed at discovering the truth.

Regarding the status of IANA, I am sure we will never agree. I see it fundamentally as a DARPA contractor subject to U.S. governmental authority; Crocker views it in almost mystical terms as the embodiment of the Internet community. He says nothing about who paid the bills. Yet, we are not as far apart on the facts as he wants to make it seem. Contrary to the review, the book does document in great detail how a new community for Internet standards development grew up around the old DARPA-funded cadre of Postel, Cerf, and the IAB, and created its own standards of legitimacy and process. My book doesn't dispute Postel's tremendous respect and legitimacy among the technical community. But when it comes to institutionalizing control and ownership of the name and address roots of the Internet, whoever pays the piper calls the tune. And Postel's ability to perform the IANA functions was supported by U.S. government money from day one.

Hence, it was unrealistic to expect Postel to be exempt from governmental authority after domain names became resources of economic value and produced legal and political conflict over that value. Nor is it correct to imply, as Crocker does, that knowledge of the operational details of a technology automatically confers wisdom as to the correct public policies that should be adopted when that happens. Of course, policy decisions must respect technical facts and technical constraints. It is this relationship between technical system, technical community, and the worlds of business, law, and government that is cntral to the story told by *Ruling the Root*.

Crocker's final stab at discrediting the book involves some rather spurious charges of ethics problems. "In his criticism of dispute-resolution activities, he neglects to mention that he is a paid arbitration panelist," he writes. Crocker here refers to the fact that I was one of the few nonlawyers allowed by WIPO to serve as one of three judges in domain name—trademark disputes brought under ICANN's UDRP. The "pay" he refers to is a $500 or $750 honorarium for each case. I do about ten cases a year. I fail to see any conflict of interest or ethical problem here. Crocker implies that my meager remuneration for assuring that justice is done in UDRP cases somehow corrupts me, but he knows perfectly well that I am an opponent of the UDRP and would happily stop receiving those honoraria if the darn thing went away. Besides, no one is in a better position to understand what is right and what is wrong with UDRP than someone who is involved in the actual cases. I do not even understand what his concern is about the noncommercial DNSO constituency. I deal with it in one sentence in the book, and most of my activity in a "management capacity" (i.e., as an elective representative) came after the book manuscript was written.

—Milton Mueller, Syracuse University
Mueller@syr.edu

The author of the book review responds:

Professor Mueller's response discusses his goals of the book and his opinions of my review, to which he is, of course, entitled. He characterizes *Ruling the Root* as an academic consideration of the policy issues pertaining to the Domain Name Service, which he casts as global Internet administrative services. Note that the tag line to the title of his book, however, casts it more even more generally as "Internet governance." Academic and policy work need to be conducted carefully. Unfortunately, Professor Mueller confuses the issues, rather than elucidating them.

The opening, mythical decree of the review was carefully constructed to make the perspective of the book on communication system administrative policy clear: Professor Mueller confuses an administrative agency, such as ICANN or its telephonic equivalent, with a national government such as Germany. He also confuses control over administrative information, such as names and addresses associated with registrations, with primary content, such as a Web page.

Professor Mueller defends his writing about the IFWP as merely reporting the view of others, rather than being his own advocacy. However, his reporting is highly selective and results in his confusing the difference between tension that was *within* the IFWP process, versus *between* IFWP and IANA. His casting the issue as being with IANA is contrary to the formal documentation of IFWP, and contrary to the style and content of its process. IFWP was not designed, nor was it conducted, as a decision-making body.

Professor Mueller confuses the actions and intent of the IAHC with those of IANA (and ISOC). He claims to have extensive substantiation for his assessment of the IAHC. Yet none that is relevant to this confusion appears in his book or his letter. This omission is in spite of the fact that his view is at odds with the formal charter for the IAHC, the group's published report, and the direct record of the group's actions.

The review cites IANA's community-based authority. Professor Mueller confuses this with a rejection of the importance of funding, which it was not. He further confuses the IETF technical standards specification process with the operations administrative work of IANA. He continues to misunderstand the role of operational expertise in policy planning for critical infrastructure services, and he ignores the particular 15-year history of successful administrative policy activities provided by operations geeks, for DNS and IP addresses.

Lastly, given the minor points that Professor Mueller chose to address in his response, it is curious that he fails to respond to the primary ethics point raised in the review, namely his pattern of erroneous or absent citations that substantially undermine many of the assertions of his book.

Zero Configuration

IPJ,

I recently read Edgar Danielyan's article on Zero Configuration Networking in the December 2002 issue of IPJ. As is always the case, as a journalist Edgar is entitled to hold and express his own opinions, so as I began the article I didn't know whether to expect glowing praise of Zeroconf, or a savage attack. Thankfully I needn't have worried. I found an excellent and well-balanced article.

I have two brief comments to make.

1. Since Edgar wrote his article, the old expired Internet Drafts have been updated. The drafts Edgar worked from discussed names ending in local.arpa. The actual shipping version of Mac OS X 10.2 ("Jaguar") uses names ending in just local. to designate link-local names, (link-local names are locally assigned, unique only within the local link, not required to be globally unique).
2. Edgar expressed the opinion that Zeroconf is only useful on small networks, not large networks.

While Edgar is correct that Zeroconf per se is aimed at solving the "small network" problem, discovering your local peers is useful no matter how big the network. At the recent IETF meeting in San Francisco, there was a large network with full connectivity to the Internet, including IPv6, yet the printers were still advertised using Rendezvous, and for Mac users those printers showed up automatically in the "Printer" popup menu in the print dialogs, with zero configuration.

There is also the issue that Rendezvous (the Apple product) will go beyond just what is required for Zeroconf (the IETF Working Group). Service Discovery, on which Rendezvous is based, doesn't have to be used only with link-local multicast DNS. It can also be used with conventional unicast DNS. For a preview of what the future might hold, you can browse to find an example list of printers at my house. Type: **`nslookup -q=ptr _ipp._tcp.stuartcheshire.org`**

Thanks for publishing a great article.

—Stuart Cheshire, Apple Computer, Inc.

Book Review

Troubleshooting Campus Networks

Troubleshooting Campus Networks: Practical Analysis of Cisco and LAN Protocols, by Priscilla Oppenheimer and Joseph Bardwell, Wiley, 2002

It is perhaps rare that a book review would encompass the acknowledgements. A break from tradition here is warranted, though, because both authors reveal up front what every prospective reader should know when faced with a purchase decision: Is this work drawn merely from professional circumstance on the part of the author or does it embody a passion held by the author? Judge for yourself. How often do the words "love," "wonderful," and "protocol analysis" congregate?

Coauthors Priscilla Oppenheimer and Joseph Bardwell consider the spectrum of protocols and technologies likely to be encountered in a campus environment. A campus network, it is said by the authors, is any one that spans buildings (whether or not in an educational setting). Of course, bricks and mortar are functionally transparent to most modern technologies, and thus the definition of campus could easily be narrowed to any collection of departments or perhaps even any collection of LANs. A contrast is simply being made against the larger metropolitan or wide-area arena.

Although this book does include substantial theory and background for context, it is not yet another rehash of how things *ought* to behave in the vacuum of a lab environment (indeed, the authors occasionally express surprise at their own observations). Neither is it a step-by-step troubleshooting checklist for novice network administrators. To generalize the format, a thorough decomposition of the whole into its many parts follows an introductory discussion of the subject protocol or technology. It is next released into the wild and is quietly observed. Some conclusions are then drawn (some by the authors, some by the reader) regarding appropriate and inappropriate behavior. Lastly, possible courses of action in response to poor or abnormal performance or behavior are considered. This, again, is merely a generalization. The authors take great care to keep the discussion interesting and relevant, often doing so by sharing real-world experiences.

Organization

The six pages that comprise chapter 1 seek to set a stage, define a scope, and target an audience. The reviewer would add only that those of us who trade in wide-area networks also stand to gain a great deal from the experience.

If chapter 2 were packaged for individual sale, it would find its way under the Christmas tree of every colleague, customer, and boss this reviewer has ever encountered. Those readers familiar with Ms. Oppenheimer's acclaimed *Top-Down Network Design*[1] may be surprised to find the expression "bottom-up" in any of her work. It is, however, cornerstone not only to the chapter, but also to the remainder of the book.

This seemingly obvious approach to trouble-shooting and analysis could not possibly be emphasized enough according to this reviewer's professional observation.

Chapters 3, 5, and 6 delve into campus datalink layer technologies, protocols, and architectures, including Ethernet, *Spanning-Tree Protocol* (STP), and *Virtual Local-Area Networks* (VLANs). Yawn? The reviewer challenges the reader to finish these three chapters without learning something of considerable value. The Ethernet discussion, for example, breaks from the traditional approach where a cursory review of frame types, cable types, and topologies is deemed sufficient. Where Ethernet came from, where it is going, how it is encoded and presented to the physical layer (and why), and how to interpret frame size distribution using *Remote Monitoring* (RMON) or a protocol analyzer are but a few of the topics considered. Extensive use of protocol analyzer capture files casts new light on STP and VLANs.

Chapter 4 additionally addresses a Layer 2 technology (IEEE 802.11 wireless LANs) but warrants honorable mention. Rare is the *radio frequency* (RF) engineer who possesses a full appreciation for the heretofore all-digital, all-wired campus realm. Perhaps less common would be the network administrator with a capacity to do much other than tune in an FM radio station on a digital set. The authors masterfully string together all the relevant RF concepts, at exactly the right level of detail, to allow for a solid fundamental comprehension of 802.11 networks, technologies, architectures, and deployment. This chapter also would do superbly for anyone with a generic interest in RF units of measurement.

Chapter 7 advances the discussion up to the network layer. Although this may seem common knowledge for readers of a publication such as the IPJ, it is written from the perspective of seasoned protocol analysts. It is worth your time.

Chapter 8 persists at Layer 3 with a thorough discussion of relevant routing protocols. It is again worth noting the emphasis on analysis versus simple textbook theory. It, too, is worthy of your investment.

Chapter 9 rounds out the protocol stack, beginning with an emphasis on Layer 4 protocols *Transmission Control Protocol* (TCP) and *User Datagram Protocol* (UDP). One of the highlights found here is a thorough lesson on TCP window size analysis. Could there perhaps be a little more to this seemingly intuitive concept than you at first thought? The chapter closes following an in-depth consideration of application layer protocols such as the *File Transfer Protocol* (FTP), *Hypertext Transfer Protocol* (HTTP), and the *Domain Name System* (DNS). The fundamental mechanics of these protocols and how they interact with their lower-layer counterparts make for a good page-turner.

Chapters 10, 11, and 12 are dedicated to troubleshooting and analysis of *Internetwork Packet Exchange* (IPX), AppleTalk, and Windows networking, respectively. The latter is arguably the more relevant. The other two are nonetheless interesting and left the reviewer longing for a decent AppleTalk trace file with which to recreate.

Chapter 13, WAN Troubleshooting for LAN Engineers, covers the obvious wide-area technologies and architectures, such as *Integrated Services Digital Network* (ISDN), Frame Relay, and *Synchronous Optical Network* (SONET) in about as much detail as the typical LAN engineer or administrator is likely to tolerate. The subject of WAN analysis warrants a volume or two on its own in any case and thus would have been out of place if explored in much greater detail.

Conclusion

The reading of Troubleshooting Campus Networks is not to be approached as a spectator sport. Although the protocol analyzer screen captures are aplenty, and they suitably complement the lessons, merely thumbing the pages would be an opportunity missed. This reviewer chose a free, open-source protocol analyzer (readily available on the Internet) as a reading companion. Although likely far less capable, particularly in terms of graphing, than the oft-referenced Wildpackets EtherPeek product, it nevertheless affords the reader a Layer 2 through 7 window into a living, breathing network.

It bears mentioning that although "Cisco" appears in the subtitle, vendor neutrality is, on the whole, maintained. The Cisco sanctioned troubleshooting methodology is given brief mention in chapter 2. Coverage of the Cisco proprietary *Interior Gateway Routing Protocol* (IGRP), the *Enhanced IGRP* (EIGRP), and the Cisco Discovery Protocol is included, as is coverage of Cisco's "enhancements" to STP. Lastly, where appropriate, Cisco IOS® "show" and "debug" output is included alongside protocol analyzer screen captures. None of this coverage appears to be included in the spirit of product promotion (bear in mind that this is not a Cisco Press title and that neither author is presently employed by Cisco Systems). Rather, it seems simply to be an acknowledgement that the target audience might very well include candidates for Cisco's professional and expert-level certification programs (and rightly so).

It is probably anticlimactic that the reviewer would offer a strong buy recommendation for those with an interest in the fundamental interworkings of campus protocols and technologies. The authors' enthusiasm for packet capture and analysis is infectious. Mr. Bardwell, in fact, is apparently so infatuated that he is at times moved to poetry. This could well be one for the ages.

Call for Papers

The Internet Protocol Journal (IPJ) is published quarterly by Cisco Systems. The journal is not intended to promote any specific products or services, but rather is intended to serve as an informational and educational resource for engineering professionals involved in the design, development, and operation of public and private internets and intranets. The journal carries tutorial articles ("What is…?"), as well as implementation/operation articles ("How to…"). It provides readers with technology and standardization updates for all levels of the protocol stack and serves as a forum for discussion of all aspects of internetworking.

Topics include, but are not limited to:

- Access and infrastructure technologies such as: ISDN, Gigabit Ethernet, SONET, ATM, xDSL, cable fiber optics, satellite, wireless, and dial systems
- Transport and interconnection functions such as: switching, routing, tunneling, protocol transition, multicast, and performance
- Network management, administration, and security issues, including: authentication, privacy, encryption, monitoring, firewalls, trouble-shooting, and mapping
- Value-added systems and services such as: Virtual Private Networks, resource location, caching, client/server systems, distributed systems, network computing, and Quality of Service
- Application and end-user issues such as: e-mail, Web authoring, server technologies and systems, electronic commerce, and application management
- Legal, policy, and regulatory topics such as: copyright, content control, content liability, settlement charges, "modem tax," and trademark disputes in the context of internetworking

In addition to feature-length articles, IPJ will contain standardization updates, overviews of leading and bleeding-edge technologies, book reviews, announcements, opinion columns, and letters to the Editor.

Cisco will pay a stipend of US$1000 for published, feature-length articles. Author guidelines are available from Ole Jacobsen, the Editor and Publisher of IPJ, reachable via e-mail at **ole@cisco.com**

The Internet Protocol Journal

June 2003 Volume 6, Number 2

A Quarterly Technical Publication for Internet and Intranet Professionals

In This Issue

From The Editor

Articles in *The Internet Protocol Journal* broadly fall into three categories. First, we have articles that explain well-established technologies or operational practices. Second, we offer tutorials on new or emerging protocols and systems, not yet deployed but on the horizon. Finally, IPJ brings you insights, lessons learned and opinions on aspects of networking that have not completely lived up to their promises. In this issue, you will find a mixture of all three.

Our first article is an example from the "nuts-and-bolts" category. The *Border Gateway Protocol* (BGP) is one of the core routing protocols that is widely used in the Internet and has been around for a long time. Kris Foster explains how the *BGP Community* attribute can be used in service provider networks.

Efforts to provide cellular telephones with Internet access systems have produced mixed results. Japan has been leading the way in this area with widespread deployment of iMode devices or variants thereof. Having used such a system I must say I am both impressed and somewhat frustrated. It is wonderful to receive e-mail while on a busy Tokyo train, but accessing the Internet on a tiny screen (typically a 2-inch display with a resolution of 120 x 160 pixels) is not particularly rewarding. Not to mention the bandwidth limitations inherent with this technology. Another system, the *Wireless Application Protocol* (WAP) has been implemented in most countries that offer *Global System for Mobile Communications* (GSM) cell phone service. WAP is the subject of our second article. Edgar Danielyan describes the WAP architecture and looks at some of the lessons learned from its deployment.

The push for deployment of *IP Version 6* (IPv6) is taking place on several fronts and we cover some of them in this issue. In the IETF, a recently formed group has been chartered to help design transition strategies from IPv4 to IPv6. We have a short overview of this effort starting on page 20. Additionally, both the U.S. and Japanese governments are promoting the use of IPv6 in various ways. The U.S. Department of Defense has recently adopted IPv6 as one of its official protocols. In Japan the "IPv6 Appli-Contest 2003" is underway in an effort to encourage development of software and applications for IPv6. See "Fragments," page 37–38 for further details.

Of course, not everyone is convinced that IPv6 is such a good idea, and with that in mind we bring you an opinion piece as well as a Letter to the Editor on this topic.

—Ole J. Jacobsen, Editor and Publisher
ole@cisco.com

Application of BGP Communities

by Kris Foster, TELUS

The *Border Gateway Protocol* (BGP) is the glue that binds networks and their individual policies together. Several attributes are passed along and possibly modified with each individual prefix, one of which is the *community* attribute. BGP communities are described poorly in most texts. The problem is not in explaining how they fit into the protocol, but in how to apply these to the real world. In this article I describe how they can be applied within a service provider network and between service provider networks. However, communities are not limited to service providers and can be applied creatively in enterprise networks.

The density of interconnection among service providers, and the various business agreements or political policies, means that controlling who can talk to whom over your network can become difficult. At a basic level there are two types of agreements between service providers: transit/customer and peers.

- Customers pay to receive every prefix from a transit provider.
- Customers advertise only the prefixes they own (along with their customers' prefixes) to the transit provider.
- Peers agree to send only their customers' prefixes to each other, and not other peers' prefixes.

Several methods are available to implement these policies. They can include prefix filters, *Autonomous System* (AS) path filters, and communities. With only prefix and AS path filters, service providers must ensure that as a new customer or peer is added, the prefixes and *AS Numbers* (ASNs) associated with the customer (and potentially *their* customers) are added to the filters on all of the BGP edge routers. This can be automated with scripts, possibly in combination with a route registry database. Very small service providers may be able to manage such a scheme, but as they grow and customer churn begins, this can quickly get out of control. The more time network operators spend in router configurations, the greater likelihood of human error. Communities provide an elegant solution for these problems.

The BGP Community Attribute

Within an AS, all BGP-speaking routers run *Internal BGP* (iBGP) in a full mesh to prevent routing loops (route reflectors can be used to relax this rule). This means that every BGP-speaking router passes its prefixes to each of its iBGP neighbors. ASs that are adjacent typically run eBGP on directly connected routers. All BGP routers share their prefixes—that is, the network number, network mask, and BGP attributes with each other—allowing each to run its own best-path selection algorithm. As a prefix is passed between ASs, an attribute called the AS-PATH is updated with the corresponding ASN. The AS-PATH is used to prevent routing loops between eBGP neighbors.

A community is a BGP attribute that may be added to each prefix. Communities are transitive optional attributes[1], meaning BGP implementations do not have to recognize the attribute and at the network operator's discretion carry it through an AS or pass it on to another AS. The community attribute can be thought of as simply a flat, 32-bit value that can be applied to any set of prefixes. It can be read as a 32-bit value or split into two portions, the first 2 bytes representing an ASN and the last 2 bytes as a value with a predetermined meaning. The format of the community attribute is shown in Figure 1.

The values **`0x00000000`** through **`0x0000FFFF`** and **`0xFFFF0000`** through **`0xFFFFFFFF`** are reserved. Most modern router software displays communities as **`ASN:VALUE`**. In this format the communities **`1:0`** through **`65534:65535`** are available for use. The convention is to use the ASN of your own network as the leading 16 bits for your internal communities and communities that you accept from and send to your customers.

Three communities are defined in RFC 1997[2] and are standard within BGP implementations: NO-EXPORT (**`0xFFFFFF01`**), NO-ADVERTISE (**`0xFFFFFF02`**), and NO-ADVERTISE-SUBCONFED (**`0xFFFFFF03`**). Additionally, NO-PEER (**`0xFFFFFF04`**) has been proposed in an Internet Draft[3].

NO-EXPORT is commonly used within an AS to instruct routers not to export a prefix to eBGP neighbors. For instance, subnets of a larger block can be advertised to influence external AS best-path selection, and those not required for this traffic engineering purpose may be tagged NO-EXPORT to prevent them from being leaked to the Internet (and thus contributing to unnecessary global routing table growth). If a neighboring AS accepts this community, it can be used to selectively leak more specifics for traffic engineering but limit their propagation to just one AS.

NO-ADVERTISE instructs a BGP-speaking router not to send the tagged prefix to any other neighbor, including other iBGP routers.

NO-ADVERTISE-SUBCONFED is used to prevent a prefix from being advertised to other members within a *confederation*. A confederation can be thought of as a single AS, broken down into sub-ASs. The use of confederations within service provider networks is rare or nonexistent, so they are not considered here.

Finally, NO-PEER is used in situations where traffic engineering control over a more specific prefix is required, but to constrain its propagation only to transit providers and not peers. That is, the prefix is advertised from AS to AS provided there is a transit/customer relationship, unlike NO-EXPORT, which restricts propagation of the prefix to only the adjacent AS. Because peers of the various upstream providers will not see this prefix, the larger prefix encompassing the more specific one is used for routing, thereby conserving an extra entry for some in the global routing table. At this time the community is not recognized by major vendors and requires manual implementation.

Adding Depth: The Extended Community

The current community attribute is getting an upgrade with a new transitive-optional attribute (Type 16) called the *Extended Community*[4]. Missing from regular communities was any real form of structure. The current Internet Draft defines the Extended Community as an 8-octet value as shown in Figure 1. The first octet specifies the type (and optionally the second value can specify a subtype). This value dictates the structure given to the remaining octets.

The Type field gives the community some immediate flexibility. The first is the use of bit 0 to represent whether the community is registered with the *Internet Assigned Numbers Authority* (IANA) or if it is specified by the *Internet Engineering Task Force* (IETF). The second bit gives the Extended Community a coarse scope, either *Transitive*, meaning it may be passed between ASs, or *Non-Transitive*, meaning it should be carried only within the local AS.

The Internet Draft also specifies numerous types available for use as templates.

The *Route Target Community* is already in popular use within *Multiprotocol Label Switching Virtual Private Networks* (MPLS VPNs). The Route Target Community identifies a set of routers that may receive this prefix. In the MPLS VPN context, this is necessary to limit the resources required to support individual VPN services; only routers that are part of the individual VPN need to hear about the routes within the VPN.

The *Link Bandwidth Community* gives the network operator additional control in influencing the best path selection. As prefixes are learned from eBGP neighbors, the local neighbor applies this community to specify in bytes per second the bandwidth of the link. It is a *Non-Transitive Community,* so its scope is limited to the local AS.

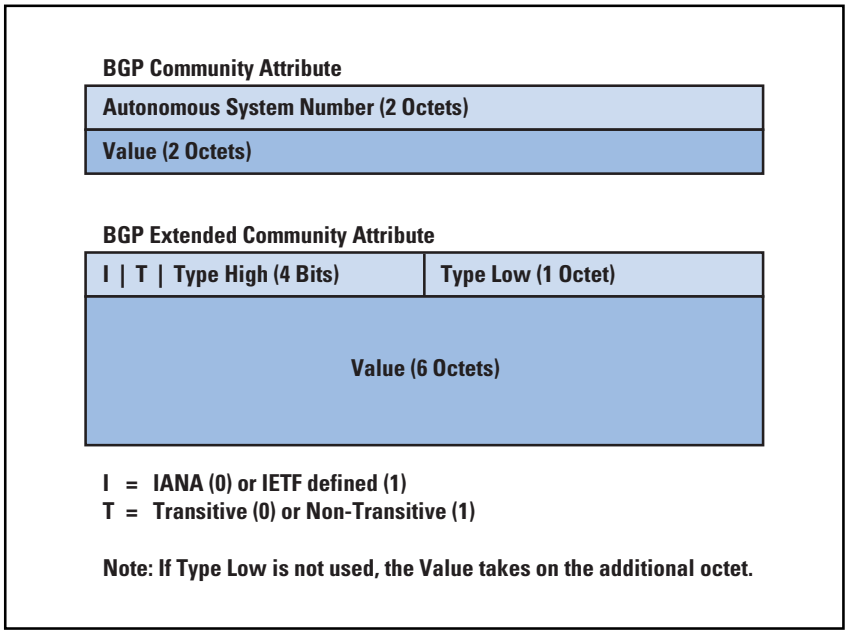

Figure 1: Community Formats

Intra-Autonomous System Communities

Policy control using communities within an AS can go farther than this, and their true value is evidenced when they are used to create new and complex policies. If we take our example of the three basic types of neighbor relationships, customers of a transit provider will want to send their customers' prefixes but not their peers' prefixes. To distinguish between a customer's prefix, a peer's prefix, and a transit provider's prefix, we can add a community to each as we learn it from the neighbor.

When advertising a prefix to a customer, peer, or transit provider, simply match all prefixes carrying the communities associated with the correct policy. As shown in Figure 2, all prefixes received from customers are tagged with **53:100**, peers are tagged with **53:200**, and transit is tagged with **53:300**. Our basic definition of a customer is someone who expects to receive all prefixes, so each customer-facing BGP session is preconfigured to send all prefixes matching **53:100**, **53:200**, and **53:300**. Again, from our definition of a peer being someone who wants to see only our customers, we would preconfigure all of our peers' BGP sessions to send only prefixes tagged with **53:100**.

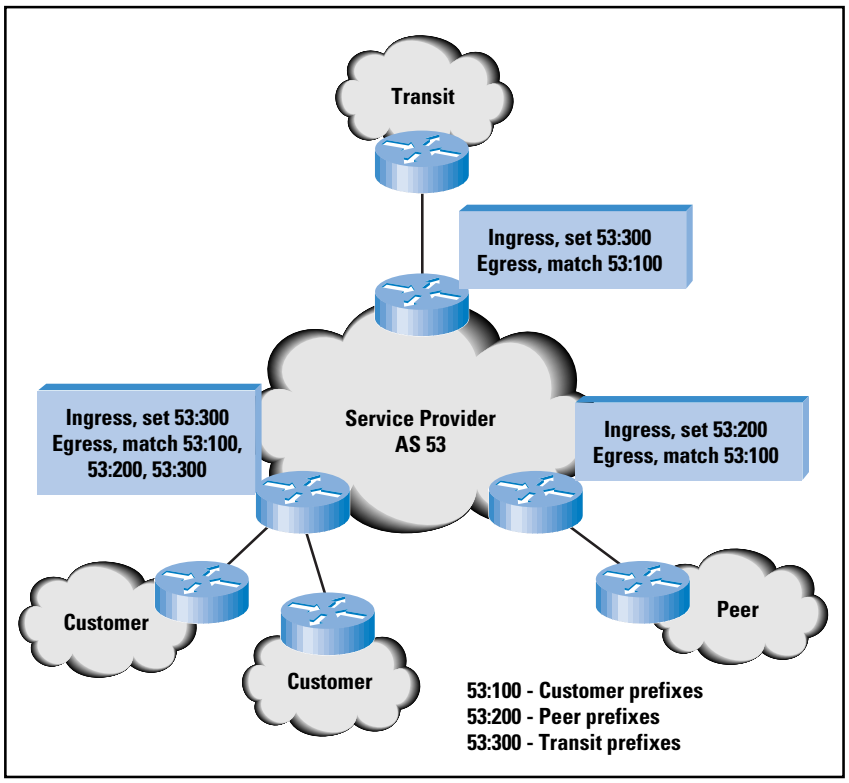

Figure 2: Internal Use of Communities for Applying a Basic Service Provider Policy

We can extend this community coding and turn it into a useful troubleshooting tool by adding more information such as where the route was learned geographically. Codes could be assigned per continent, country, state/province, city, or central office.

During redistribution from an Interior Gateway Protocol, a community can be used to specify the original protocol (for example, *Intermediate System-to-Intermediate System* [IS-IS], *Open Shortest Path First*

[OPSF], or *Routing Information Protocol* [RIP]). These can be used to quickly determine where a prefix came from without tracing it back to the point of its origination.

It is possible to assign these additional properties in two different ways (or a combination). A single community value may represent a single meaning, such as **`53:100`**, meaning a customer-learned prefix. We could then add additional communities such as **`53:1`** to mean a prefix learned on the east coast, **`53:2`** to mean central, and **`53:3`** to mean west coast. Alternatively, a single community could represent both a customer and a prefix learned on the west coast by tagging with the single tag **`53:103`**. To support these complex values, most vendors allow for pattern matching of specific values, ranges of values, and logical operators such as OR and NOT, in the form of regular expressions. Using regular expressions and complex communities can help to make a router configuration more economical and easier to read.

Inter-Autonomous System Communities
